# PREFACE

This Supplement has been prepared following the general editorial policies already outlined in the Prefaces to Volume II, Supplement I (originally called Supplement II, Part I) and Volume VII, Supplement II. However, in certain respects this Supplement differs from previous volumes of the series; it represents a serious effort to tailor the 'Mellor' treatment to the prevailing balance of importance of the different areas of chemistry treated, and to aspects of special interest in the chemical industry. This volume therefore gives prominence, on the fundamental side, to the extremely interesting structural chemistry of phosphorus compounds, the diversity of compounds of phosphorus and nitrogen, and organophosphorus chemistry. Section XXXIII, on organic derivatives of phosphorus, is in fact a monograph providing, with almost 2500 literature references, a unique key to organic compounds of which phosphorus is an important constituent; it is a definite but useful break from the early traditions of 'Mellor'. The thorough treatment of metal phosphides as a group is also of special interest, because these interesting substances are so often covered in reference literature by scattered sections linked with the metals they contain.

A further new feature in this Supplement is the participation of a specialist Editor to give general guidance and supervision to the general arrangement of the volume, selection of contributors, and preparation of manuscripts. Dr A. F. Childs, Research Director of Albright & Wilson Ltd (Oldbury Division) has given extremely valuable help to the Editorial Board in this capacity, and the whole volume reflects the close acquaintance with phosphorus chemistry shown by Dr Childs and members of his staff. The Editors and Publishers also gratefully recognize the extensive help given by Miss M. J. Moore, formerly Secretary to Dr Childs, in preparing and checking the typescript of this Supplement.

Much of the initial editorial work on this Supplement was done by the senior member of the Editorial Board, Mr A. A. Eldridge, who died in 1970 after a long and fruitful period of work on 'Mellor'. Mr Eldridge was one of the small team of chemists which developed, after the Second World War, the general plan for supplementation of the original 'Mellor Treatise', and he retained a very active part in editorial planning, revision of manuscripts, and proof correction until a few weeks before his death. His thorough appreciation of the requirements of a reference work on inorganic chemistry, and the high standard set by his editorial work, have been sadly missed by the other editors in completing the present volume.

## EDITORIAL BOARD

(The late) A. A. Eldridge, B.SC., F.R.I.C.
G. M. Dyson, M.A., D.SC., F.R.I.C., M.I.CHEM.E., F.INST. PET.
A. J. E. Welch, PH.D., D.I.C.
D. A. Pantony, T.D., PH.D., B.SC., A.R.C.S., F.R.I.C.

## LIST OF CONTRIBUTORS

# PHOSPHORUS

## SECTION I

## THE HISTORY AND OCCURRENCE OF PHOSPHORUS

BY D. R. PECK

DURING the past thirty years the distribution and composition of phosphate deposits have been studied extensively, particularly with reference to ores of commercial value. Geological explorations of the earth's crust, together with an examination of meteorites, have enabled estimates to be made of the abundance of phosphorus in the universe. F. W. Clarke and H. S. Washington (Mellor, VIII, 732) calculated the average composition of rocks from the results obtained by analyzing many rocks and minerals. The method used in this calculation has been said[1] to give high results for phosphorus pentoxide. After revision of the earlier data and calculations, it was estimated that the average percentages of phosphorus in igneous and sedimentary rocks were 0·075–0·080 and 0·072, respectively. The analysis of meteorites[2] indicates that these contain about 0·2% by weight of phosphorus. The more recent values[3] for the distribution of phosphorus have been summarized by Van Wazer[4] as shown in Table 1.

*Table I.—The Abundance of Phosphorus*

| Source | Wt.-% of P |
|---|---|
| Meteorites—metal phase | 0·22 |
| Meteorites—sulphide phase | 0·31 |
| Meteorites—silicate phase | 0·0145–0·0170 |
| Gross abundance in meteorites | 0·18–0·19 |
| Igneous rocks | 0·07–0·13 |
| Sandstones | 0·04 |
| Red clay | 0·14 |
| Shales | 0·08 |
| Limestones | 0·02 |
| Gross abundance on earth's surface | 0·10–0·12 |

From the above data phosphorus is eleventh in the order of abundance of the elements in the igneous rocks of the earth's crust, thirteenth in meteorites and twenty-fourth in the sun's atmosphere. Van Wazer computed the amount of phosphorus in the earth to be $10^{25}$ grams or $10^{19}$ tons, and estimated that the abundance in the universe was about the same as the gross abundance in the earth's crust (Table I).

Phosphorus differs from carbon, hydrogen, oxygen, nitrogen and sulphur, the other major non-metallic elements in the animal and vegetable kingdoms, in not being present in the earth's atmosphere. It is, however, found in traces in lakes, rivers and oceans. In sea water the concentration of dissolved phosphorus is very low at the surface. This increases to a maximum value of 0·04–0·10 p.p.m. at a depth of about 800 metres, and thereafter remains almost constant at this value down to the sea bottom.[5] According to Van Wazer[4] the total amount of phosphorus dissolved in the seas is about $10^{17}$ grams.

## GENESIS AND FORMATION OF PHOSPHATE ORES

### IGNEOUS ROCKS

The geology and mineralogy of phosphate deposits indicate that all the phosphorus was present originally in igneous rocks. Phosphate is found, even if only to the extent of about 0·1%, in almost all present-day igneous rocks, where it usually occurs as apatite. The latter is most often in the form of minute crystals in gneiss, granite and diabase, and nearly all the recognized species of phosphates are to be found in the pegmatites or coarsely crystallized granites. It has been estimated that at least 95% of the phosphorus content of igneous rocks is present in the form of apatite.[6]

### SEDIMENTARY DEPOSITS

In the course of geological time the igneous apatites became transformed into phosphorites of marine origin, the second main type of phosphate deposit. Joly[7] put forward a theory of periodic revolutions to account for the changes in the earth's crust known to have occurred in the geological history of the world. There is evidence to show that frequent catastrophic events, such as extensive earthquakes, volcanic eruptions and huge tidal waves, have occurred during periods when the earth's surface was unstable. These phenomena could have caused the igneous apatites to disintegrate, and subsequent leaching of the rocks by water would result in large quantities of phosphate being carried into the seas, where it was subject to biological utilization. Eventually the greater part of this leached phosphate was again deposited as sedimentary formations, usually as pellets a few millimetres in diameter. In some areas, such as the Western United States[8] and the Kara-Tau region of the U.S.S.R.,[9] this type of deposit occurs in layers, probably as the result of geological action causing compression followed by lifting.

The part played by sea water in the formation of sedimentary phosphate deposits has been discussed by a number of authors.[10, 424] Kazakov[11] reviewed and discussed the earlier theories of the origin of phosphates[12] in the world and considered that many of the deposits were of marine origin. They were formed by chemical precipitation of the phosphoric acid present in sea water. Ocean currents carried the phosphate, which was in solution in the open sea, to regions where calcium carbonate predominated and thus caused precipitation of calcium phosphate.[13] Phosphorite deposits were therefore formed on or near Continental shelves. Kazakov described the temperature conditions and the chemical composition of sea water necessary for the formation of phosphorites, in relation to their basicity and the variation in their content of fluoride and phosphate ions. Equilibria in the $CaO–P_2O_5–H_2O$ and $CaO–P_2O_5–HF–H_2O$ systems at low ion concentration were investigated in order to determine the physicochemical conditions relating to phosphate deposition.[14] However, the results of this work did not entirely prove the theory put forward, mainly because the concentrations of CaO, $P_2O_5$ and F, corresponding to the solid phases in the systems studied, differed from the concentrations of fluorapatite and hydroxyapatite found in sea water. Further, the presence of carbonate and other salts in sea water was not taken into consideration. On the other hand, chemical analysis and geological examination of phosphorite deposits supported the hypothesis. More recent studies[15] in which the systems were examined in the presence of 3·5% sodium chloride showed that the CaO content in Kazakov's data was much too low to correspond with that in sea water. In the $CaO–P_2O_5–NaCl–CO_2–H_2O$ system the phosphorus content of the saturated solutions increased with the carbonate ion concentration. This may be a factor in the enrichment of phosphates in marsh waters containing carbonate.

In an alternative hypothesis[16] it is considered that calcium carbonate becomes phosphated on the sea-bed. Nodules of calcium carbonate are formed from the remains of plant and animal life and shells deposited in the sea, by the movement of currents along the ocean floor. Sea water at depths of more than a few hundred metres is thought to be saturated with apatite,[17] so that stationary or slow moving particles of calcium carbonate can become phosphatized slowly by a process of exchange with the saturated apatite solution. Oceanographic expeditions show that phosphate concretions are forming around the remains of fish lying in the ooze on the bottom of deep seas. Phosphate deposits may therefore have formed simultaneously with the laying down of the strata in which they occur.

In some land areas, particularly where wind, temperature and moisture conditions were suitable, extensive weathering of rocks occurred. Some limestone and dolomite rocks of marine origin in these regions contained apatite, and in the process of weathering, the calcium carbonate was slowly dissolved away, leaving a higher grade phosphate deposit behind.[18] Near river areas, boulders, nodules and pebbles of this enriched phosphate were carried from the original site and subsequently deposited on the river bottom.[19, 20] Such deposits are generally small, occur in patches and usually have a low phosphorus content.

### EFFECT OF VEGETATION

A third type of phosphate deposit has been formed by a phosphating process similar to that described above. Water in contact with decaying vegetation may become sufficiently acidic to dissolve phosphate from sedimentary rocks. This is carried in solution and subsequently reprecipitated on suitable rock formations to give rise to a phosphatized rock. Exposure of guano deposits to rain removes their soluble constituents, and the dissolved phosphate may become fixed by reaction with the underlying rock. In this way the coral limestone of the Ocean Islands has been phosphatized. A similar reaction occurs with igneous rocks such as basalt, but these are a less important source of phosphorus because of the presence of iron and aluminium in the original rock. These leached guanos and phosphatized limestones are sometimes known as sombrerite.

### GUANO

Guano is the fourth principal type of phosphate. In coastal areas such as those of Peru and Chile and on some islands, e.g. the Seychelles and Ocean Islands, bats and sea-fowl have nested for long periods of time. The excreta of these, together with such remains as bones and feathers, have given rise to the material known as guano. The main constituents of this are nitrogenous substances such as guanine and uric acid, calcium phosphate, and potassium and ammonium salts.

Igneous rocks in general are not important as a commercial source of phosphorus because of their low phosphate content. Exceptions to this are the igneous phosphate deposits of the Kola peninsula in the U.S.S.R. and those found in Uganda and eastern Transvaal regions of Africa. The main sources of phosphates at the present time are the sedimentary deposits. They occur in rock formations of all ages as far back as the Cambrian period (about 500 million years ago). Guano deposits are of value more as fertilizers rather than as a raw material for production of elemental phosphorus or phosphoric acid. At present they account for between 5 and 10% of world phosphate production, but in some areas the deposits have been depleted.

## DISTRIBUTION, NATURE AND COMPOSITION OF PHOSPHATE DEPOSITS

Deposits of phosphate have been found in many countries, but not all of the ores are suitable as a commercial source of phosphorus. New deposits are still being revealed by geological surveys and prospecting. It is apparent that in Africa, Asia and South America large areas where phosphates are likely to be found have still to be searched. Estimates of the reserves of phosphates in the world have been made from time to time, but these depend on what is meant by a reserve. Some deposits, for example, are isolated or too small and patchy to be of value. Many low grade ores, some marine phosphorites, and material which could be recovered from phosphate-containing iron ores cannot at present be utilized economically. Some of these types of deposit may well be larger than those of the higher grade phosphates now being mined. For example, it has been estimated that in the Western United States the low grade ores may amount to $10^{11}$ tons.[21] Taking these factors into account, Van Wazer[4] states that the world reserves of phosphate which can be mined economically are probably $3 \times 10^{16}$ grams ($3 \times 10^{10}$ tons). He gave estimates, compiled from various sources of information,[21-3] of the maximum reserves which could be mined in various countries. A summary of these is shown in Table II.

*Table II.—World Deposits of Phosphates*

| Location | Maximum deposit (million tons) |
|---|---|
| Morocco | >21,000 |
| Tunisia | 2,000 |
| Algeria | 1,000 |
| Egypt | 180 |
| U.S.A. | 13,500 |
| Brazil | 570 |
| Mexico | 215 |
| U.S.S.R. | 7,600 |
| Europe | 440 |
| Australia, Nauru and Ocean Islands | 180 |
| Christmas Island | 50 |
| Indo-China | 18 |
| India | 10 |
| Israel, Jordan | 4 |
| China | 3 |

The higher grade deposits, containing 20% $P_2O_5$ or more, are mostly found in the United States, the Kola peninsula of the U.S.S.R., North Africa and the Nauru and Ocean Islands in the Pacific. Typical percentages[22, 24, 114] of the major constituents of the highest grade ores from these regions are shown in Table III.

*Table III.—Composition of High Grade Phosphate Ores*

| | Florida | Tennessee | Morocco | Tunisia | U.S.S.R. | Pacific |
|---|---|---|---|---|---|---|
| $P_2O_5$ | 35·2 | 34·2 | 35·0 | 27·8 | 40·3 | 39·2 |
| $CaO$ | 49·2 | 49·0 | 53·0 | 46·0 | 52·3 | 53·8 |
| $Al_2O_3$ | 1·0 | 1·2 | 0·3 | 1·8 | — | 0·2 |

### AMERICAN DEPOSITS

From an examination of their structural characteristics, using microscopic and *X*-ray diffraction techniques, it has been shown that many of the American deposits are submicro-crystalline fluorapatite.[25-6] In some of the ores the fluorine content is greater than that corresponding to the fluorapatite composition $3Ca_3(PO_4)_2,CaF_2$, and it has been suggested[27-8] that this could be due to the presence in them of a fluorophosphate, in which a fluorine replaces an oxygen atom in the phosphate ion.

In Florida there are two main types of rock phosphate.[22, 24, 29] One of these, known as pebble phosphate, covers an area of some 600 or 700 square miles to the east and south-east of the city of Tampa. The rock formation in this region is composed of a number of strata. As far as phosphorus is concerned the lowest stratum lies at a depth of about 250 ft. and consists of limestone overlaid with clay. This is a phosphate-bearing layer which was formed about 20 million years ago. On top of this there is a 20 ft. bed comprising a mixture of sand, clay and phosphate rock and pellets. About 5 million years ago these two strata were subjected to erosion and weathering by sea water, giving rise to a third layer containing sand, clay, and calcium and aluminium phosphates. Surmounting this is an overburden, about 20 ft. thick, of sand and quartz. As a result of weathering some of the calcium phosphate reacted with the surrounding clay to form aluminium phosphate.

Some 60 miles to the north of Tampa a second type of deposit, the hard-rock phosphate, is found. This extends northwards for about 120 miles and consists mainly of whitish boulders. The deposits are underneath a layer of sand and clay and vary in thickness from about 5 to 90 ft.

Phosphate rock has been mined since 1868 in South Carolina, mainly in the coastal region near Charleston and Beaufort. The phosphate occurs in lumps of varying size, usually covered by alluvial sands and clays. The beds contain phosphatized fossils, some 50 or 60 million years old, and fragments of vertebrata such as mastodon, horse and elephant, of the more recent Pleistocene period. South Carolina was the principal mining area until the Florida deposits were first worked in 1883. Smaller deposits have also been mined in North Carolina, Pennsylvania, Alabama and Arkansas.

The phosphate deposits of Tennessee, which are derived from limestones about 370 million years old, are small compared with those of Florida. They were formed by deposition from shallow seas and the ore occurs in the form of blue, brown and white rock. The last is heavy and massive, while the blue rock consists of phosphate pellets embedded in calcium carbonate. These two types are of less commercial importance than the brown rock which is composed of carbonate–apatite mixed with sand and clay.

The largest deposits of phosphates in the United States occur in the Western fields, covering parts of the states of Utah, Idaho, Wyoming and Montana. Although the area extends to some 100,000 square miles and is perhaps the biggest potential source of phosphates in the world (Van Wazer, loc. cit., page 980), the ores, because of their relatively unfavourable location, have only recently been worked to any extent. The deposits are known as the Phosphoria formation and originated in the Permian period about 200 million years ago. The phosphate is chiefly a carbonate–fluorapatite[30] and occurs as dense nodules, mudstones and soft shales. It may contain as much as 5% of organic carbon. The conditions of deposition were similar to those postulated by Kazakov.[13] The beds have a maximum thickness of 73 ft.[31] and are compressed and folded, particularly in the western part of the region where the rock structure is complex. A general petrographic study and classification of 21 Western phosphate ores has been made[421] and the resources of the area have been reviewed.[422]

Phosphorite deposits containing 14–21% $P_2O_5$ have been found in Mexico[32] and Texas,[33] and in California phosphate pellets containing up to 33% $P_2O_5$ occur.[34] These deposits, however, are small. Examination of the marine phosphates off the coasts of these areas showed that the minerals were chemically fluorapatite.[35] On the sea-bed off Southern California most of the phosphates are of igneous and volcanic origin[36] with about one-third as sedimentary rocks. The latter were formed mainly by direct precipitation *in situ*.[37] The rock formations in these regions date from about 170 million years ago, the most abundant being those of the Miocene period.[38]

Apatite, phosphorite, guano and aluminium phosphate deposits of commercial value occur in Brazil. In the southern area, mainly in the state of Minas Gerais, it is estimated that there are about 100 million tons of apatite containing 12–22% or more of phosphorus pentoxide,[39] and new deposits are still being discovered.[423] What may be the world's largest deposit of phosphate, containing 31·8% $P_2O_5$, has been reported from Peru.[40]

### NORTH AFRICAN DEPOSITS

The Moroccan phosphates occur to the west of the Atlas mountains, mining being centred on Khouribga about 75 miles to the south-east of Casablanca.[41] In Algeria phosphorite is found to the east of the Atlas range, mainly near Tocqueville and Tébessa. These deposits extend to the Tunisian border in the region of Jebel Kouif and thence to the area of the Tunisian ores at Gafsa. Most of these ores belong to the Lower Eocene period, about 75 million years ago. Egypt has deposits east of Keneh and in the Dakla oasis in the Libyan desert.

Major reserves of phosphate occur in Turkey. The deposits, estimated to contain at least 200 million tons of carbonate fluorapatite, are found to the south of the Anti Taurus mountains in a belt 500 km. long by 100 km. wide.[430-1]

### U.S.S.R. DEPOSITS

Phosphate deposits in the U.S.S.R. have been surveyed and examined systematically since the year 1910. The location of those known up to 1922 was mapped by Samoilov.[42] About 65% of the ores contain less than 20% $P_2O_5$ and in the remainder the maximum content is usually about 35%. In the White Sea area, however, there are on the Kola peninsula phosphates of igneous origin which contain as much as 41% $P_2O_5$. The age of these deposits, as determined by the radioactive lead method, was found to be 312–400 million years. By the argon and helium methods the figure found was 230–400 million years.[43] The mineralization of igneous phosphates of the Mtavari series has been discussed.[425] Further south near Grodno on the Polish border[44] and in the region of Podolia[45] the phosphates are mainly of sedimentary origin and contain about 20–25% $P_2O_5$. In the area of the Horyn river on the borders of the Ukraine the deposits are mostly apatite, dating from about 350 million years ago. The phosphate content is about 32% $P_2O_5$.[46]

The Moscow Basin contains phosphorites of various kinds, mostly with a $P_2O_5$ content of 10–25%.[47] Some of these originate from rocks 100–150 million years old.[48] Others are of more recent origin, resulting from sea-bottom deposits and sediments.[49] Interaction of phosphorite sands with iron-containing glacial deposits such as moraines and pyritic clays formed a mineral very similar to delvauxite, $Fe_2O_3,P_2O_5,nH_2O$.[50]

Black phosphorite nodules having the composition $2Ca_3(PO_4)_2,CaF_2,CaCO_3$ were discovered near Kursk, some 300 miles south of Moscow, and were later found in the Ukraine.[51] Petrographic examination of the phosphorites of Western Russia supported the existence of a new mineral, which was named *kurskite*, and which was shown to be distinct from *staffelite*, $3Ca_3(PO_4)_2,CaF_2,CaCO_3$.[52] Phosphate deposits in the Moscow region were said to be mainly kurskite.[49] It is possible, however, that these may have been confused with *francolite*. The separation of phosphorites into kurskite and staffelite has been criticized[53] because $X$-ray examination does not support this. Both minerals were shown to have the fluorapatite lattice and the lattice structure was not changed on removal of the carbon dioxide by heating the phosphorites to a high temperature.

Near Kursk, and extending along the basin of the Seim river to Rylsk on the border of the Ukraine, phosphorites containing 13–37% $P_2O_5$ are found. These were formed 50–100 million years ago by precipitation of the phosphate in a shallow sea, and consist mostly of quartz sandstones cemented together with the phosphate. Similar deposits occur about 300 miles to the east of Kursk in the valley of the Khoper river, and extend north-east towards Ribkin in the province of Penza. They resulted from the leaching of phosphorus-containing limestones of the Cretaceous period. The phosphorite is mixed with clay, mica and glauconite, a potassium iron silicate derived from Secondary and Tertiary rock formations.[54-5] In the Ukraine sedimentary deposits occur as a clay pebble phosphate containing 22–27% $P_2O_5$ and as sandy pebbles with a $P_2O_5$ content of 15–18%.[56] Phosphorite nodules are present in the glauconitic marl and in ammonites found in the Daghestan area of the Caucasus. These average about 21% $P_2O_5$.[57] One of the largest of the phosphorite deposits of the U.S.S.R. occurs in the region between the Vyatka and Kama rivers, 500–600 miles east of Moscow. This also is of glauconitic origin and contains about 25% $P_2O_5$.[58] South of this area, on the western slopes of the Ural mountains, there are phosphorites of limestone and dolomite origin. These are located near Sterlitamak and in the valley of the Seleuk river, about 120 miles west of Magnitogorsk.[59] The $P_2O_5$ content ranges between 15 and 34%,[60] but is mostly around 20%. The rock formation usually consists of alternate strata of grey and brown phosphorite and limestone or calcite. Weathering has resulted in the phosphate being preserved only in spots or in lenses. In the thinner strata the phosphate is amorphous or fine-grained and is mixed with carbonates, iron oxides and quartz grains.[61] The phosphorites along the Seleuk river are less stratified and often consist of a grey or black phosphate embedded in dolomite. The black variety contains as much as 31% $P_2O_5$. It is thought that they were formed by chemical precipitation from sea water.[62] On the eastern slopes of the Urals phosphorites occur in the gorge of the river Tech. They are sedimentary in nature, often consisting of layers of glauconite cemented together by calcium phosphate. The $P_2O_5$ content is about 20%. Some sediments also consist of a white, finely-grained layer of phosphorite deposited on quartz sand and feldspar, the phosphate portion containing up to 37% $P_2O_5$.[63] The phosphates of the Urals are not of great industrial importance mainly because of the depth of the deposits, their scattered distribution or the thinness of the phosphorite bed. They are, however, of some interest because they occur at the boundary of two sea sediments, which may indicate much larger deposits in the region.

Large quantities of phosphorites occur in South Kazakhstan, mainly in the Kara-Tau mountain area, approximately 350 miles north of Afghanistan.[64, 426] The deposits have been estimated to be some 315 million tons, yielding 25 tons of ore per square mile.[65] The average $P_2O_5$ content is 28%, but in some beds it is as high as 36%.[66]

In Northern Bessarabia near the Ukraine phosphorites are found in the valley of the Dniester river. They are mostly apatites and contain 36% $P_2O_5$ corresponding to 80% $Ca_3(PO_4)_2$. Geological examination indicates that they are derived from rocks about 250 million years old and their petrographic characteristics show that they are lake deposits.[67]

Polish phosphorites contain 15–22% $P_2O_5$ and occur mostly on the borders of White Russia as far north as Raków near Lithuania.[68] In middle Poland the deposits are of Cretaceous origin and contain up to 3·5% $Fe_2O_3$ and 7·0% $Al_2O_3$.[69]

## EUROPEAN DEPOSITS

European phosphate deposits are small in comparison with those of North Africa, the U.S.A. and the U.S.S.R., and are generally scattered. The location of the main phosphate-bearing regions has been previously described (Mellor, VIII, 735). Phosphate ores found in the British Isles are not of commercial value and occur as nodules and concretions and phosphatized fossils in geological strata dating back 350 million years. Near Bala in North Wales the phosphorites are in the form of black nodules associated with limestone formations. Phosphates of the Cretaceous period occur in isolated areas extending from the Isle of Wight to Yorkshire. They are found as nodules in the chalk beds and marl of Cambridgeshire and Bedfordshire, and in Sussex the chalk is occasionally phosphatized. In East Anglia the phosphate formations belong to the more recent Pliocene period and are largely composed of phosphatized fossils.[70] Marine phosphorites containing up to 28% $P_2O_5$ occur in Ireland in lenses and thin discontinuous layers.[71]

In Belgium and north-east France the deposits occur as phosphatic chalk and phosphate sand.[72] In south-western France the phosphates occur mixed with clay and are mostly derived from Jurassic limestones. Under the tropical conditions of the later Eocene period (about 50 million years ago) the clay became largely converted into hydrated alumina. This subsequently became phosphatized and the phosphatic clays accumulated in caverns in the limestone.[73] Phosphorites, both pure and mixed with red clay, quartz sand, bauxite and iron and manganese oxides occur as concretions in limestone pockets in the Bas-Languedoc district of south-eastern France.[74]

The Alentejo district of Portugal contains small deposits of apatites of igneous origin containing up to 10% $P_2O_5$.[75] Across the Spanish border similar ores are found in the Toledo mountains, associated with slate formations. They also occur in the Almeria district of south-eastern Spain.

In Austria, in the region of Linz, phosphorites containing up to 28% $P_2O_5$ are found in small quantities, mixed with sandstone, clay and dolomite.[76] To the north-west of this, at Auerbach in Germany, there is a deposit containing 20–24% $P_2O_5$, which appears to have originated in the reaction of limestone with decayed animal matter, which once accumulated in an isolated inlet of the sea.[77] A fluorapatite from Dalmatia in Yugoslavia has been reported.[78]

On the Swedish island of Gotland in the Baltic Sea there is a phosphorite conglomerate consisting of grey pebbles having a $P_2O_5$ content of 35%. Associated with this are phosphorite–sandstone pebbles, varying in colour from yellow to dark brown, which contain 12% $P_2O_5$.[79]

### OTHER AFRICAN DEPOSITS

South Africa has some phosphorite deposits in the form of lenses and nodular masses in the Laingsburg area of Cape Province. These contain 24–35% $P_2O_5$ and are believed to be chemical precipitates formed in shallow water.[80] Other districts of South Africa, including the Transvaal, also contain phosphates in the form of apatites, phosphate nodules and marine phosphorites. The $P_2O_5$ content of these varies from 10–41%, but most of the deposits are localized and are of little commercial importance.[81] Fluorapatite, containing $P_2O_5$ 41–43%, CaO 54–55%, and F 2·3–4·2%, is found associated with the pegmatites of the Kibaro–Urundian area of the eastern Congo in Central Africa.[82]

In Uganda there are large deposits of apatite minerals.[83] Amblygonite $[(Li,Na,Al)_4(PO_4,F,OH)_4,H_2O]$ associated with augelite $[Al_2(OH)_3PO_4]$, containing 36% $P_2O_5$ and 43% $Al_2O_3$, is mined at Mbale.[84] Apatite which by weathering on the surface has been converted into francolite occurs in Eastern Uganda.[85] This contains 41% $P_2O_5$, 55% CaO and 2·3% F.[86] Apatite is also found in the Sukulu mineral deposits of Uganda.[87] In the south-eastern region of the province, near Tororo, there is a weathered material which contains 13% $P_2O_5$ and 0·2% $Nb_2O_5$. The reserves of this have been estimated to be 130 million tons.[88]

The Thiès and Tivanouane regions of Senegal in French West Africa contain deposits of calcium phosphate averaging 34% $P_2O_5$ and 47% CaO, and of calcium aluminium phosphates averaging 34% $P_2O_5$ and 12% CaO.[89] The latter were formed by leaching of the phosphate from calcium phosphates and subsequent reaction with the underlying aluminous clays.[90] Crandallite $[CaAl_3(OH)_5(PO_4)_2H_2O]$ and augelite $[Al_2(OH)_3PO_4]$ are also found in this area.[91]

Deposits of sedimentary phosphates containing 12–43% $P_2O_5$ and estimated at 15 million tons have been located in Angola, Portuguese West Africa.[92] Very large deposits of high grade apatite ore have also been discovered in the northern part of the Spanish Sahara.[432]

### FAR EAST DEPOSITS

Apatite containing 20–25% $P_2O_5$ is found near Bihar in India.[93] In Trichinopoly and near Mussoorie there is a deposit in the form of nodules which contains 27% $P_2O_5$, 7% CaO and 2·5% F. The reserves are estimated at 8 million tons. Another deposit, also estimated at 8 million tons, occurs at Trichy in the form of phosphatic nodules. It contains on an average 25·6% $P_2O_5$. Conversion to superphosphate is uneconomical because of the high calcium carbonate content of the ore. Fusion with magnesium oxide and silica at 1500°C. converts it into a silicophosphate, the phosphorus of which is available to plants.[94, 433] The deposits at Mussoorie are of low to medium grade, but smaller deposits of higher grade ore occur at Jaisalmer in Rajasthan.[433]

Deposits of apatite having a very high phosphorus content have been reported to exist in Vietnam. Some of these are said to contain as much as 41% $P_2O_5$.[95] Two types of ore are present, one a sedimentary, micro-crystalline apatite and the other a weathered phosphate of limestone origin.[96]

The phosphate reserves of Japan have been estimated to be some 25 million tons and are found at Noto, Central Japan, where the $P_2O_5$ content is 33%. Other regions include Rasa Island and the Kita Daito Islands of the Okinawa group and the Palau or Pelew Islands to the east of the Philippines. Here the $P_2O_5$ content varies between 10 and 40% and between 29 and 40% respectively.[97] In South Japan some deposits contain 25–30% $P_2O_5$, but more usually the content is 15–20%. The fluorine present in the rock varies between 0·02 and 0·5%.[98]

Phosphate deposits containing 18–33% $P_2O_5$ and estimated to amount to about 18 million tons have been located in the Paracel Islands, Indo-China. They are said to have been formed by reaction of limestone with phosphate solutions derived from the leaching of guano.[23]

The phosphate resources of China do not seem to have been studied in any detail. Active mining operations take place in Kiang-Su province of Eastern China and guano occurs on Tungsha Island, south-east of Hong Kong.[97] In the Kiang-Su and An-Hwei regions to the north and north-west of Shanghai most of the rock is sedimentary and belongs to the late Cambrian period.[99] The phosphate, which does not seem to be pyrogenic in origin, rarely contains more than 30% $P_2O_5$. Some deposits contain 20% $P_2O_5$ but the more usual content is 8–15%.[100] The known ores of China have been estimated to be about 3 million tons.[4]

### AUSTRALASIAN DEPOSITS

Phosphate minerals in minor quantities occur in Australia. Phosphorites of secondary origin are found near Kapunda, apatite north of Adelaide and cretaceous phosphates at Dandarragan north of Perth.[97] The last occur as nodules in greensand and contain 12–17% $P_2O_5$.[101] Some apatites containing 27% $P_2O_5$ have also been found at Dandarragan.[102] Deposits of guano containing 4–27% $P_2O_5$ occur in the coastal areas of Western Australia between Perth and Dongara, 250 miles to the north, and on some islands off the east coast.[97] Xenotime, monazite and amblygonite ores containing 20–35% $P_2O_5$ are found in North-western Australia in the region of the Pilbara goldfields. Apatite associated with yttrium, lanthanum and other rare earths occurs in the New South Wales district.[103] A few deposits of phosphorite, mainly of academic interest, occur in New Zealand. North of Otago there is some phosphate rock containing 10–20% $P_2O_5$. Taranakite, vivianite and wavellite have also been found in South Auckland.

## Uranium in Phosphorus Minerals

Many phosphorites, phosphate minerals and rock contain uranium, the amount depending on the type of phosphate deposit, but usually being less than 0·2% $U_3O_8$. Fossil bones, however, may contain as much as 0·5% $U_3O_8$.

*Table IV.—Uranium in Phosphate Rock*
(p.p.m. $U_3O_8$)

| Source | $U_3O_8$ p.p.m. |
|---|---|
| Morocco, Algeria, Tunisia, Egypt | 40–160 |
| Florida, South Carolina | 10–1500 |
| Pacific, Indian and Caribbean Islands | 10–180 |
| British Isles | 30–1080 |
| Belgium, Germany, France, Spain | 10–70 |
| Nigeria | 40–110 |
| Russia, Norway, Uganda, South Africa | 10–300 |

The uranium content of phosphate rock and minerals has been determined by radiometric and chemical analysis, with the results shown in Table IV, which gives the parts per million found in deposits from various sources.[104]

Auto-radiographs suggested that the uranium in apatites was derived from the action of uranium-containing solutions, rather than from the magma from which the minerals were formed. The apatite structure has a greater geochemical affinity for uranium than has any other phase normally found during the dissolution or weathering of rocks.

Uranium occurs as an essential and major constituent of some twenty-two known phosphorus minerals (see Table XVI). These are mainly secondary minerals containing 15% or less of $P_2O_5$ and are formed by the weathering of ore deposits. They are less important as a possible source of uranium than the more abundant apatites and phosphorites. The uranium present in igneous rocks is most often found in or associated with apatite. It seems likely that the greater part of the uranium in the earth's crust is concentrated in apatites. Fluorapatite usually contains less than 0·01% $U_3O_8$, but in some igneous apatites this may be as high as 0·04%.[105] Although much apatite is used for the production of phosphorus and phosphates, it is not a suitable material for the easy recovery of uranium as a by-product.

All marine phosphorites contain some uranium, generally between 0·01 and 0·03% $U_3O_8$, but sometimes in amounts up to 0·2%. Since the greater part of world phosphate production uses marine phosphorites as raw material, they are a potential source of uranium as a by-product. The uranium is derived from sea water, either during deposition or by subsequent reaction with uranium-containing solutions.[106] This reaction is influenced by such factors as time, size of phosphorite grains and the permeability of the ore bed. Calcium, carbonate and hydroxyl ions hinder the removal of uranium from solution.[107] The Phosphoria formations of Wyoming and Northern Colorado, for example, contain up to 0·07% $U_3O_8$, the uranium content being very roughly proportional to the $P_2O_5$ and inversely proportional to the $CO_2$ in the phosphorite.[108] In the marine phosphorites the uranium is adsorbed on or is present in the lattice of the phosphate, the substitution mechanism probably involving isomorphous replacement of calcium by uranium.[109] Reducing conditions favour deposition of uranium in the phosphate, and in the lattice it is tetravalent. When adsorbed on apatite crystallites, however, the uranium is hexavalent and is present as the $UO_2^{2+}$ ion.[110] Because it is present in marine phosphorites in an acid-soluble form,[111] the uranium may be recovered as a by-product in the manufacture of superphosphate.[112] It is, however, more economical to carry out this recovery when the phosphorite is used for making wet-process phosphoric acid.[113]

Prolonged weathering of apatites and phosphorites, particularly under slightly acid conditions, can result in the decomposition of the phosphate. Where this has occurred in the presence of clay the apatite is converted to wavellite, $[(AlOH)_3(PO_4)_2,5H_2O]$, crandallite, $[CaAl_3(OH)_5(PO_4)_2,H_2O]$, and similar aluminium phosphate minerals.[114] This has happened with some of the Florida phosphate deposits[115] and with those in Senegal in Africa.[116, 91] In the latter instance the evidence is that uranium was initially present in apatite, from which an aluminium calcium phosphate was formed. During the primary phase of evolution of the deposits the uranium was retained in the mineral pallite, $[(AlFe)_{12}Ca_3(OH)_{18}(PO_4)_8,6H_2O]$. The latter under more recent climatic conditions became transformed by weathering into crandallite in which the uranium was concentrated.[117] Crandallite from this region contains 0·02–0·05% $U_3O_8$ and pallite 0·01–0·015%. In some of the North African phosphates of sedimentary origin the uranium content is 0·005–0·01% and appears to have been co-precipitated with the phosphate during the formation of the deposit.[118] The uranium content of aluminium phosphates which do not also contain calcium is negligible, presumably because the size of the aluminium ion is too small to allow substitution by the much larger uranium ion.

Guano phosphate deposits contain no uranium and the uranium content of phosphatized rock and river pebble phosphate deposits is usually very low. Fossil bones are an interesting example of the affinity of apatite for uranium. Ordinary bone, which is mainly carbonate-apatite, contains no uranium, but in fossil bones the uranium content increases with age. When associated with phosphorites, fossil bones usually have the same uranium content as the phosphorite. In some instances, however, particularly with isolated bone piles, the uranium content may be quite high. For example, fossil bones from the old red sandstone formations contain as much as 0·55% $U_3O_8$.[104] In the Salt Wash sandstone in the U.S.A. fossilized dinosaur bones have acted as a nucleus around which uranium has precipitated during mineralization.[119]

## Minor and Trace Elements in Phosphorites

As many as thirty-two elements have been found to be present in phosphate rock in trace amounts.[120, 427] Some of these are important because of the possibility of recovering sizeable amounts of the element from the vast quantities of phosphate ores used for the manufacture of phosphorus, phosphoric acid and phosphates. They may also be significant as trace elements in the fertilizing action of phosphorites when directly applied to the soil.

*Table V.—Minor Metallic Constituents of Phosphate Rock*

| Source | Metallic constituent in p.p.m. | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | $Na_2O$ | $K_2O$ | CuO | ZnO | MgO | MnO | $Cr_2O_3$ | $V_2O_3$ | $TiO_2$ | $As_2O_3$ |
| Florida | 0–7000 | 500–5000 | 0–30 | 0–120 | 0–8500 | 0–500 | 0–400 | 0–200 | 300–3500 | 0–50 |
| Tennessee | 1300–4000 | 400–6000 | 0–40 | 0–10 | 600–5500 | 0–3000 | 0–100 | 0–100 | 400–900 | 10–40 |
| Western States | 1600–8000 | 2000–6000 | 30–110 | 0–10 | 0–3000 | 0–300 | 500–1500 | 400–4000 | 400–1000 | 10–140 |
| South Carolina | 3000–4000 | 2000–3000 | 50 | 0–5 | 3000–4000 | 300–900 | 300 | 0 | 700–800 | 5 |
| Morocco | 11,900 | 1,600 | — | — | 1,600 | 20 | 400 | 0 | 250 | — |
| Tunis | 12,500 | 4,400 | — | — | 4,500 | 30 | 450 | 0 | 500 | — |
| Curacao | 8,800 | 900 | — | — | 12,300 | 30 | 50 | 100 | 200 | — |

The amounts of some minor metallic constituents of phosphate rock from the U.S.A., North African and West Indies deposits are given in Table V. The $P_2O_5$ content of the samples which were examined was between 27 and 39%, except for one or two specimens from Florida and Tennessee, which contained 21 and 11% $P_2O_5$, respectively.[121]

*Table VI.—Trace Elements in United States Phosphate Rock*

| | Florida p.p.m. | Tennessee p.p.m. | Western p.p.m. |
|---|---|---|---|
| $As_2O_5$ | 2–30 | 7–75 | 6–140 |
| BaO | — | 100–300 | 500–900 |
| $B_2O_3$ | 20–100 | 35–75 | 20–70 |
| $Cr_2O_3$ | 1–130 | 30–70 | 500–1300 |
| CuO | 5–30 | 20–30 | 30–100 |

The minor constituents of phosphate deposits in other parts of the world are probably similar to those shown above. In the case of lower grade ores, however, some modification is to be expected owing to the variations in composition and type of rock formation in contact with the phosphorite. For example, the phosphorite nodules in the Podolia region of the Dniester river in the U.S.S.R. are sulphide-bearing ores. They are characterized by intergrowths of galena, sphalerite and globules of pyrite and chalcopyrite. The phosphorite is a typical fluorapatite containing 20–35% $P_2O_5$, 1·8% $CO_2$ and 2·5–3·5% F, together with several per cent of copper, zinc and lead. It also contains traces of lithium, silver, cadmium, tin, selenium, nickel, cobalt, zirconium, yttrium and ytterbium.[122]

A number of phosphorites have been found to contain rare-earth elements in small quantities. The Kara-Tau deposits of the U.S.S.R. contain 0·13% of rare earth oxides, mostly yttrium, but also some lanthanum, cerium and ytterbium.[123] The phosphate rock from Ocean Island in the South Pacific contains about 60 p.p.m. of rare earths, mainly cerium, neodymium, lanthanum and praseodymium. The neighbouring Nauru Island phosphate contains none of these elements. The difference is attributed to metamorphism of the Nauru rock.[124]

More recent data on the trace elements in phosphate rock found in the U.S.A. have been collected together by Van Wazer.[4] A summary is given in Table VI, the information referring to the Florida, Tennessee and Western States deposits, containing 20–35% $P_2O_5$.

Florida rock may also contain up to 100 p.p.m. of beryllium, cadmium, cæsium, lead, lithium, mercury, rubidium, silver and zirconium.

## THERMODYNAMIC PROPERTIES OF APATITES

The heat capacities of calcium fluorapatite and of calcium hydroxyapatite have been determined in the temperature range 15–1500°K. These measurements were made on synthetic materials. Calcium hydroxyapatite was prepared according to the procedure of Rathje.[125] 0·2 M. aqueous calcium nitrate and 0·12 M. aqueous mono-ammonium phosphate were added at a rate of 100 ml./hr. to water at 95°C. The mixture was stirred and the pH kept at 4·5 (bromophenol blue indicator) by addition of ammonium hydroxide. After settling, filtering and washing, the precipitate was dried at 110°C. and then heated for 72 hr. at 950°C. in an atmosphere containing 20% of water vapour, to promote crystallization. The equation for the reaction is:

$$10Ca(NO_3)_2 + 6NH_4H_2PO_4 + 14NH_4OH \\ = Ca_{10}(OH)_2(PO_4)_6 + 20NH_4NO_3 + 12H_2O$$

The product contained 42·38% $P_2O_5$ and 55·68% CaO as compared with theoretical values of 42·39% and 55·80% respectively. There was also present 0·30% $Al_2O_3$.

Calcium fluorapatite was made by heating a mixture of tricalcium phosphate and calcium fluoride. $\beta$-Calcium metaphosphate was first prepared by slowly heating to 500°C. monocalcium phosphate which had been recrystallized from hot phosphoric acid solution. Tricalcium phosphate was then made by heating for 5 hr. at 1150°C. a stoicheiometric mixture of the calcium metaphosphate and calcium carbonate which had been precipitated by ammonium carbonate from a hot solution of recrystallized calcium nitrate. Calcium fluoride was made by neutralizing hydrofluoric acid with calcium carbonate. Finally a stoicheiometric mixture of tricalcium phosphate and calcium fluoride was heated for 30 min. at 1370°C. in an atmosphere of nitrogen and in the presence of calcium fluoride vapour to prevent loss of fluorine. The product contained 42·20% $P_2O_5$, 55·60% CaO and 3·75% F, as compared with theoretical values of 42·22%, 55·60% and 3·77%, respectively. There were also present 0·02% MgO, 0·03% $SiO_2$ and 0·12% SrO. Microscopical examination showed that the material contained less than 0·1% of unreacted calcium fluoride. The purity of both products was also checked by *X*-ray examination and they were found to be identical with naturally occurring apatites. It was also confirmed that their structure and composition were unchanged after heating to 1500°K.

The experimental values of the low temperature heat capacities, in g.-calories per mole, are given in Table VII and Table VIII.

*Table VII.—Heat Capacity of Calcium Hydroxyapatite* ($Ca_{10}(PO_4)_6(OH)_2$) *in the Temperature Range* 15–298·16°K.[126]

| 105 | 82·30 | 205 | 147·6 | | |
| 110 | 86·49 | 210 | 150·0 | | |

The high temperature heat capacity of calcium hydroxyapatite for the temperature range 298–1500°K. is given by the following equation:

$$C_p = 228{\cdot}52 + 39{\cdot}62 \times 10^{-3}T - 50 \times 10^{5}T^{-2} \text{ g.-cal./mole} \pm 0{\cdot}22\%$$

The equations for the heat content and entropy, as derived from the heat capacity equation, are:

$$H_T - H_{298} = 228{\cdot}52T + 19{\cdot}81 \times 10^{-3}T^2 + 50 \times 10^{5}T^{-1} - 86{,}670 \text{ g.-cal./mole}$$
$$S_T - S_{298} = 526{\cdot}19 \log T + 39{\cdot}62 \times 10^{-3}T + 25 \times 10^{5}T^2 - 1342 \text{ g.-cal./mole/degree}$$

*Table VIII.—Heat Capacity of Calcium Fluorapatite* ($Ca_{10}(PO_4)_6F_2$) *in the Temperature Range* 15–298·16°K.[127]

| Temp. $T$°K. | $C_p$ g.-cal./mole | Temp. $T$°K. | $C_p$ g.-cal./mole | Temp. $T$°K. | $C_p$ g.-cal./mole |
|---|---|---|---|---|---|
| 15 | 0·98 | 115 | 90·32 | 215 | 149·7 |
| 20 | 2·47 | 120 | 94·33 | 220 | 151·8 |
| 25 | 4·81 | 125 | 98·18 | 225 | 153·8 |
| 30 | 7·87 | 130 | 101·9 | 230 | 155·8 |
| 35 | 11·67 | 135 | 105·5 | 235 | 157·8 |
| 40 | 15·86 | 140 | 109·0 | 240 | 159·8 |
| 45 | 20·51 | 145 | 112·3 | 245 | 161·7 |
| 50 | 25·65 | 150 | 115·6 | 250 | 163·6 |
| 55 | 31·01 | 155 | 118·7 | 255 | 165·4 |
| 60 | 36·58 | 160 | 121·8 | 260 | 167·2 |
| 65 | 42·08 | 165 | 124·7 | 265 | 168·9 |
| 70 | 47·47 | 170 | 127·6 | 270 | 170·6 |
| 75 | 52·73 | 175 | 130·3 | 275 | 172·2 |
| 80 | 58·03 | 180 | 132·9 | 280 | 173·9 |
| 85 | 63·22 | 185 | 135·5 | 285 | 175·6 |
| 90 | 68·15 | 190 | 138·0 | 290 | 177·2 |
| 95 | 72·87 | 195 | 140·5 | 295 | 178·8 |
| 100 | 77·42 | 200 | 142·9 | 298·16 | 179·73 |
| 105 | 81·85 | 205 | 145·3 | | |
| 110 | 86·16 | 210 | 147·5 | | |

To obtain the heat content and entropy referred to the absolute zero of temperature the following values should be added to those calculated from the above equations:

$$H_{298}-H_0 = 30{,}710 \text{ g.-cal./mole}$$
$$S_{298}-S_0 = 186{\cdot}6 \text{ g.-cal./mole/degree}$$

The heat capacity, heat content and entropy equations for calcium fluorapatite in the temperature range 15–1600°K. are as follows:

$$C_p = 226{\cdot}04+28{\cdot}88\times10^{-3}T-48{\cdot}82\times10^5T^{-2} \text{ g.-cal./mole}$$
$$H_T-H_{298} = 226{\cdot}04T+14{\cdot}44\times10^{-3}T^2+48{\cdot}82\times10^5T^{-1}-85{,}050 \text{ g.-cal./mole}$$
$$S_T-S_{298} = 520{\cdot}48\log T+28{\cdot}88\times10^{-3}T+24{\cdot}41\times 10^5T^2-1324 \text{ g.-cal./mole/degree}$$

*Table IX.—Heat Content and Entropy of Calcium Hydroxyapatite* ($Ca_{10}(PO_4)_6(OH)_2$) *in the Temperature Range* 298–1500°K.

| 1400 | 263,810 | 355·3 |
| 1500 | 290,130 | 373·4 |
| 1600 | 315,000 | 389·6 |

The heat content and entropy referred to the absolute zero of temperature are found by adding the following values to those derived from the above equations:

$$H_{298}-H_0 = 30{,}340 \text{ g.-cal./mole}$$
$$S_{298}-S_0 = 185{\cdot}5 \text{ g.-cal./mole/degree}$$

The actual experimental data found for the heat content and entropy of the two materials in the temperature range 298–1500°K. are shown in Table IX and Table X.

The calcium hydroxyapatite was not heated above 1472°K. because of slight decomposition occurring. The values for 1500°K. were therefore extrapolated, but were considered to be reasonably accurate.

The heats of formation of calcium fluorapatite, hydroxyapatite and chlorapatite have been determined by measuring the heats of reaction of these compounds with 20% and 30% nitric acid solution.[128] Calcium fluorapatite was prepared by a slight modification of the method of Egan, Wakefield and Elmore.[127] The purity was 97%. Calcium hydroxyapatite was made by neutralizing with ammonium hydroxide to pH 12 a 5% solution of diammonium phosphate. To this there was then added, with stirring, the stoicheiometric quantity of a 20% solution of calcium nitrate, also neutralized to pH 12 with ammonium hydroxide. The mixture was boiled for 10 min., filtered, washed and the product dried at 250°C. to remove traces of ammonium nitrate. It was then heated at 800°C. for a short time.[129] The material had a purity of 98·5%. Calcium chlorapatite was prepared by heating a stoicheiometric mixture of tricalcium phosphate and calcium chloride for 12 hr. at 800–900°C. in a stream of dry nitrogen.[130] The purity was 98·5%.

The mean values of the heats of formation were:

Fluorapatite = −3262 kcal./mole
Chlorapatite = −3171 kcal./mole
Hydroxyapatite = −3231 kcal./mole.

These values were estimated to be correct to within ±0·07%. The impurities in the materials were considered to be calcium fluoride and tricalcium phosphate in the fluorapatite, calcium pyrophosphate in the hydroxyapatite, and calcium chloride and tricalcium phosphate in the chlorapatite. The effect of these would be to lower the above heats of formation by 1·8 kcal./mole for fluorapatite and by 0·5 and 1·0 kcal./mole, respectively, for the hydroxy- and chlorapatite. A more recent estimate[131] has put the heat of formation of calcium fluorapatite at −3267·2±0·4 kcal./mole.

Careful examination of the mechanism involved when calcium fluorapatite is dissolved in 30% nitric acid revealed that the reaction might not take place according to the simple equation:

$$3Ca_3(PO_4)_2{,}CaF_2+14HNO_3+3H_2O = 3Ca(H_2PO_4)_2{,}H_2O+7Ca(NO_3)_2+2HF$$

Monocalcium phosphate did not precipitate from 30% nitric acid solution and there was no evidence to support the conclusion that other calcium phosphates or fluorophosphates were absent. It was also possible that some interaction occurred between calcium nitrate, calcium phosphates and hydrogen fluoride in solution.

To avoid having to make assumptions as to the compounds in solution and possible reactions among them, heats of reaction were measured for the following changes:

1. $3Ca_3(PO_4)_2{,}CaF_2+14HNO_3 = 3Ca(H_2PO_4)_2+7Ca(NO_3)_2+2HF$
2. $3Ca_3(PO_4)_2+CaF_2+14HNO_3 = 3Ca(H_2PO_4)_2+7Ca(NO_3)_2+2HF$
3. $6H_3PO_4+CaF_2+9Ca(OH)_2+14HNO_3 = 3Ca(H_2PO_4)_2+7Ca(NO_3)_2+2HF+18H_2O$
4. $6H_3PO_4+CaF_2+9CaO+14HNO_3 = 3Ca(H_2PO_4)_2+7Ca(NO_3)_2+2HF+9H_2O$.

The experiments were carried out in 31 wt.-% nitric acid and in a mixture containing 31% nitric acid and 0·10 M. phosphoric acid. The heat of mixing nitric and phosphoric acids in the proportions used for equations 3 and 4 was also determined. By eliminating undetermined quantities from these measurements, three independent values of −3298, −3294 and −3295, average −3296±2·5 kcal./mole, were obtained for the heat of formation of calcium fluorapatite. The latter was a sample of natural fluorapatite containing 40·9% $P_2O_5$, 54·8% CaO, 2·2% F, 0·09% Cl, 0·86% $Al_2O_3$, 0·41% $Fe_2O_3$ and 0·19% MgO.

Similar determinations were made on a sample of calcium hydroxyapatite prepared by calcining human teeth at 800°C. *X*-Ray examination indicated a very pure apatite structure with a trace of tricalcium phosphate. The product contained 0·15% of fluorine, equivalent to 4·2% of calcium fluorapatite. The heats of the following reactions were measured:

$$\begin{aligned}
3Ca_3(PO_4)_2,Ca(OH)_2+14HNO_3 &= 3Ca(H_2PO_4)_2+7Ca(NO_3)_2+2H_2O\\
3Ca_3(PO_4)_2+Ca(OH)_2+14HNO_3 &= 3Ca(H_2PO_4)_2+7Ca(NO_3)_2+2H_2O\\
6H_3PO_4+10Ca(OH)_2+14HNO_3 &= 3Ca(H_2PO_4)_2+7Ca(NO_3)_2+20H_2O\\
10CaO+6H_3PO_4+14HNO_3 &= 3Ca(H_2PO_4)_2+7Ca(NO_3)_2+10H_2O
\end{aligned}$$

These determinations gave three values of $-3229\pm2{\cdot}7$ kcal./mole for the heat of formation of calcium hydroxyapatite.[132]

Another value for the heat of formation of calcium fluorapatite is $-3269$ kcal./mole at 25°C. This figure was obtained for a naturally-occurring apatite from the Kola Peninsula, U.S.S.R., and for a synthetic apatite which was prepared by heating for 4 hr. at 900°C. a stoicheiometric mixture of calcium fluoride, calcium oxide and dicalcium phosphate. The Kola apatite contained 41·5% $P_2O_5$ and 52·5% CaO, and the analysis of the synthetic material was: 42·2% $P_2O_5$, 55·6% CaO and 3·76% F.[133]

The heat of formation at 25°C. of calcium hydroxyapatite made by the procedure described above (p. 12)[125–6] was found to be $-3212$ kcal./mole.[133]

The thermodynamic properties of berlinite ($AlPO_4$) have been determined,[134] with the results shown in Table XI.

*Table XI.—The Thermodynamic Properties of Berlinite* ($AlPO_4$)[134]

| 150 | 12·69 | 9·820 | 885·3 | | | | |

The berlinite used in these measurements was a synthetic material made by reacting 1·92 mole of sodium aluminate with 1 litre of 8 M. phosphoric acid:

$$NaAlO_2+2H_3PO_4 = AlPO_4+NaH_2PO_4+2H_2O$$

The material was crystallized from phosphoric acid in an autoclave at 132–315°C.[135] It contained 58·23% $P_2O_5$ and its optical and *X*-ray properties agreed with those of the naturally-occurring mineral.[134] The entropy of variscite ($AlPO_4,2H_2O$) was estimated to be 40·5 g.-cal./mole/degree.[134]

The thermodynamic properties of potassium taranakite, $K_3H_6Al_5(PO_4)_8,18H_2O$, and of ammonium taranakite, $(NH_4)_3H_6Al_5(PO_4)_8,18H_2O$, are given in Table XII.

The heat and entropy of formation of potassium and ammonium taranakite from their elements at 25°C. are shown in Table XIII.

*Table XII.—Thermodynamic Properties of Potassium and Ammonium Taranakite*[136]

| Temp. °K. | $K_3H_6Al_5(PO_4)_8.18H_2O$ (Units g.-cal., mole, degree) | | | $(NH_4)_3H_6Al_5(PO_4)_8.18H_2O$ (Units g.-cal., mole, degree) | | |

*Table XIII.—Heat and Entropy of Formation at 25°C. of Potassium and Ammonium Taranakite*[136]

| Product | $\Delta H^\circ_f$ at 25°C. kcal./mole | $\Delta S^\circ_f$ at 25°C. g.-cal./mole/degree |
|---|---|---|
| $K_3H_6Al_5(PO_4)_8,18H_2O$ | −4523·2 ± 5 | 335·6 ± 0·6 |
| $(NH_4)_3H_6Al_5(PO_4)_8,18H_2O$ | −4432·5 ± 5 | 339·9 ± 0·6 |

*Table XIV.—Heat and Entropy of Formation of Water and Various Ions at 25°C.*[136]

| | $\Delta H^\circ_f$ kcal./mole | $\Delta S^\circ_f$ g.-cal./mole/degree |
|---|---|---|
| $H_2O$ (l) | −68·317 | 16·72 |
| $H^+$ aq. | 0 | 0 |
| $K^+$ aq. | −60·04 | 24·5 |
| $NH_4{}^+$ aq. | −31·74 | 26·97 |
| $Al^{3+}$ aq. | −125·4 | −74·9 |
| $PO_4{}^{3-}$ aq. | −306·9 | −52 |

From the data given above and those of Table XIV the heat of solution in water at 25°C. was calculated to be 31·14 kcal./mole for potassium taranakite and 27·32 kcal./mole for the ammonium compound. The corresponding entropies of solution were −751·7 g.-cal./mole/degree and −748·5 g.-cal./mole/degree, respectively.

The solubility product constant derived from:

$$R - T \ln K_{\text{sp}} = \Delta H_{(\text{aq.}-\text{c})} - T\Delta S_{(\text{aq.}-\text{c})}$$

gave values for $\text{p}K_{\text{sp}}$ of 187·1 and 183·7 for the potassium and ammonium compounds, respectively. The measured values were 178·7 for potassium taranakite and 175·5 for the ammonium salt.[137] These values were considered to be apparent, rather than true, thermodynamic figures, because of the presence of complex ions in solution.

The potassium taranakite used in all the above measurements was made by dissolving 21·6 g. of aluminium in 870 ml. of 53·5% phosphoric acid, filtering and diluting to 2 l. After adjusting to pH 3·4 with 10% potassium hydroxide and diluting to 3·5 l., the solution was digested at 50°C. for 24 hr. The crystals were dried over calcium chloride in a vacuum at room temperature. The analysis was 56·6% $P_2O_5$, 9·6% Al and 8·6% K.

The ammonium salt was made in a similar way except that the aluminium phosphate was neutralized to pH 4 with 28% ammonium hydroxide. The product contained 59·6% $P_2O_5$, 10·5% Al and 4·1% $NH_4$.[137]

## PHOSPHORUS MINERALS

Phosphorus occurs in minerals in combination with some thirty other elements, the ores of commercial value generally being either fluorapatite or hydroxyapatite. There are, however, many phosphate deposits which are not distinctly crystalline like apatite, but occur as fibrous or compact masses or in the form of nodules. These are usually lower grade ores which contain little or no fluorine and in which the calcium oxide is generally not distributed in a regular manner throughout the lattice as it is in apatite. Such minerals have been given the name *phosphorite*, a term which was originally used to describe a Spanish mineral which phosphoresced when heated. In many instances, however, the distinction between apatite and phosphorite is not precise, the structures of both often being very similar.

Apatite, which is the most important of the phosphorus minerals, shows a wide variety of appearance. The crystals may be opaque or transparent, white or colourless, or various shades of yellow, green, blue, violet or brown. The crystal form is hexagonal and exhibits pyramidal hemihedrism, apatite being the best example of this type of symmetry.

The crystal structure of the apatites enables a large number and variety of substitutions to occur, particularly isomorphous replacement among similar ions. Because of this it is not possible to give a satisfactory general formula which would indicate all the possible substitutions which may arise. For most purposes, however, the unit cell of the crystal may be represented as $M_{10}X_2(RO_4)_6$.[138] In this formula M can be lithium, sodium, potassium, the alkaline earth metals, lead, magnesium, zinc, cadmium, iron, manganese, aluminium, copper, uranium or the rare earths. X may be fluorine, chlorine, bromine, the hydroxyl ion and possibly carbonate. R is generally phosphorus or arsenic, but may be sulphur, silicon or vanadium, and, more rarely, chromium or boron.

Apatites are usually grouped into two classes, each having distinct characteristics but possessing the same type of structure. In one of these, generally referred to as the apatite series, the dominant cation is calcium and the unit cell dimensions are approximately $a_0 = 9{\cdot}4$ A. and $c_0 = 6{\cdot}9$ A. The major anions are hydroxyl and fluoride and a wide range of substitutional solid solutions can occur in the series.

In the other, known as the pyromorphite series, lead is the dominant cation and the unit cell dimensions are a little larger, with $a_0 = 10{\cdot}2$ A. and $c_0 = 7{\cdot}5$ A. approximately.

The major anion in this series is chloride and there are no analogues of hydroxyapatite or fluorapatite.

Silicon and sulphur can replace phosphorus in the apatite series of minerals, while arsenic and vanadium are not usually present in large amounts. Calcium is not replaced by lead to any extent in the apatites. In the pyromorphite series on the other hand substitution of silicon and sulphur for phosphorus occurs to a lesser extent, whereas almost complete replacement of phosphorus by arsenic and vanadium can occur. Calcium does not often replace lead.

## The Structure of Apatite

The first descriptions of the apatite structure were given by Náray-Szabó[139] and by Mehmel.[140] The structures determined by both authors were very similar, differing only in the positions assigned to the fluorine atoms. It was said that the structure proposed by Mehmel applied to chlorapatite, while that described by Náray-Szabó was applicable to fluorapatite and hydroxyapatite.[141]

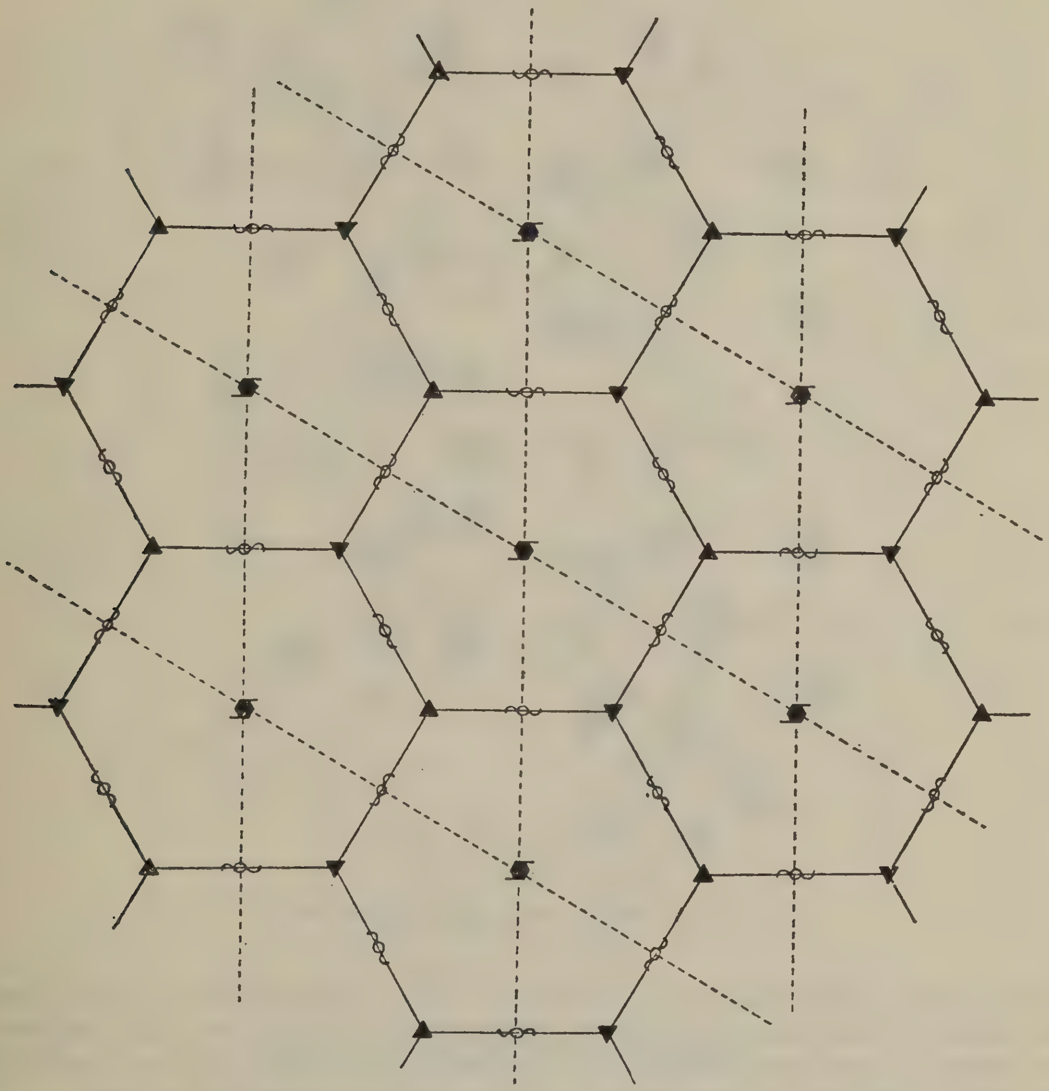

FIG. 1.—The arrangement of the vertical symmetry-axes in the apatite structure. The dotted lines show the hexagonal *a*-axes of reference.

The structure of calcium fluorapatite was determined in greater detail by Beevers and McIntyre, who were able to use a more refined *X*-ray technique.[142] This confirmed the findings of Náray-Szabó, in so far as the general arrangement of the bonding was concerned. However, small changes were found to be necessary in the co-ordinates of the phosphorus atom and in some of the interatomic distances, although these alterations became of significance only if accurate values of interatomic distances were required.

The work of these authors has been confirmed by later investigations and no further structural modifications have been found to be necessary. The general arrangement of the apatite lattice was described as follows.

Along each of the three-fold axes of the structure there is a chain of calcium atoms separated from one another by a distance equal to one-half of the *c*-axis. These are bonded to their neighbours above and below by means of three shared oxygen atoms, thus forming vertical chains of alternate calcium and oxygen atoms. Each calcium is also linked to three other oxygen atoms at about the same level as its own position on the *c*-axis. This gives an arrangement which can be represented as follows:

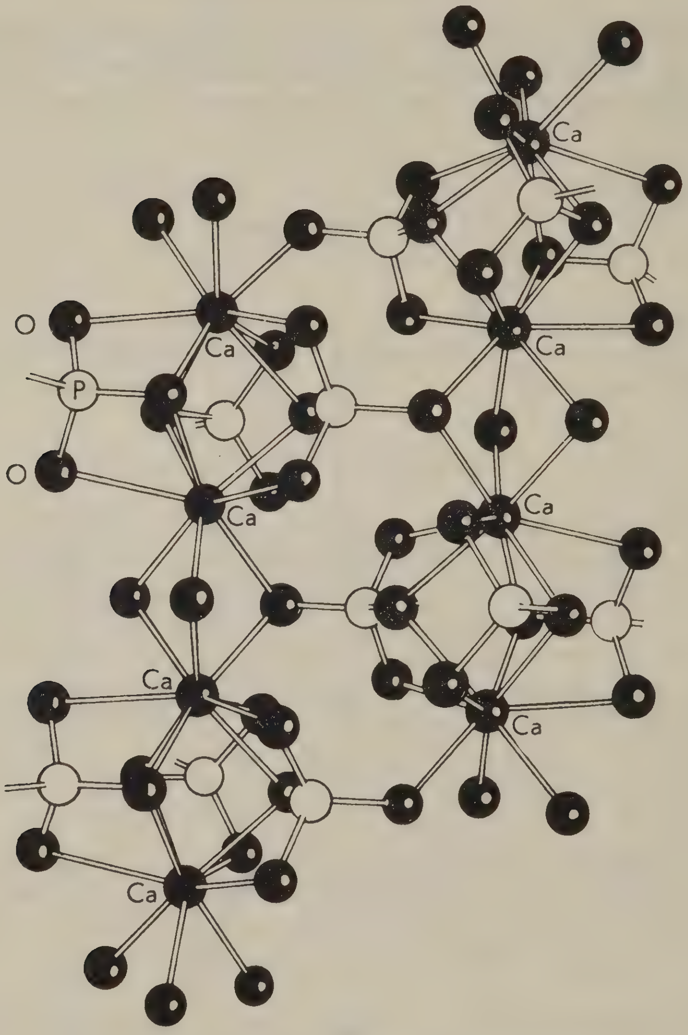

Fig. 2.—Atomic structure of fluorapatite

$$\begin{array}{ccccccccc} -\text{Ca}- & 3\text{O} & -\text{Ca}- & 3\text{O} & -\text{Ca}- \\ | & & | & & | \\ 3\text{O} & & 3\text{O} & & 3\text{O} \end{array}$$

The net effect is that every calcium atom is surrounded by nine oxygen atoms. However, because of the sharing of the oxygen atoms the calcium to oxygen ratio in the chain is 1:6.

The vertical columns of calcium and oxygen atoms are also linked to $PO_4$ groups so as to form an hexagonal network as shown in Fig. 1.

This results in a honeycomb structure having channels extending right through it in the direction of the *c*-axis. In the walls of these channels there are oxygen atoms which are so arranged as to form six recesses per unit length of each channel. Calcium atoms fit about halfway into these recesses and the fluorine atoms fit between the groups of three calcium atoms positioned at the same level. The channels and the recesses formed by the oxygen atoms are shown in Fig. 2.

In Fig. 3 the effect of inserting the calcium and fluorine atoms in the channels is seen.

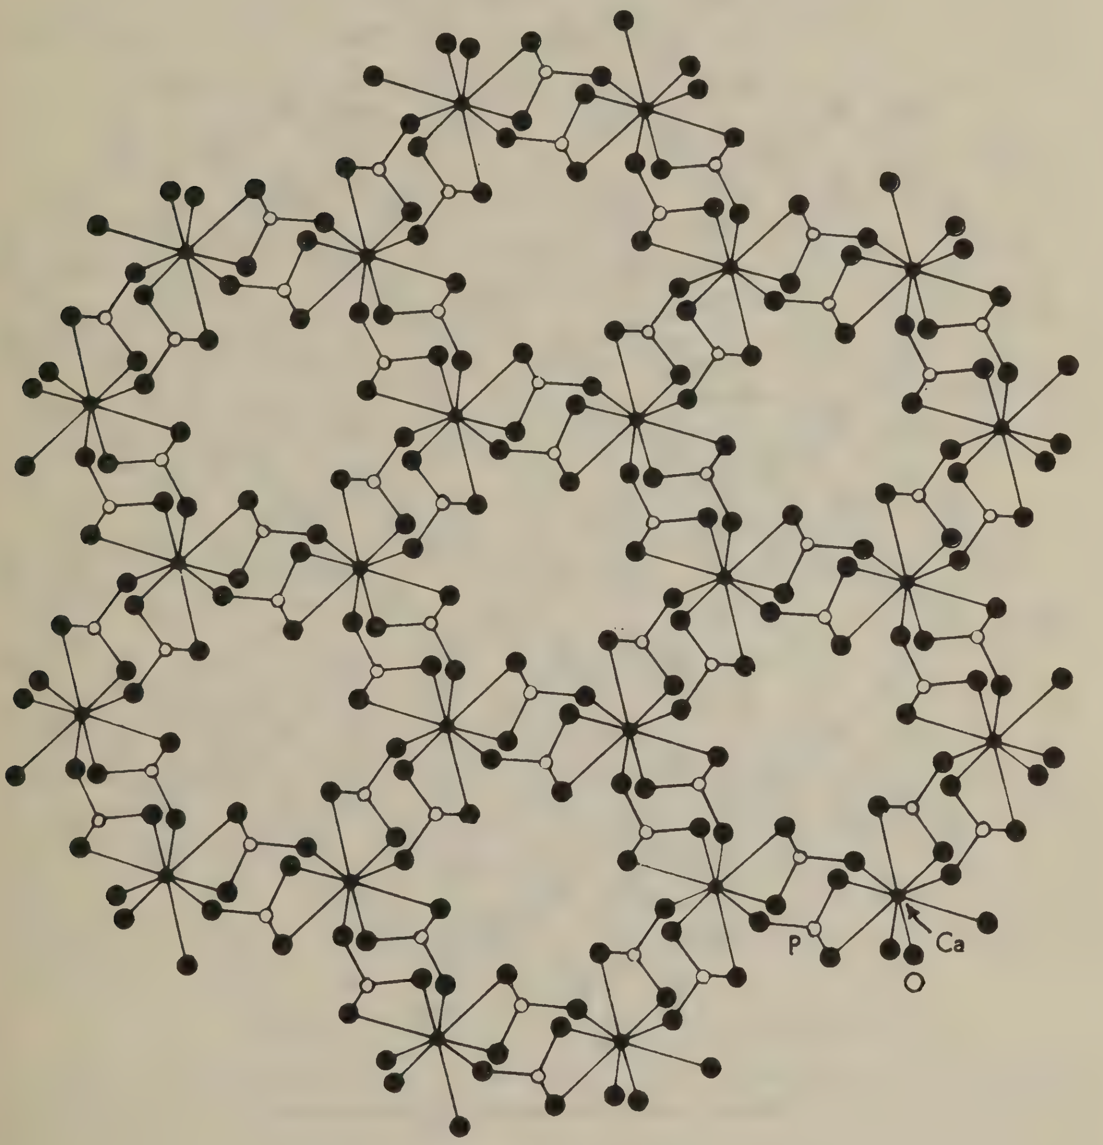

FIG. 3.—Atomic structure of fluorapatite

Fig. 4 shows the vertical columns formed by the calcium, oxygen and phosphorus atoms.

The arrangement of the calcium atoms and $PO_4$ groups gives a very stable lattice structure and determines the size of the hexagonal channels. The planar arrangement of three calcium atoms around each fluorine atom makes the whole structure very selective as regards ions which can occupy the positions of the fluoride ions. This is shown by a comparison of fluorapatite with hydroxyapatite. Since the hydroxyl ion is a little larger than the fluoride ion, the effect is to expand the hydroxyapatite structure as compared with that of fluorapatite.

These conclusions have received support[143] from more recent studies (see below) on the effect of substituting various ions in fluorapatite. Halogens do not take part in directly building up the lattice and replacement of fluorine atoms by chlorine or bromine atoms or by hydroxyl ions does not give rise to any serious alteration of the hexagonal structure. The general lattice arrangement is also still preserved, with some increase in dimensions, when strontium or barium is substituted for calcium.[144]

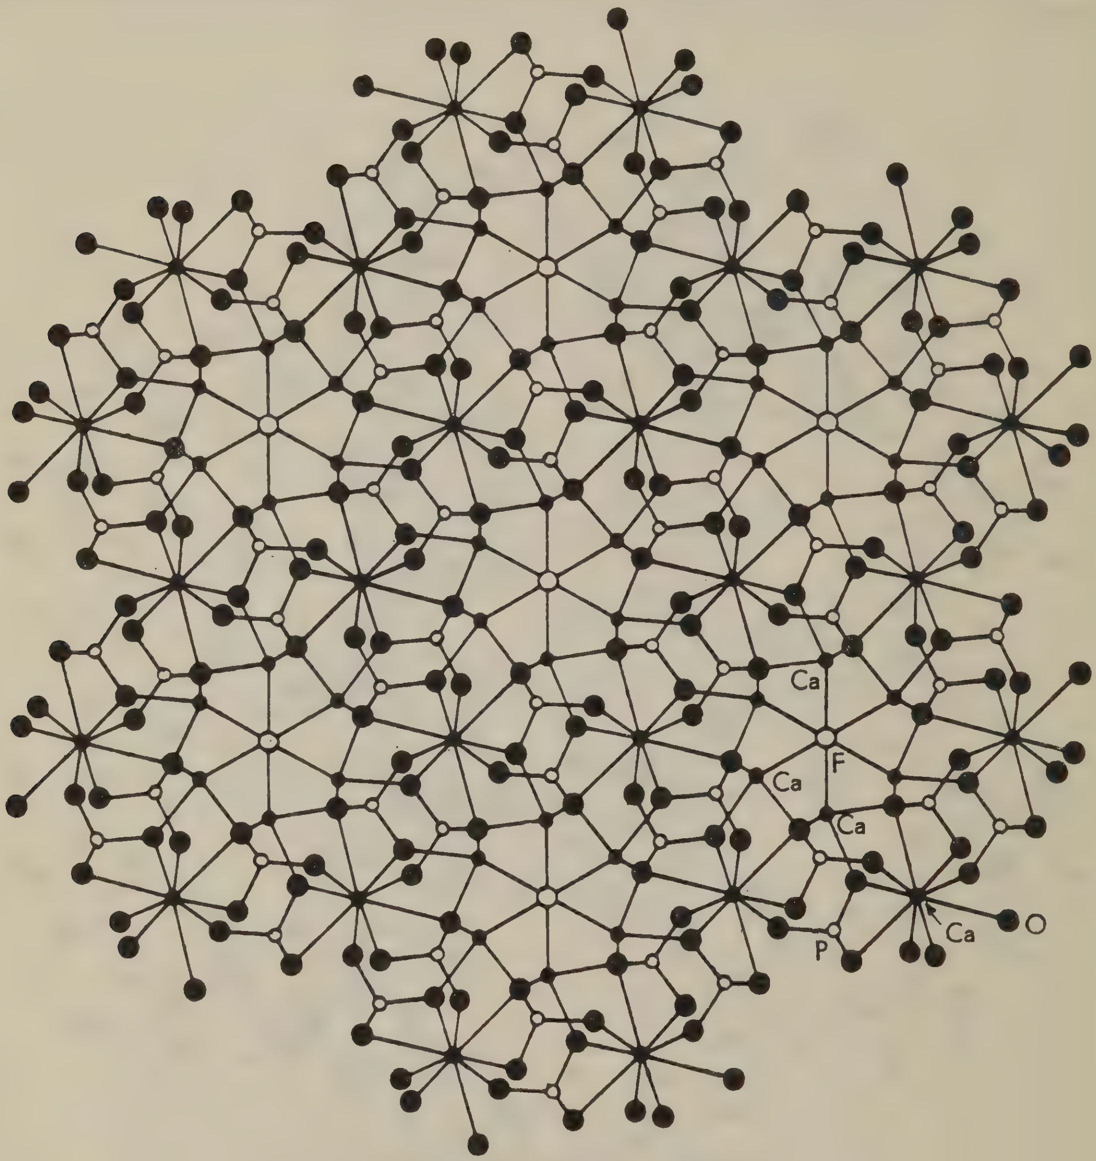

Fig. 4.—Atomic structure of fluorapatite

## Anionic Substitutions in Apatite

Fluorapatite, $Ca_{10}F_2(PO_4)_6$ or $3Ca_3(PO_4)_2,CaF_2$, is often considered to be the primary mineral from which chlorapatite and hydroxyapatite are derived by replacement of the fluorine by chlorine or hydroxyl ions. Chemically, however, fluorapatite is the most stable of the apatites and hydroxyapatite the least stable, the general direction of substitution reactions favouring the fluoride ion. Direct replacement of the fluoride ion in fluorapatite by other ions does not occur.[130] Several chlorapatite minerals are known, but the corresponding bromapatite and iodoapatite minerals have not been reported. From structural considerations it has been stated[145] that an iodoapatite is unlikely to exist. However, this possibility does not seem to have been investigated in the light of more recent knowledge of the structure of apatites.

### SUBSTITUTION BY HALOGENS

The substitution of halogens in the apatites has been studied by examining the reactions of calcium hydroxyapatite and tricalcium phosphate. Pure hydroxyapatite was prepared by saturating a solution of phosphoric acid at 100°C. to the phenolphthalein end-point, using calcium hydroxide.[146] The precipitate was dried and then calcined for a few hours at 800°C.[147] Heating hydroxyapatite with calcium chloride for 12 hr. at 800–900°C. *in vacuo* or in a dry, inert atmosphere formed chlorapatite according to the equation[148]:

$$3Ca_3(PO_4)_2{,}Ca(OH)_2 + CaCl_2 = 3Ca_3(PO_4)_2{,}CaCl_2 + CaO + H_2O$$

Under similar conditions the following reactions occurred with calcium fluoride:

$$3Ca_3(PO_4)_2{,}Ca(OH)_2 + CaF_2 = 3Ca_3(PO_4)_2{,}CaF_2 + CaO + H_2O$$
$$3Ca_3(PO_4)_2{,}CaCl_2 + CaF_2 = 3Ca_3(PO_4)_2{,}CaF_2 + CaCl_2$$

When the above reactions were carried out with insufficient calcium halide for complete conversion, mixed apatites were obtained.[149] At temperatures above 600°C. water reacted with chlorapatite to replace the chlorine atom by hydroxyl ion. It was therefore necessary to ensure rapid removal of the water formed in the first of the reactions given above. Calcium bromapatite was much more readily hydrolyzed, so that it was not possible to prepare this material by causing calcium hydroxyapatite to react with calcium bromide.[130, 143] Under these conditions fluorapatite on the other hand was stable in the presence of moisture. Hydroxyapatite was stable when heated alone at 1000°C. and lost no water, indicating that an oxyapatite does not exist as was previously thought.[139, 150]

For reactions starting with anhydrous tricalcium phosphate, this salt was prepared by heating at 900°C. an equimolecular mixture of calcium oxide and calcium pyrophosphate. The following reactions were found to occur when the reactants were heated in the solid state[130]:

$$3Ca_3(PO_4)_2 + CaX_2 = 3Ca_3(PO_4)_2{,}CaX_2$$

where X is F, Cl, Br or OH.

The formation of fluorapatite occurred easily at temperatures above 550°C. Chlorapatite was formed at temperatures above 625°C. in the absence of moisture. More rigorous precautions to exclude moisture were required to form bromapatite. The reaction between tricalcium phosphate and calcium hydroxide did not produce hydroxyapatite under dry conditions at any temperature below the decomposition point of the calcium hydroxide. In the presence of water vapour at 850°C. however, the formation of the apatite was fairly rapid, the reaction being more correctly represented by the equation:

$$3Ca_3(PO_4)_2 + CaO + H_2O = 3Ca_3(PO_4)_2{,}Ca(OH)_2$$

Under anhydrous conditions at 800–900°C. solid solutions were obtained with tricalcium phosphate and varying proportions of calcium halides, the general reaction being:

$$3Ca_3(PO_4)_2 + xCaF_2 + (1-x)CaCl_2 = 3Ca_3(PO_4)_2{,}Ca[xF_2(1-x)Cl_2]$$

Partial substitution also occurred in reactions such as:

$$3Ca_3(PO_4)_2{,}CaCl_2 + xCaF_2 = 3Ca_3(PO_4)_2{,}Ca[xF_2(1-x)Cl_2] + xCaCl_2$$

The products of the above reactions could take part in inter-diffusion processes of the type indicated below. These, however, were generally slow reactions:

$$x[3Ca_3(PO_4)_2{,}CaF_2] + (1-x)[3Ca_3(PO_4)_2{,}CaCl_2] = 3Ca_3(PO_4)_2{,}[xF_2(1-x)Cl_2]Ca$$

In all the materials obtained from the above reactions of calcium hydroxyapatite or of tricalcium phosphate the general arrangement of the apatite structure was preserved, with small changes in lattice dimensions. As fluorine was replaced by other halides or by hydroxyl ion the *a*-parameter of the unit cell increased and the *c*-parameter decreased. The variations in these parameters are shown graphically in Figs. 5 and 6.[130]

Fig. 7 shows the relationship between the lattice parameters of the calcium halogen-apatites and the ionic radii of the halogen ions.[143]

Somewhat different results were obtained[130] when halogen substitution reactions were studied using *precipitated* tricalcium phosphate as starting material. This salt was obtained by double decomposition from solutions of calcium chloride and disodium phosphate at room temperature. It had an *X*-ray diagram similar to, but not identical with, that of calcium fluorapatite, and was shown to be $3Ca_3(PO_4)_2, \frac{1}{2}H_2O$. At 625°C. dehydration occurred to form mainly anhydrous tricalcium phosphate with a little calcium hydroxyapatite. Heating at 800°C. produced a pure, anhydrous tricalcium phosphate.

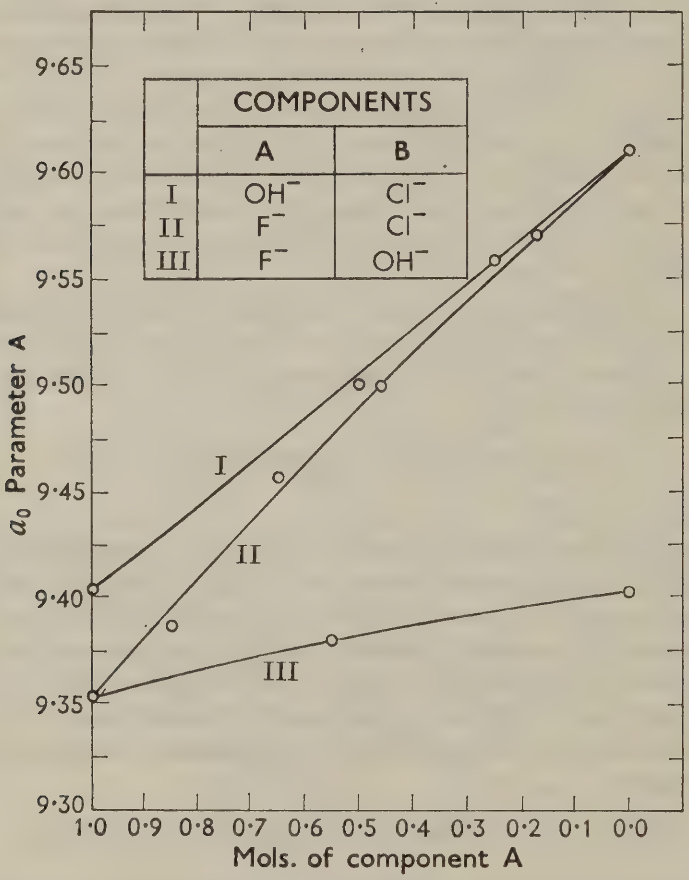

FIG. 5.—Effect of anion substitution on $a_0$-parameter of calcium apatites

Precipitated tricalcium phosphate reacted slowly with calcium fluoride at 550°C. and above to give calcium fluorapatite. With calcium chloride a mixed chlorohydroxyapatite was formed at temperatures below 625°C., but at higher temperatures a pure chlorapatite was obtained by heating the mixture rapidly over phosphorus pentoxide in a vacuum. A bromapatite was not obtained from precipitated tricalcium phosphate unless the latter was dehydrated before being mixed with calcium bromide. Heating mixtures of the phosphate and calcium hydroxide did not give a pure hydroxyapatite. At 350°C. the lime was dehydrated to calcium oxide, and above 625°C. the tricalcium phosphate lost its water. The product was mainly anhydrous tricalcium phosphate, calcium oxide and a little hydroxyapatite. By prolonged heating at 850°C. a nearly pure hydroxyapatite could be obtained in the presence of water vapour.

Precipitated tricalcium phosphate removes the fluoride from water containing calcium fluoride and in the presence of excess of the latter is slowly converted into calcium fluorapatite.[151] In the above reactions it appeared that the halogen ions entered the lattice of the calcium phosphate in preference to replacing the water of hydration. These observations were in agreement with the view[130, 152] that precipitated tricalcium phosphate is an apatite in which calcium and fluoride ions are replaced by $\frac{1}{2}H_2O$.

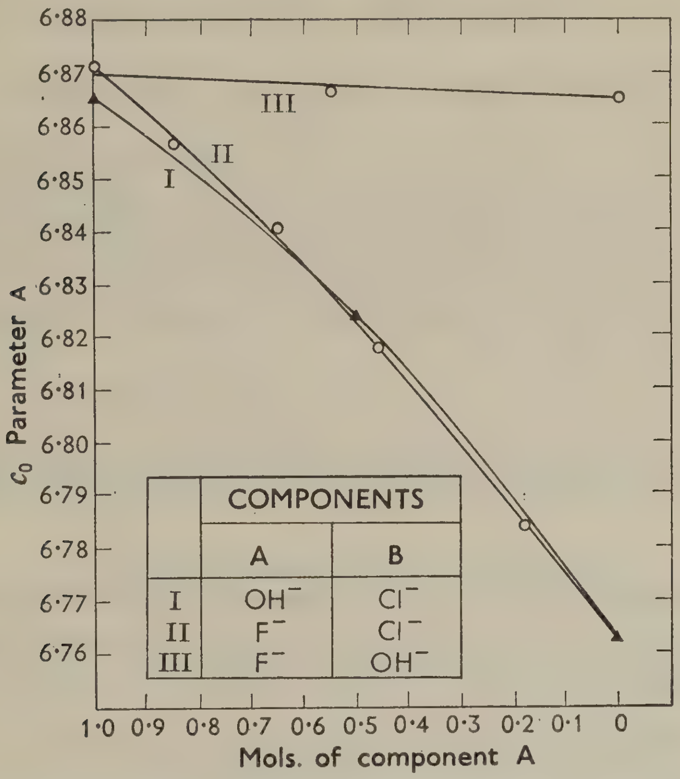

FIG. 6.—Effect of anion substitution on $c_0$-parameter of calcium apatites

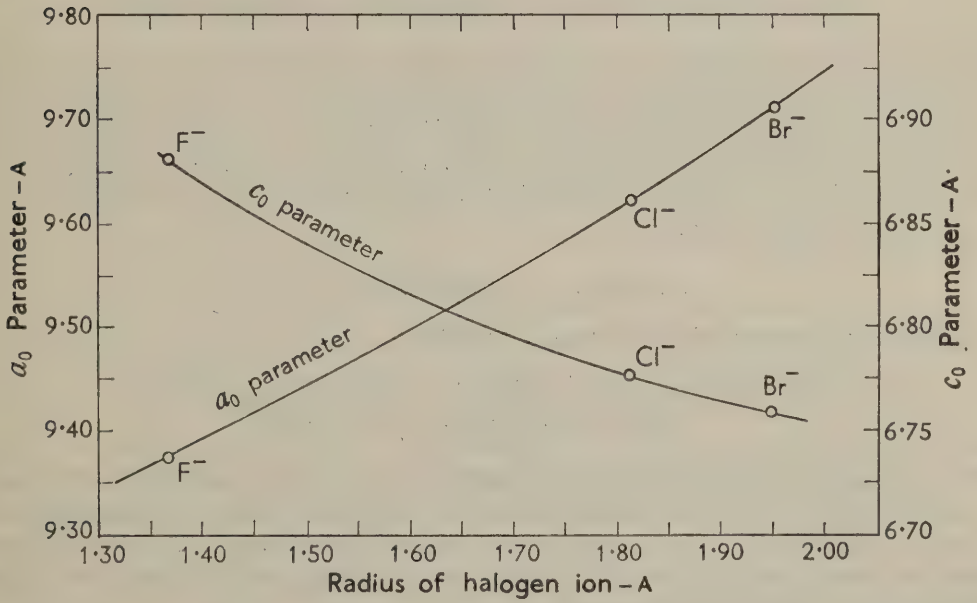

FIG. 7.—Relationship between lattice constants of calcium halogen-apatites and ionic radius of halogen ions

Other reactions involving the fluoride ion and leading to the formation of calcium fluorapatite have been studied. Although these are not anionic substitutions of the type discussed above, the reactions are of interest in showing how the fluorapatite structure can be built up from other phosphates. Calcium fluoride and calcium pyrophosphate react in the solid state at 800–1000°C. in the proportions given by the equation:

$$18Ca_2P_2O_7 + 14CaF_2 = 5[3Ca_3(PO_4)_2,CaF_2] + 6POF_3$$

The product[153] contains a small amount of calcium pyrophosphate and the weight loss is less than corresponds to the above equation. The reaction, however, is complex, and the equation agrees with the experimental results only if the reaction is carried out very rapidly, e.g. by putting small quantities into a furnace at 1000°C. At lower temperatures or with slower heating there is evidence[154] that a fluorophosphate, in which one of the oxygen atoms in a $PO_4$ group is replaced by fluorine, is formed by the reaction:

$$2Ca_2P_2O_7 + CaF_2 = Ca_3(PO_4)_2 + 2CaPO_3F$$

In the presence of calcium fluoride the fluorophosphate gives an unstable intermediate compound which then decomposes into fluorapatite and phosphorus oxyfluoride:

$$6CaPO_3F + CaF_2 = Ca_7(PO_3F)_6.F_2$$
$$3[Ca_7(PO_3F)_6,F_2] = 6POF_3 + 2[3Ca_3(PO_4)_2,CaF_2] + CaF_2$$

The main reaction can therefore be represented as the sum of four others according to the following scheme:

$$\begin{aligned} 18Ca_2P_2O_7 + 9CaF_2 &= 9Ca_3(PO_4)_2 + 18CaPO_3F \\ 18CaPO_3F + 3CaF_2 &= 3Ca_7(PO_3F)_6,F_2 \\ 3[Ca_7(PO_3F)_6,F_2] &= 6Ca_3(PO_4)_2 + 3CaF_2 + 6POF_3 \\ 15Ca_3(PO_4)_2 + 5CaF_2 &= 5[3Ca_3(PO_4)_2,CaF_2] \\ \hline 18Ca_2P_2O_7 + 14CaF_2 &= 5[3Ca_3(PO_4)_2,CaF_2] + 6POF_3 \end{aligned}$$

By using a mixture of one mole of calcium fluoride and 0·90 moles of calcium pyrophosphate and heating quickly at 800–950°C. a pure calcium fluorapatite is obtained.

At higher temperatures, e.g. above 1300°C., calcium pyrophosphate reacts with fluorapatite to form tricalcium phosphate, calcium metaphosphate and phosphorus oxyfluoride. This reaction is probably brought about by the decomposition[155] of the pyrophosphate at 1200°C.:

$$3Ca_2P_2O_7 = 2Ca_3(PO_4)_2 + P_2O_5$$

The phosphorus pentoxide then reacts as follows:

$$3[3Ca_3(PO_4)_2,CaF_2] + 22P_2O_5 = 30Ca(PO_3)_2 + 2POF_3$$
$$Ca_3(PO_4)_2 + 2P_2O_5 = 3Ca(PO_3)_2$$

The corresponding reaction between calcium fluoride and calcium metaphosphate is equally complex and is markedly affected by the molar ratio of the reactants. Rapid heating at 800–900°C. of a mixture of 4 moles of fluoride and 3 moles of metaphosphate gives calcium fluorapatite as the final solid product. This agrees approximately with the overall equation:

$$9Ca(PO_3)_2 + 11CaF_2 = 2[3Ca_3(PO_4)_2,CaF_2] + 6POF_3$$

On the other hand calcium metaphosphate and fluorapatite react at temperatures above 600°C. giving calcium pyrophosphate as the end-product.[156] At 1000°C. this reaction is represented by the equation:

$$3[3Ca_3(PO_4)_2,CaF_2] + 14Ca(PO_3)_2 = 22Ca_2P_2O_7 + 2POF_3$$

It appears therefore that the reaction between calcium fluoride and metaphosphate can best be represented as taking place in the following stages[154]:

$$\begin{aligned} 5Ca(PO_3)_2+3CaF_2 &= 4Ca_2P_2O_7+2POF_3 \\ 6Ca_2P_2O_7+3CaF_2 &= 5Ca_3(PO_4)_2+2POF_3 \\ 3Ca_3(PO_4)_2+CaF_2 &= 3Ca_3(PO_4)_2,CaF_2 \end{aligned}$$

Reviews[157-9] and summaries[160, 161] of the reactions discussed above and of related subjects[130, 143, 162-3] have been made by a number of authors.

### SUBSTITUTION BY HYDROXYL IONS

After fluorine, the hydroxyl ion is the anion which is most commonly found in the apatite minerals and phosphorites. From a purely chemical point of view the hydroxyl ion may be regarded as taking the place of the fluoride ion in calcium fluorapatite. This view, however, does not explain some of the observations and conclusions resulting from crystallographic and *X*-ray investigations into the structure of apatites. Although it is now known that the hydroxyl ion can occupy the same position in the lattice as halide ions, and that pure specimens of hydroxyapatite can be made,[125, 126, 129, 130] it is still necessary to explain the variable composition found in the naturally occurring mineral. Many views and explanations, some of which are discussed below, have been put forward to account for the behaviour of the hydroxyl ion.

Some of the earlier attempts (Mellor, III, 901–5) at explaining the variation in the composition of hydroxyapatite considered the latter as being composed of tricalcium phosphate and basic calcium phosphates. This view, however, did not agree with the results later obtained by *X*-ray methods of examination. In particular, it was found that hydroxyapatites having different chemical compositions gave the same type of *X*-ray diffraction pattern. It was also observed that compounds which gave almost identical *X*-ray powder diagrams could have a molar calcium to phosphorus ratio which varied between 4/3 and 2. These facts were at first explained by assuming that calcium or phosphate ions were adsorbed on the surface of the apatite in amounts required to bring the calcium to phosphorus ratio to the observed value.[164-5] However, as Van Wazer[166] (p. 536) has pointed out, for a material having a calcium to phosphorus ratio of 1·5 this hypothesis requires an abnormally thick adsorption layer on the crystal surface. In addition, experiment has shown that apatites having a low ratio do not lose phosphate ions when heated with water.[167] Similar results have been obtained in hydrothermal bomb experiments on the crystal growth of hydroxyapatite at 300°C. and pressures up to 2000 lb. per sq. in.[168] The use of radioactive isotopes to study exchange reactions in calcium phosphates has shown that the rate of exchange of both calcium and phosphorus is the same irrespective of the calcium to phosphorus ratio of the material.[169-73]

An alternative suggestion has been put forward[174-5] according to which actual substitution rather than adsorption[176] of ions occurs on the crystal surface. According to Van Wazer[166] (p. 537) calculation shows that this hypothesis would account for the existence of hydroxyapatites having a calcium to phosphorus ratio between 1·4 and 1·8 if isomorphic substitution of hydronium for calcium ions also takes place.

It has also been postulated[177] that isomorphic substitution throughout the crystal lattice could occur, as distinct from only surface phenomena. In this view it was supposed that calcium is replaced by hydrogen ions and water. Although the idea was explained in some detail, it does not seem to have been developed to any extent.

The fact that the same *X*-ray diffraction pattern was obtained from hydroxyapatites of different compositions has been accounted for by assuming the existence of a defect apatite structure.[178] According to this view calcium atoms are missing from certain positions in the apatite lattice, electrical neutrality being preserved by the addition of hydrogen ions. It was thought[179] that this would explain the structure of the mineral whitlockite, $Ca_3(PO_4)_2$. On the other hand, the concept of a defect apatite lattice has been rejected as misleading. It was emphasized that any interpretation of the structure of either the hydroxyapatites or the carbonate-apatites must take into account the amounts of water and carbon dioxide present.[180] These were important because of isomorphic substitutions which can occur and which involve the following ionic replacements:

$$PO_4^{3-} \rightarrow 4OH^-, \quad 3PO_4^{3-} \rightarrow 4CO_3^{2-}, \quad Ca^{2+} \rightarrow H_3O^+$$

The problem of the structure and composition of hydroxyapatite has been investigated by examining precipitated calcium phosphates, compounds derived from melts, and by the study of the solid state reactions already discussed. On occasion apparently conflicting evidence has been obtained because of the failure to recognize the anomalous behaviour of the phosphates.

In the case of the precipitated phosphates it has been suggested[181] that many contradictions could be resolved by taking into account the following considerations:

Between the CaO and $CaHPO_4$ phases of the ternary system $CaO–P_2O_5–H_2O$, there exists a series of solid solutions which have an apatite structure. Hydroxyapatite and tricalcium phosphate do not always exist in aqueous solution as unique stoicheiometric compounds. In addition the apatite structure is very stable, but permits a number of unusual types of substitution which involve considerable numbers of ions. The last point was originally made by McConnell,[182] who showed that although hydroxyapatite could be formulated as $3Ca_3(PO_4)_2,Ca(OH)_2$, from a structural point of view this could not represent a definite compound with a unique composition.

In the study of phosphate melts it has been emphasized that traces of moisture can give rise to unsuspected complications, and the necessity for the rigorous exclusion of water from the system has been stressed.[181] Hydroxyapatite has been shown to be formed from binary mixtures of CaO and $P_2O_5$ at temperatures as high as 1050°C. if moisture is present.[183] Calcium phosphate and apatite melts lose all their water only at temperatures of 1400–1500°C.[184] The fact that apparently contradictory conclusions could arise through neglecting reactions caused by the presence of water has been more recently emphasized with reference to investigations into the stoicheiometry of hydroxyapatite.[185]

### OXYAPATITES

The question as to the existence of an oxyapatite was a problem which at one time engaged the attention of a number of investigators. Such a compound, in which the fluorine was supposed to be replaced by oxygen, appears to have been postulated originally to account for the variation in composition of hydroxyapatite and various precipitated phosphates (Mellor, III, 903). However, from a study of the behaviour of calcium phosphates in precipitation reactions[186–7] and an examination of phase relations in aqueous systems,[188] no evidence was found to support the existence of an oxyapatite. The phase diagrams of calcium phosphate melts also failed to indicate an oxyapatite as a solid phase.[183] From a crystallographic point of view and from a study of the substitution of silicate and sulphate groups in apatite minerals it has been concluded that an oxyapatite is unlikely to exist because an oxygen atom could not replace two hydroxyl groups in the lattice of hydroxyapatite.[189] Van Wazer[166] (pp. 510–30) reviewed the literature and from a discussion in some detail of the aqueous and the melt phase diagrams of calcium phosphates considered that there was no reason to assume that an oxyapatite existed.

Although the evidence is against the possibility of there being an oxyapatite in which the fluorine in fluorapatite is replaced by oxygen only, it appears that oxygen atoms can be accommodated in the apatite lattice when carbonate ions are present. An investigation of the structure of naturally occurring apatites resulted in the conclusion that the mineral dahllite, which may be formulated as $10CaO,3P_2O_5,CO_2,xH_2O$, is a carbonate oxyapatite.[190]

### CARBONATE APATITES

The carbonate ion is found associated with a number of phosphorus minerals and is also involved in the formation of bones, teeth and calcified tissues. The nature of the relationship between the apatite lattice and the carbonate ion has therefore been studied from the biological, chemical and mineralogical viewpoints. These investigations have resulted in many explanations and hypotheses regarding the structure of the carbonate-apatites, the conclusions reached often being very conflicting.

In the early views of the subject (Mellor, III, 896–904) it was supposed that the carbonate-apatites were mixtures or double compounds of calcium carbonate and calcium hydroxyapatite[191] or fluorapatite.[192] *X*-Ray diagrams, however, showed no diffraction lines supporting the presence of crystalline calcium carbonate. As an alternative it was suggested that the carbonate ion took the place of hydroxyl or fluoride ions[26] in the lattice.[141] On the other hand, this type of substitution did not agree with the results of *X*-ray structural investigations of the minerals. The latter work showed that the carbonate ion could not enter into the apatite structure in the same way as other anions,[193] at least so far as calcium fluorapatite was concerned.

In later investigations the problem was approached in two ways and this has given rise to two main explanations to account for the presence of carbonate in phosphorus minerals. One line of approach was concerned with the structure and biological nature of bones and teeth.[175] From a study of the surface chemistry of bone the idea emerged that carbonate ions were adsorbed on the bone surface by a process which involved an exchange of phosphate for carbonate ions.[169, 174, 194–5] Bicarbonate ions were found[196] to penetrate the hydration shell[197] of the apatite crystals in bone and to displace phosphate ions from the crystal surface. This could account for the relatively large amounts of carbonate found in bone, and the exchange reaction appeared to be the more important part of the mechanism of bone formation. Although it is generally assumed that the carbon dioxide occurs in bone as carbonate, there is fragmentary evidence that at least some of it is present as bicarbonate.[176]

The above hypothesis was supported by the fact that infra-red examination of carbonate-apatite minerals showed absorption bands due to calcite. In addition, most of the carbon dioxide could be removed by treatment of the minerals with acid, without any change in the *X*-ray pattern.[198] It was also found that synthetic apatites could take up carbon dioxide from solutions, the amount adsorbed being proportional to the carbon dioxide:phosphorus pentoxide ratio in the solution.[196] In a similar manner tricalcium phosphate can adsorb water[199] or remove calcium ions from solution.[200]

Although the adsorption theory explains many of the observations made on the nature and composition of bone material and can in part be used to account for the structure of naturally occurring carbonate-apatites, a too liberal interpretation of the theory can lead to erroneous conclusions. It has been pointed out[201] that in attempts to relate the structure and composition of the apatite in calcified tissues to those of the mineral carbonate-apatites, the following considerations must be taken into account. The nature of the apatite in bone is difficult to establish because of its small particle size. This applies less to tooth enamel which has a larger particle size, but in both instances surface phenomena are important. Because the interruption of the arrangement of atoms at the surface of a crystal results in free charges being available, the surface can bind ions from an aqueous phase. In bone the crystals are generally in contact with a constant ionic medium and this accounts for the constancy in the composition of bone salts. Surface exchange of ions is rapid, but penetration of ions into the interior of the lattice is slow and occurs only with ions capable of isomorphic substitution. There is also a close relationship between the mineral crystallites and the organic collagen fibres in bone,[202] in which the crystal growth of the apatite present may be affected.[203] Chemical analysis of bone mineral can be rendered inaccurate because of the impossibility of removing the organic component without changing the composition of the inorganic constituent. For example, in the standard procedure for removing organic material by boiling with a solution of potassium hydroxide in anhydrous glycerol, any hydrated tricalcium phosphate present in the bone will be almost completely converted to hydroxyapatite. It is therefore necessary to consider the conclusions drawn from an investigation in conjunction with actual experimental conditions.

**Refs. p. 60**

The second approach referred to above has been concerned mainly with chemical and mineralogical studies of bones, teeth and phosphorus minerals, including synthetic apatites. Early chemical analysis showed that the inorganic constituent of bones and teeth was apatite,[204] and the apatite structure was later confirmed by *X*-ray diffraction methods.[205] The composition of the apatite has been discussed on the basis of its being carbonate hydroxyapatite, hydrated tricalcium phosphate or hydroxyapatite.[206] An early conclusion, derived from a consideration of many analyses, was that bone was substantially a carbonate-apatite to which the formula $3Ca_3(PO_4)_2,CaCO_3$ was given.[207] Attention was drawn to the similarity of this to the carbonate-hydroxyapatite mineral dahllite.[208] It was later suggested[209] that the carbonate content of bone might be accounted for by considering it to be present as a separate phase in the form of calcium carbonate. The amount of calcium remaining was taken to be present in the apatite itself and this gave a calcium to phosphorus ratio near to that of hydrated tricalcium phosphate.[210] Similarities in *X*-ray patterns of bone and hydrated tricalcium phosphate[211] were put forward in support of the idea, but this had little significance because most poorly crystalline apatite precipitates give almost identical *X*-ray patterns. There is also very little evidence that calcium carbonate is present as a separate phase. Similarities in the refractive indices of bone salts and mixtures of calcium carbonate and hydrated tricalcium phosphate have also been noted.[212]

An alternative suggestion was that bone consists of hydroxyapatite and a separate phase of calcium carbonate.[213] It is well established[174-5] that although the mineral phase of bone is not simply hydroxyapatite, the latter is the major constituent.[165] The assumption of calcium carbonate as a separate phase is, however, less easy to justify, particularly in view of the effects of surface phenomena referred to above.[214] The presence of carbonate in the bone structure must therefore be accounted for in some other way. Many of the investigations concerned with this problem were connected with studies of carbonate-apatite minerals, especially francolite.[215] This mineral contains, in addition to phosphate, variable proportions of fluoride, hydroxyl and carbonate ions.[216] Its composition[217] and structure are intermediate between those of fluorapatite and the carbonate-apatite dahllite.[190]

The designation carbonate-apatite, following the original suggestion,[182] is generally applied to mineral apatites containing 2–5% of carbon dioxide. Only two varieties of this type of apatite are at present known. One of these, francolite, is a carbonate fluorapatite which contains 2–6% of fluorine and was formerly known as staffelite or grodnolite. The other, dahllite, is a carbonate hydroxyapatite, previously known as podolite, which contains less than 1% of fluorine. Investigations of the structure of these minerals have largely been concerned with the question as to whether the carbonate-apatites consist of a single phase with the carbonate as part of the lattice or a heterogeneous system consisting of micro-crystalline apatite with the carbonate as a separate phase. The earlier chemical, *X*-ray and structural data[193] showed that the carbonate ion could not replace fluorine in apatites, so that francolite was not represented by the formula $3Ca_3(PO_4)_2,CaCO_3$. From geometrical considerations[218, 193] it appeared to be very doubtful whether there was room for the carbonate ion in other positions in the lattice. Gruner and McConnell therefore suggested that carbon could replace phosphorus in the tetrahedral phosphate groups. Carbon could also replace calcium in certain positions in the lattice and fluorine and hydroxyl groups could replace some of the oxygen atoms. On this basis the formula for the apatites became $[Ca(F,Cl,OH)](Ca,C)_4[(P,C)(O,OH,F)_4]_3$ and francolite was represented as being[182] $(Ca_3,F)_2(P,C)_6(O,OH,F)_{24}(Ca,C)_4$. Investigations on a number of samples of francolite[219, 220] showed that they could all be interpreted in terms of this structure. A sample from New Zealand was shown[217] to have the formula

$$(Ca,Na,K,C)_{10}(P,C,Si,Al)_6(OH,F)_{3\cdot3}O_{22\cdot7}$$

In one from the coal measures carbon was thought to enter the lattice in some of the calcium and phosphorus positions and not to be present as carbonate.[216] A later and more accurate chemical and *X*-ray analysis gave a structure in which there was isomorphous substitution of carbon for phosphorus, water for calcium atoms and $(OH)_4$ groups for phosphate. Taking into account some replacement of calcium by magnesium and strontium as well as the presence of small quantities of sodium, the formula proposed[221] was

$$[(Ca,Mg,Sr)_{9\cdot89}Na_{0\cdot01}(H_2O)_{0\cdot1}]F_2[P_{5\cdot36}(\tfrac{4}{3}C)_{0\cdot51}(4H)_{0\cdot13}]O_{23\cdot88}F_{0\cdot12}$$

The above types of structure were suggested for the apatite in calcified tissues,[222] attention being drawn to the close relationship between the nature of the carbonate in bone and tooth minerals and that in the natural carbonate-apatites.[223] The structure proposed for dentin and enamel of teeth was $(OH)_2Ca_6[(P,C)O_4]_6(Ca,C)_4$. This indicated that all the calcium ions were united to the $PO_4$ groups and that the hydroxyl groups were in contact with six calcium atoms only and were separated from the phosphate groups. Carbon replaced a number of calcium and phosphorus atoms, with the restriction that only the calcium atoms on the internal threefold axes could be replaced by carbon. More recently it has been concluded that dental enamel is a carbonate-hydroxyapatite similar to dahllite.[224]

The structures proposed for francolite have been criticized both on account of the unusual types of substitution proposed and also because of the $CO_4$ group. An alternative structure in which carbon could replace phosphorus but not calcium was proposed. This postulated the molecule $3CaCO_3,Ca(F,OH)_2$ in which the carbon was present as carbonate, the formula of francolite being supposed[225] to be

$$Ca_5C_3O_9(F,OH)_4$$

The other opinion, viz., that the carbonate in the carbonate-apatites is present as a separate phase, has been supported by the fact that the carbonate ion is too large to fit into the apatite lattice.[218] Since crystalline calcium carbonate has not been detected by *X*-ray diffraction it is assumed that the carbonate is present in an amorphous form. On the other hand, only with very refined techniques would it be possible to detect by this means crystalline carbonate in the amounts (2–5%) usually present in carbonate-apatites. Carlström reviewed the evidence and favoured the existence of a separate carbonate phase.[201] McConnell,[226] however, considered that there was insufficient evidence to support this conclusion. A study of the $Na_3PO_4$–$CaCO_3$–$H_2O$ system at low temperatures, in which carbonate-apatites of variable composition were obtained, supported the view that carbonate could be entirely present in the apatite lattice.[227] It has also been claimed[228] that a carbonate-apatite can be prepared by heating a suspension of calcium carbonate in monopotassium phosphate solution at 90°C. From an infra-red examination it was concluded that hydroxyl had been replaced by carbonate ions. This was criticized on the basis of insufficient data and the use of concepts which had been shown not to be valid.[229] Independent examination showed that the reference specimen used for the infra-red spectrum examination was a mixture of calcium carbonate and calcium hydroxyapatite.[196] It also contained water and had not been ignited, and allowing for this the conclusion was that carbonate did not replace hydroxyl ion. Hydrothermal bomb experiments, in which the amorphous form of calcium hydroxyapatite was heated with solutions of sodium carbonate or sodium bicarbonate at 400°C., showed that although the carbonate ion disturbed the arrangement of the lattice, it did not enter it.[230]

More recent work has been concerned with attempts to prepare carbonate-apatites by solid-state reactions.[231] Calcium carbonate and tricalcium phosphate do not react at temperatures below 700°C., and above this the carbonate dissociates to give a mixture of phosphate and calcium oxide, no apatite being obtained. Under extremely dry conditions no further reaction occurs on heating to 900°C., but if traces of atmospheric moisture are present, some hydroxyapatite is formed according to the equation:

$$3Ca_3(PO_4)_2 + CaO + H_2O = 3Ca_3(PO_4)_2,Ca(OH)_2$$

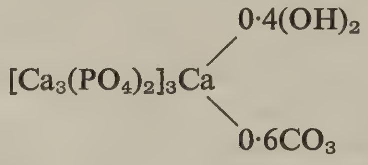
When heated at 850–900°C. in the presence of dry carbon dioxide, about half of the phosphate is converted to carbonate-apatite in 8 days. At 1000°C. in a closed vessel and in the presence of carbon dioxide at 10–20 atm. pressure, a 30% yield of apatite is obtained in 120 hr., according to the equation:

$$3Ca_3(PO_4)_2 + CaCO_3 = 3Ca_3(PO_4)_2,CaCO_3$$

By heating calcium hydroxyapatite for 48 hr. in a stream of carbon dioxide at 850–950°C., approximately 60% of the hydroxyl groups were replaced according to the reaction:

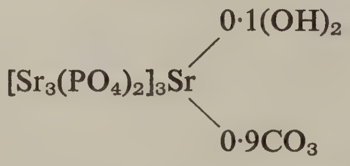
$$3Ca_3(PO_4)_2,Ca(OH)_2 + CO_2 = 3Ca_3(PO_4)_2,CaCO_3 + H_2O$$

The product was considered to be a solid solution of hydroxyapatite and carbonate-apatite and was represented by the formula:



$$[Ca_3(PO_4)_2]_3Ca\begin{matrix} / \, 0{\cdot}4(OH)_2 \\ \backslash \, 0{\cdot}6CO_3 \end{matrix}$$

The reaction of carbon dioxide with hydroxyapatite at 900–950°C. under dry conditions has been applied to the corresponding strontium and barium compounds The replacement of calcium in the apatite structure by strontium and barium causes a progressive increase in the lattice dimensions. Consequently it is possible to replace 90% of the hydroxyl groups in strontium hydroxyapatite,[232] to give a material formulated as:



$$[Sr_3(PO_4)_2]_3Sr\begin{matrix} / \, 0{\cdot}1(OH)_2 \\ \backslash \, 0{\cdot}9CO_3 \end{matrix}$$

With barium hydroxyapatite[233] complete replacement of hydroxyl occurs to give barium carbonate apatite, $3Ba_3(PO_4)_2,BaCO_3$.

These investigations showed that partial or complete replacement of two hydroxyl ions by one carbonate ion can take place in the alkaline earth hydroxyapatites. It was concluded[143] therefore that the carbonate ion can occupy the same positions in the apatite lattice as the halogen ions. This is in disagreement with the earlier conclusions[193] resulting from *X*-ray and crystallographic studies on calcium apatites. Three hypotheses have thus been put forward to account for the structure of the carbonate-apatites. There does not seem to be conclusive evidence with which to support any one of them completely.

### SUBSTITUTION OF THE $PO_4$ GROUP

In addition to the replacement of the fluorine in fluorapatite by mono-valent ions, substitution by a number of polyvalent ions can occur. This type of substitution, however, takes place in the phosphate groups. Arsenic as $AsO_4^{3-}$ ion replaces phosphorus in minerals such as fermorite, $(Ca,Sr)_{10}(PO_4,AsO_4)_6.F,OH$,[234] and svabite, $(CaPb)_{10}(PO_4,AsO_4)_6.F,OH$.[235] This substitution is more common in the pyromorphite series, giving rise to mimetite, $Pb_{10}(AsO_4,PO_4)_6Cl_2$, in which nearly all of the phosphorus may be replaced by arsenic.

Phosphate ions are also replaced by silicate and sulphate. In ellestadite,[189] $Ca_{10}(PO_4,SO_4,SiO_4)_6.F,Cl,OH,CO_3$, for example, half of the phosphate is replaced by these two ions. A similar replacement occurs in wilkeite,[236]

$$Ca_{10}(PO_4,SO_4,SiO_4)_6F,OH$$

This mineral has been prepared by sintering at 1200°C. a stoicheiometric mixture of tricalcium phosphate, calcium orthosilicate, $Ca_2SiO_4$, calcium sulphate and calcium fluoride.[237] The apatite structure is still retained when all of the phosphate has been replaced by sulphate.[238–9]

As will be seen from Table XV (p. 39) there are other phosphorus minerals in which phosphate is replaced by vanadate, uranyl, borate and chromate ions.

### Cationic Substitutions in Apatite

A number of artificial apatites containing various combinations of cations have been prepared, and are of interest in connection with the structure and general behaviour of the apatite lattice.

Strontium hydroxyapatite has been made by hydrolyzing tristrontium phosphate with 0·10N. sodium hydroxide solution, by precipitating strontium-containing solutions with alkali phosphates or by heating a stoicheiometric mixture of tristrontium phosphate and strontium carbonate in hydrogen at 1150°C.[240] It has also been prepared by neutralizing phosphoric acid solution with strontium hydroxide (to phenolphthalein) in the cold and then boiling the mixture.[143] Addition of excess of potassium dihydrogen phosphate solution to one of strontium chloride yields strontium hydroxyapatite if the mixture is maintained at pH 10–14 by adding potassium hydroxide. With excess of strontium chloride some strontium chlorapatite is also formed under these conditions. In more acid solutions (pH 6–10) mixtures of strontium hydroxyapatite and distrontium phosphate are obtained.[241] A hydrothermal synthesis from strontium phosphate and strontium hydroxide in 2N. sodium hydroxide solution at 420°C. has been described.[242]

A hydrated tristrontium phosphate, $3Sr_3(PO_4)_2,\frac{1}{2}H_2O$, which has an apatite structure similar to that of the calcium compound, has been prepared by causing disodium phosphate and strontium chloride solutions to react under ammoniacal conditions at pH 9·5 and at room temperature according to the equation[243, 143]:

$$6Na_2HPO_4+9SrCl_2+6NH_4OH = 3Sr_3(PO_4)_2,\tfrac{1}{2}H_2O+6NH_4Cl+12NaCl+5\tfrac{1}{2}H_2O$$

After being washed, the precipitate is dried at 90°C. The product loses its water of hydration between 650° and 850°C.

Strontium fluorapatite is formed when solid strontium hydroxyapatite is caused to react with strontium fluoride at 600–1050°C., the reaction being:

$$3Sr_3(PO_4)_2,Sr(OH)_2+SrF_2 = 3Sr_3(PO_4)_2,SrF_2+SrO+H_2O$$

Fluorapatite is also obtained by solid state reaction of strontium fluoride with anhydrous tristrontium phosphate at 550°C. or with the hydrate at 1000°C.[244] Under anhydrous conditions, strontium fluorapatite has been prepared by heating strontium mono-fluorophosphate mono-hydrate. The latter dehydrates at 150°C. and between 450° and 550°C. is transformed into strontium pyrophosphate, with volatilization of phosphorus oxyfluoride:

$$5SrPO_3F = 2Sr_2P_2O_7+SrF_2+POF_3$$

At 800°C. the pyrophosphate and strontium fluoride react to form strontium fluorapatite and phosphorus oxyfluoride:

$$18Sr_2P_2O_7+14SrF_2 = 5[3Sr_3(PO_4)_2,SrF_2]+6POF_3$$

In the presence of moisture and at temperatures above 450°C., no apatite is obtained, the products being strontium pyrophosphate and hydrogen fluoride[245]:

$$2SrPO_3F+H_2O = Sr_2P_2O_7+2HF$$

Strontium chlorapatite and bromapatite are made by heating tristrontium phosphate with strontium chloride or bromide for 2 hr. at 900°C. in a stream of dry nitrogen.[143]

Solid solutions of the strontium halo-apatites have been obtained by heating at 1000°C. mixtures in varying proportions of the individual halo-apatites. The effect of changing the halogen ion on the lattice constants is shown in Figs. 8 and 9 where the constants for the pure apatites are plotted against the radius of the halogen ion.[143]

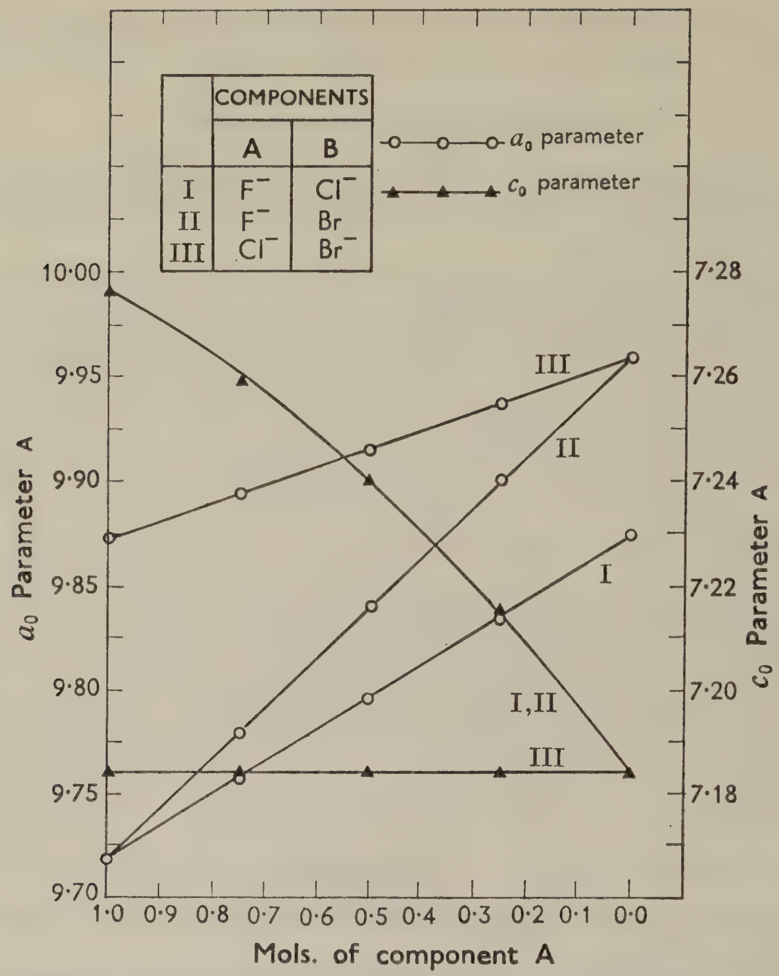


FIG. 8.—Effect of halogen substitution on lattice constants of strontium apatites

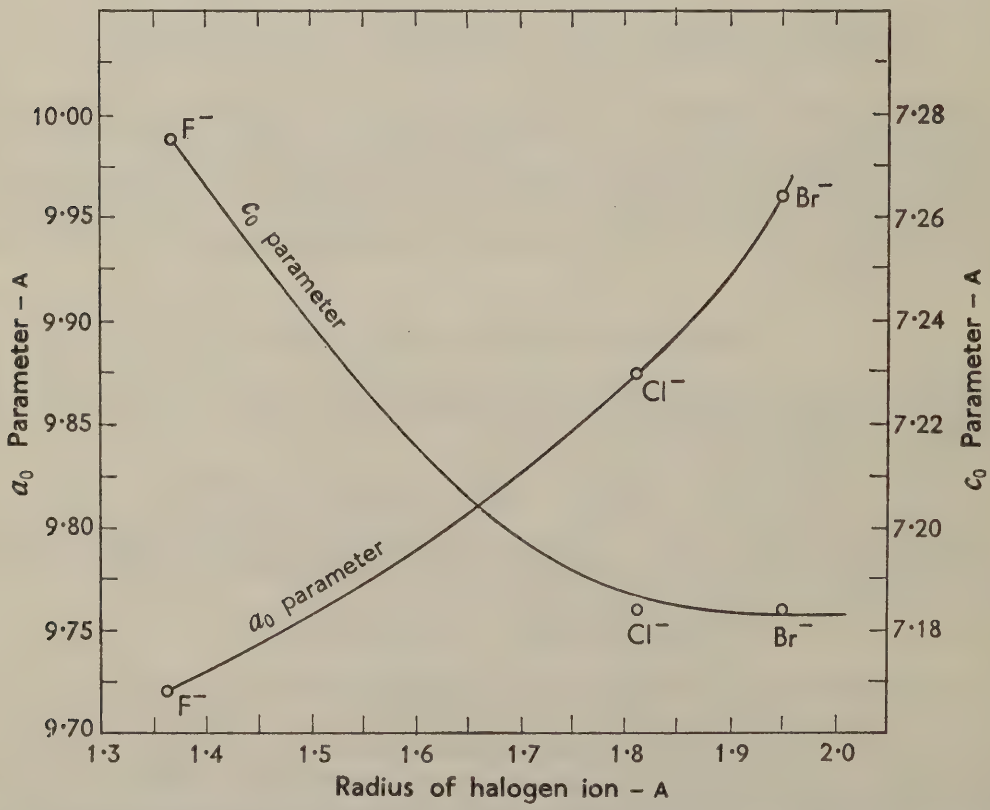

FIG. 9.—Relationship between lattice constants of strontium halogen-apatites and ionic radius of halogen ion

Barium hydroxyapatite cannot be prepared by precipitation from aqueous solutions in the same way as calcium and strontium hydroxyapatites. The latter form the most stable phase in boiling solutions, whereas for barium the most stable compound is tribarium phosphate. Neutralization of phosphoric acid with barium hydroxide in the manner described previously for strontium, does not therefore lead to a pure barium hydroxyapatite as the product is invariably heavily contaminated with tribarium phosphate. The latter does not have an apatite structure and it is interesting to note that a hydrate corresponding to $3Ba_3(PO_4)_2,\frac{1}{2}H_2O$ cannot be prepared.[246] Pure barium hydroxyapatite is formed, however, when barium hydroxide solution is only partly neutralized with phosphoric acid.[247] In the preparation from barium chloride solution and monopotassium phosphate, barium hydroxyapatite is formed only in the presence of excess of barium chloride and in solutions at least 3M. in chloride ion. The solution must be kept at pH 10 by addition of potassium hydroxide.[241] Barium hydroxyapatite has also been synthesized by heating tribarium phosphate with barium peroxide for 6 hr. at 1000°C. in an atmosphere of water vapour.[248] The reaction is:

$$3Ba_3(PO_4)_2 + BaO_2 + H_2O = 3Ba_3(PO_4)_2,Ba(OH)_2 + \frac{1}{2}O_2$$

Barium fluorapatite, chlorapatite and bromapatite have been made by heating stoicheiometric mixtures of anhydrous tribarium phosphate and the appropriate barium halide at 600–900°C. The lattice constants of these materials are shown in Fig. 10.

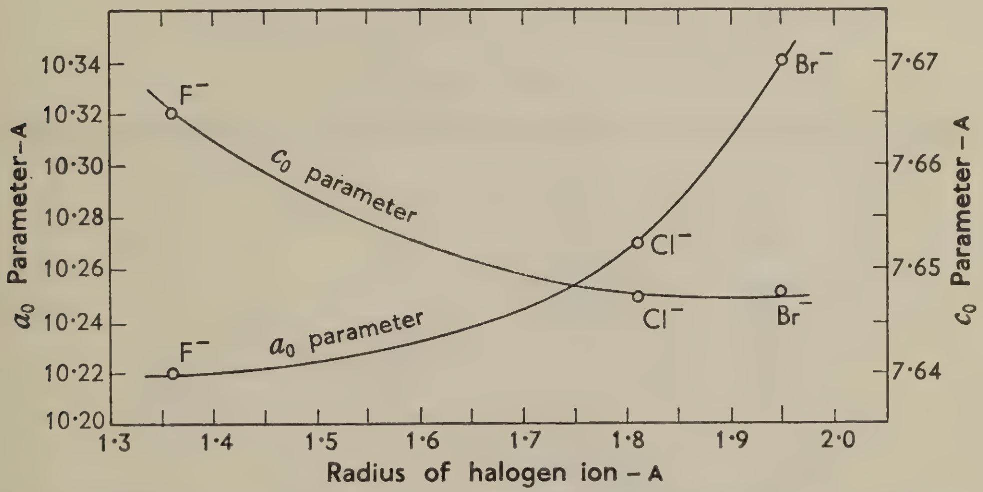

FIG. 10.—Variation in lattice constants of barium halogen apatites with ionic radius of halogen ion

These three apatites are miscible in all proportions and form solid solutions in the same way as the calcium and strontium compounds. The lattice constants vary linearly with the composition of the solid solution.[143]

The formation of solid solutions of apatites containing the same halogen but two different alkaline-earth cations has also been studied.[249] The solutions were prepared by heating together known quantities of the pure components for 3 hr. at 1000°C. The products were then submitted to *X*-ray examination. The calcium and strontium apatites and the strontium and barium apatites were found to be miscible in all proportions. The lattice constants were a linear function of the composition of the solid solutions as shown in Figs. 11 and 12. On the other hand complete miscibility was not observed with calcium and barium apatites. For the fluorapatites the region of non-miscibility extended from 6 to 64 atom-% of barium. Outside this range the $a_0$-parameter was linearly related to the composition, the same function applying to areas on both sides of the two-phase zone. For the $c_0$-parameter, however, two linear functions are required to relate parameter and composition. These observations are shown for the fluorapatites in Fig. 13. Similar results were found for the mixed calcium–barium chlorapatites and the corresponding bromapatites. The region of non-miscibility lay between 8 and 61 atom-% of barium in both instances.

Solid solutions of calcium and strontium hydroxyapatites have been prepared by

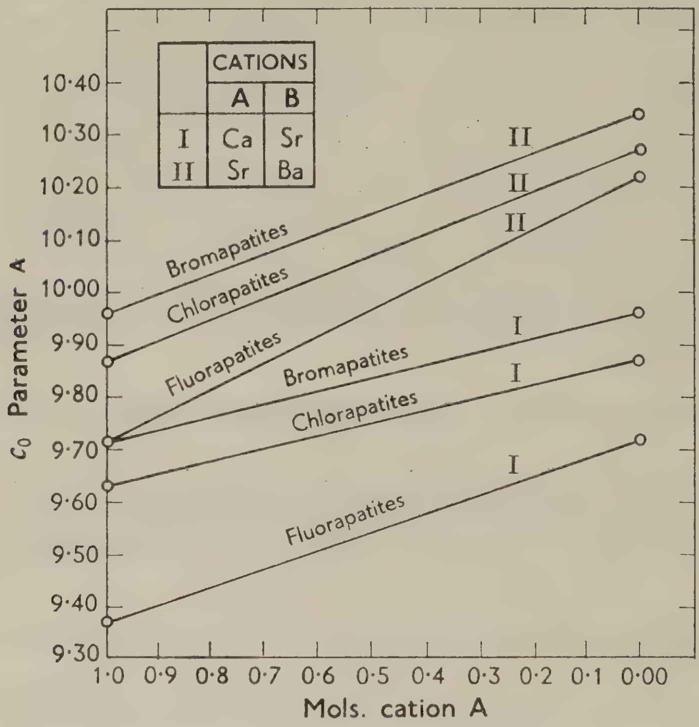

FIG. 11.—Variation of $a_0$-parameters with composition of alkaline-earth apatites

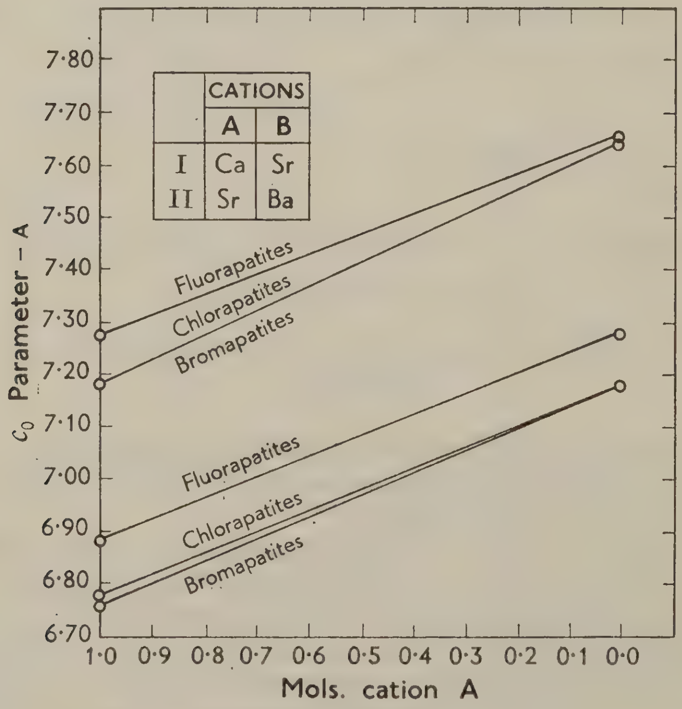

FIG. 12.—Variation of $c_0$-parameters with composition of alkaline-earth apatites

precipitation reactions using calcium and strontium nitrates and precipitating with diammonium phosphate solution in the presence of ethylenediamine. An excess of calcium and strontium ions (3 atoms per mole of phosphate) is necessary to give the required product.[250] The material is then dried and heated at 900°C. Drying of the

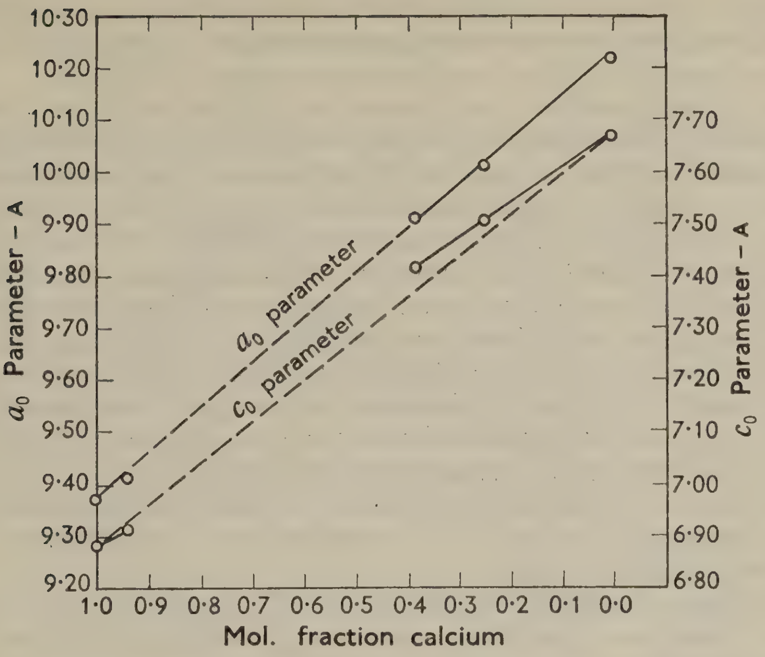

FIG. 13.—Variation of lattice constants in calcium–barium fluorapatites

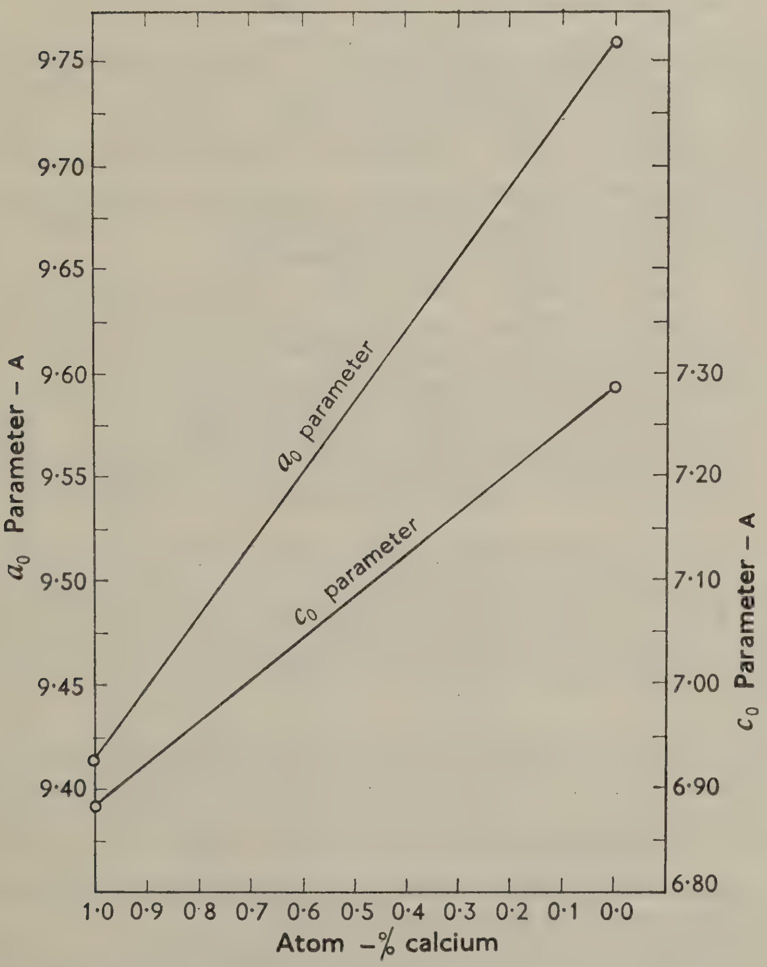

FIG. 14.—Lattice constants of mixed calcium–strontium hydroxyapatites

apatite at 110°C. without heating to 900°C. was satisfactory only if the calcium/strontium ratio was kept constant during precipitation.[251] The lattice constants were related to the composition in a linear manner as shown in Fig. 14.

Magnesium hydroxyapatite is not formed by the type of reaction used to obtain the alkaline-earth compounds. A product having a composition corresponding to $Mg_3(PO_4)_2,Mg(OH)_2,9H_2O$ is obtained by hydrolyzing magnesium monohydrogen phosphate for 6 weeks in 0·01N. sodium hydroxide at 37°C. Analysis and *X*-ray examination show that this is a basic magnesium phosphate and that it does not have an apatite structure.[252] On boiling a mixture of trimagnesium phosphate with excess of 0·01N. sodium hydroxide a hydrated product is obtained the analysis of which corresponds to a magnesium hydroxyapatite of formula $3Mg_3(PO_4)_2,Mg(OH)_2,xH_2O$. The degree of hydration is 11, 15 or $23H_2O$, according to the conditions of preparation. When heated to 500–600°C. the material becomes incandescent and forms a compound with an analysis agreeing with that of an oxyapatite, $3Mg_3(PO_4)_2,MgO$.[253] In a somewhat similar way a lithium hydroxyapatite, $3Li_3PO_4,LiOH$, is said to be formed by adding 1 mole of phosphoric acid to 6 or more moles of lithium hydroxide solution and boiling for 100 hr.[254] No *X*-ray evidence supporting the structure of these two compounds was given.

A cadmium hydroxyapatite, $3Cd_3(PO_4)_2,Cd(OH)_2$, has been made by reacting 2 g. of tricadmium phosphate, $Cd_3(PO_4)_2$, with 0·10 g. of cadmium hydroxide and 10 ml. of 0·10N. sodium hydroxide.[242]

Lead hydroxyapatite, $3Pb_3(PO_4)_2,Pb(OH)_2$, is obtained by hydrolyzing lead monohydrogen phosphate in 0·01N. sodium hydroxide for 7 days at 40°C. An alternative procedure is to heat a mixture of trilead phosphate and lead oxide at 950°C. in a stream of air saturated with water vapour, the reaction being[255]:

$$3Pb_3(PO_4)_2 + PbO + H_2O = 3Pb_3(PO_4)_2,Pb(OH)_2$$

A synthetic lead oxyapatite, $3Pb_3(PO_4)_2,PbO$, has been prepared from the components. *X*-Ray examination confirmed the apatite structure, the lattice constants being $a_0 = 9{\cdot}84$ A. and $c_0 = 7{\cdot}43$ A.[256] Subsequent phase studies of the $PbO–P_2O_5$ system and *X*-ray diffraction data indicated that half the halogen sites in the pyromorphite $[3Pb_3(PO_4)_2,PbCl_2]$ structure were occupied by oxygen ions. Since there was an ordered distribution of the latter in the lattice, the $c_0$ parameter was doubled, giving $a_0 = 9{\cdot}84$ A. and $c_0 = 14{\cdot}86$ A. as the constants.[257]

Replacement of the $PO_4$ groups in lead apatite by $SiO_4$ and $SO_4$ groups was shown to occur if an intermediate ion such as $Na^+$ was also present. This can give rise to apatite structures such as $Pb_4NaPO_4.SiO_4.SO_4$.[258] The pyromorphite type of apatite structure is still retained when all the phosphate groups have been replaced by silicate. The anions of these compounds are then composed solely of $SiO_4$ tetrahedra from which it appears that the halogen positions in the apatite structure are unoccupied or only partly occupied. These conditions have not been observed in the calcium apatites.[259]

Compounds of the type $3Pb_3(ZO_4)_2,PbX_2$, where Z = P, As or V and X = F, Cl, Br or I, have been prepared by sintering at 600°C. the stoicheiometric amounts of $Pb_3(ZO_4)_2$ and $PbX_2$. All these have an apatite structure and are stable in water except $3Pb_3(PO_4)_2,PbI_2$. The last compound appears to have an apatite structure in that it gives an *X*-ray pattern which does not show lines due to lead iodide or $Pb_3(PO_4)_2$.[260]

Alkali metal–lead apatites have been obtained by causing lead pyrophosphate to react with sodium carbonate in the presence of moisture. The compound $NaPb_4(PO_4)_3$ is formed, together with lead hydroxyapatite, $3Pb_3(PO_4)_2,Pb(OH)_2$. Under anhydrous conditions a sodium lead orthophosphate, $NaPbPO_4$, which does not have an apatite structure, is produced. The corresponding potassium compounds have been prepared by using potassium instead of sodium carbonate.[261]

A number of compounds having an apatite structure are known, in which the major cation is lead and the anion may be phosphate, arsenate, silicate, vanadate or sulphate. These were obtained from melts in which they were present as congruently melting compounds.[262] The lattice constants of these materials are given in Table XV.

*Table XV.—Lattice Constants of Some Lead Compounds having an Apatite Structure*

| Compound | Lattice constants, A. | |
|---|---|---|
| | $a_0$ | $c_0$ |
| $Pb_5GeO_4(PO_4)_2$ | 9·88 | 7·32 |
| $Pb_5(Si_{0\cdot5}Ge_{0\cdot5}O_4)(PO_4)_2$ | 9·81 | 7·30 |
| $Pb_5(Si_{0\cdot5}Ge_{0\cdot5}O_4)(PO_4)(AsO_4)$ | 9·92 | 7·34 |
| $Pb_5SiO_4.VO_4.PO_4$ | 9·88 | 7·33 |
| $Pb_5SiO_4(VO_4)_2$ | 9·99 | 7·35 |
| $Pb_5SiO_4(AsO_4)_2$ | 10·02 | 7·38 |
| $Pb_5GeO_4(VO_4)_2$ | 10·06 | 7·37 |
| $Pb_5GeO_4(AsO_4)_2$ | 10·10 | 7·40 |
| $Pb_4Na(PO_4)_3$ | 9·71 | 7·18 |
| $Pb_4K(PO_4)_3$ | 9·81 | 7·28 |
| $Pb_4Tl(PO_4)_3$ | 9·82 | 7·37 |
| $Pb_4Rh(PO_4)_3$ | 9·86 | 7·37 |
| $Pb_4Bi(SiO_4)_2(PO_4)$ | 9·76 | 7·26 |
| $Pb_3BiTl(SiO_4)(PO_4)_2$ | 9·78 | 7·34 |
| $Pb_{4\cdot5}Na_{0\cdot5}(PO_4)_{2\cdot5}(SiO_4)_{0\cdot5}$ | 9·76 | 7·25 |

### Naturally Occurring Phosphates

Phosphate minerals form a group with the arsenates and vanadates in which the structural units are trivalent tetrahedral $XO_4^{3-}$ groups. In these, partial or complete replacement of phosphorus by arsenic or vanadium is possible. Sulphate, chromate and silicate groups are also known to be present in some phosphorus minerals. There is, however, no series of minerals which directly links the phosphates with sulphate, chromate, silicate, tungstate and molybdate minerals in which divalent $XO_4^{2-}$ groups are present.

The known minerals, reported up to the end of 1965, which contain more than 1% of phosphorus, are given in Table XVI. Complete data, together with some physical and chemical properties, are given in Dana's *System of Mineralogy*[263] which describes minerals known up to 1951.

In Table XVI the minerals are given in order of the groups in the Periodic Table and according to the cation which is present in the greatest percentage. Exceptions have been made where isomorphous replacement of one element by another takes place. Formulæ are given for purposes of identifying a mineral and as an indication of the chemical composition of pure specimens. These formulæ do not necessarily refer to unit cell contents or other structural units.

The percentage composition refers to the analysis of authentic specimens of each mineral. Where several specimens, usually from different sources, have been analyzed, the variation in the analytical results is shown. Constituents which do not enter into the chemical composition but are present as impurities in the mineral, are not included in the analysis. Literature references are given only for those minerals which have been reported since 1951 and which are not described by Dana.

Several of the older known minerals have been re-examined more recently. This has been done where the previously accepted analysis or composition was open to doubt. These investigations are indicated below.

*Abukumalite* has been identified as a yttrium silico-phosphate.[264]

*Avelinoite and cyrilovite* have been shown to be identical,[265-6] the name cyrilovite having priority.[267] The mineral differs from *wardite* in containing iron instead of aluminium. The original analysis appears to be in error in that no sodium was reported.[268]

*Baldaufite, wenzelite and hureaulite* are listed as separate minerals in Table XVI. It has, however, been reported that these are identical, the name hureaulite having priority.[269]

*Britholite* is an older mineral[270] which has been characterized by more recent examination[271] and analysis.[272] A specimen found in Siberian pegmatites has been shown to be a rare earth silicophosphate having the following composition: $SiO_2$ 19·0, $P_2O_5$ 4·5, CaO 14·8, $ThO_2$ 9·8, $UO_3$ 2·1, $Ce_2O_3+La_2O_3+Y_2O_3$ 40·9, F 1·9 and $H_2O$ 3·0%. Associated with this mineral is a new variety, an alumino-britholite which analyzes as follows: $SiO_2$ 19–22, $P_2O_5$ 1·9–4·0, CaO 17·3–22·6, $ThO_2$ 4·8–9·3, $UO_3$ 0·6–2·1, $Ce_2O_3+La_2O_3+Y_2O_3$ 27·6–32·3, $Al_2O_3$ 9·5–14·9, $ZrO_2$ 1·0, $Fe_2O_3$ 0·4–5·4, F 1·4–1·7 and $H_2O$ 0·6–1·5%. It has an apatite structure in which the parameters of the unit cell are $a_0=9{\cdot}47$ A. and $c_0=6{\cdot}95$ A.

Comparison of britholite with *beckelite* ($SiO_2$ 17·1–20·4, $P_2O_5$ 3·25, CaO 11·4–15·5, $Ce_2O_3$ 28·1, $La_2O_3$ 27·8–31·6, $Y_2O_3$ 2·9–3·5, $ZrO_2$ 2·5, $ThO_2$ 0·9 and $H_2O$ 2·6%) and *lessingite* ($SiO_2$ 19·9, $P_2O_5$ 1·1, CaO 11·7, $Ce_2O_3$ 22·5, $La_2O_3$ 36·7, $Y_2O_3$ 3·4, $Al_2O_3$ 0·3, $Fe_2O_3$ 0·65, MnO 0·9, $CO_2$ 0·4, F 0·5 and $H_2O$ 1·9%) and *X*-ray examination of the three minerals show that they belong to the same mineral species.[273] A more recent examination[393] of a specimen containing more $P_2O_5$ than $SiO_2$ gave the analysis $P_2O_5$ 17·0, $SiO_2$ 12·3, CaO 28·8, $ThO_2$ 5·6, F 2·1, and rare earth oxides 33·4%. This corresponds to the formula $(Ca,Ce,Th)_5(PO_4,SiO_4)_3,OH,F$.

*Churchite and weinschenkite.* Churchite was originally thought to contain cerium, but a later analysis[274] showed that the rare earth element present in the mineral was yttrium. It was also shown[275] that it was identical with another phosphate known as *weinschenkite*. The name *churchite* has priority.

*Dewindite* appears to be a doubtful mineral.[276] It was originally formulated as a lead compound, $Pb_3(UO_2)_5(PO_4)_4(OH)_4,10H_2O$,[277] but was later shown to have an analysis corresponding closely to $Pb_3(UO_2)_6(PO_4)_4(OH)_6,9H_2O$.[278] Although it is known to be iso-structural with *phosphuranylite* and *renardite*, the chemical formulæ are not analogous.[279]

*Florencite.* A more recent analysis has given: $P_2O_5$ 26·0, $Al_2O_3$ 29·8, $Ln_2O_3$ 17·6, SrO 9·0, CaO 1·6, $SO_3$ 1·7, F 1·6 and $H_2O$ 12·9% from which the specimen was formulated as $(Ce,Sr,Ca)(PO_4,SO_4)_2.Al_3(F,OH)_6,H_2O$.[387, 388] The mineral belongs to the *goyazite* series which includes *crandallite*, *gorceixite*, *goyazite* and *florencite*.[6, 388]

*Hopeite.* The crystal structure of this mineral, $Zn_3(PO_4)_2,4H_2O$, has been shown to have a close relation to that of *phosphophyllite*, $Zn_2Fe(PO_4)_2,4H_2O$.[428]

*Huttonite.* Compounds of the type $M^{II}Th(PO_4)_2$ have a huttonite ($ThSiO_4$) structure.[429]

*Leucophosphite.* Early analyses showed that significant amounts of aluminium were present in this mineral, but a re-examination of a purer specimen showed only minor amounts of this metal.[280] The formula and composition have been reported as being those shown in Table XVI. It has also been reported that the mineral contains ammonium ion,[281] but again the analysis was of an impure specimen. A synthetic material has been made.[282] On the other hand more recent *X*-ray studies[297] have suggested that the formula is $(K,NH_4)(Al,Fe)_2(OH)(PO_4)_2,2H_2O$.

*Liroconite* is strictly an arsenate mineral, but some specimens contain a small percentage of phosphorus.

*Lomonosovite.* New data indicate that this mineral may be nearer in composition to the formula $Na_2MnTiSi_4O_{16},2Na_3PO_4$ than the earlier one given in Table XVI. It is also claimed that a meta-lomonosovite, $Na_3H_3MnTiSi_4O_{18},2NaPO_3$, exists.[283–4]

*Messelite* is similar to *collinsite* with an analysis corresponding to $(Ca,Fe,Mn,Mg)_3(PO_4)_2,3H_2O$.[285] The mineral has also been considered to be *anapaite* partly altered to *collinsite*.[394] The formula $Ca_2Fe(PO_4)_2,3H_2O$ has been reported.[395]

*Mitridatite* appears to have a variable composition in which calcium and iron are present in varying proportions, and phosphate is partly replaced by hydroxyl. It has been suggested[286] that the general formula is $Ca_2Fe_3(PO_4)_{3-x}(OH)_{4+3x},nH_2O$.

*Morinite* was originally given the formula $Na_2Ca_3Al_3H(PO_4)_4,F_6,8H_2O$. Subsequent variations were $(Ca,Na)_3Al_2(PO_4)_2.(F,OH)_6,H_2O$,[287] $(Na,Ca,Al)_2(PO_4)_2F_3(OH)_2, 1\frac{1}{2}H_2O$[288] and $Na_2Ca_4Al_4(PO_4)_4(F,OH)_{10},3H_2O$.[289] A more recent examination of a purer specimen including chemical and thermal analysis studies gives the composition as $Na_2(Ca,Al)_4(F_6,O_2)(PO_4)_4,5H_2O$.[290]

*Phosphophyllite.* The structure of this mineral, having the composition $Zn_2Fe(PO_4)_2, 4H_2O$, has been determined.[420]

*Phosphuranylite* is an older known mineral which was initially given the empirical formula $3UO_2,P_2O_5,6H_2O$. Later analysis[277] showed that it contained calcium and had a composition which was close to $Ca(UO_2)_7(OH)_4(PO_4)_4,10H_2O$. Subsequently it was shown to be $Ca(UO_2)_4(OH)_4(PO_4)_4,7H_2O$.[278–9] This has now been confirmed by more detailed examination and synthesis of the mineral.[276]

*Roscherite.* From the original analysis the mineral was thought to contain aluminium and was given the composition $(Ca,Mn,Fe)_2AlOH(PO_4)_2,2H_2O$. Newer data and a re-examination of the analytical procedure used in the original analysis showed that the trivalent metal present was beryllium and not aluminium. The correct formula was found to be $(Ca,Mn,Fe)_3(BePO_4)_3(OH)_3,2H_2O$.[291]

*Saléeite.* A more recent examination of specimens of this mineral, giving further analytical data to those of Table XVI, confirms the previous findings.[292–3]

*Scorzalite, lazulite and barbosalite.* These three minerals have recently been shown to be iso-structural.[294] The common structure consists of octahedra of oxygen and metal ions which are packed with $PO_4$ tetrahedra to give a unit cell content of $(Fe,Mg)_2(Al,Fe)_4(PO_4)_4(OH)_4$. The individual structures are as follow:

| | |
|---|---|
| *Scorzalite* | $Fe_{1\cdot 53}Mg_{0\cdot 47}Al_4(PO_4)_4(OH)_4$ |
| *Lazulite* | $Fe_{0\cdot 23}Mg_{1\cdot 77}Al_4(PO_4)_4(OH)_4$ |
| *Barbosalite* | $Fe_2Fe_4(PO_4)_4(OH)_4$ |

*Taranakite.* Analytical and other data have been reported more recently for this mineral, and show the presence of up to 2% $Fe_2O_3$. It is identical with the minerals *minervite* and *palmerite* which were discovered later, but is distinct from *minyulite* and other potassium aluminium phosphates.[295–6] *X*-Ray studies[297] and synthetic preparations[136, 137] show that the formula is $H_6(K,NH_4)_3Al_5(PO_4)_8,18H_2O$. The one given previously, $K_2Al_6(OH)_2(PO_4)_6,18H_2O$, was originally considered to be doubtful (reference 263, p. 999).

*Vauquelinite.* Analysis of a Russian specimen[363] gave the following results: $P_2O_5$ 0–8·7, CuO 10·3–11·9, PbO 61·1–67·6, $Cr_2O_3$ 26·8–17·4, $Fe_2O_3$ 0–0·7% corresponding to a mixture of copper and lead chromates and phosphates represented by $n[3(Pb,Cu)O(P_2O_5)_2]+m[(Pb,Cu)O(CrO_3)_2]$. A subsequent examination[364] suggested that the mineral was a solid solution of chromates and phosphates and formulated as $(Cu,Pb)_3[CrO_4,PO_4]_2$. The mineral is also known under the name *laxmannite*.

*Viséite* was originally[299] given the formula $3SiO_2,3P_2O_5,5Al_2O_3.5CaO,nH_2O$ with $n=25$–30. A more recent examination[300] shows that the structure and optical and physical properties are closely related to analcime. The mineral is a zeolite, formulated as $Na_2Ca_{10}(Al_{20}Si_6P_{10}H_{36})O_{46},16H_2O$.

*Wardite* was originally supposed to contain calcium and to have the formula $Na_4CaAl_{12}(PO_4)_8(OH)_{18},6H_2O$. Later examination,[265] however, showed that the calcium was an impurity and was not present in the unit cell.[298]

Many of the phosphorus minerals described in the earlier literature are of doubtful validity or have since been discredited for various reasons. The following list gives details and notes on these minerals. The page numbers in this list refer to Dana's *System of Mineralogy*.[263]

*Amphithalite* is an aluminium calcium phosphate containing $Al_2O_3$ 48·5, CaO 5·8, MgO 1·6, $P_2O_5$ 30·1 and $H_2O$ 12·5%. The validity and analysis, however, require verification (p. 873).

*Asovskite*. The analysis $P_2O_5$ 15·9–17·0, $Fe_2O_3$ 52·7–57·2, MnO 0–1·7, and $H_2O$ 23·2–25·8% corresponds to a basic ferric phosphate $Fe_3PO_4(OH)_6$,[396] but the mineral needs verification (p. 795).

*Attacolite*. The analysis of a specimen of doubtful authenticity was $Al_2O_3$ 29·8, MnO 8·0, $Fe_2O_3$ 4·0, CaO 13·2, $Na_2O$ 0·5, $P_2O_5$ 36·1 and $H_2O$ 6·9%. This corresponds roughly to the formula $(CaMn)_3Al_4(PO_4)_4(OH)_6$ (p. 845). A more recent examination confirms the validity of the mineral, and analysis gave $P_2O_5$ 32·6, $SiO_2$ 9·4, $Al_2O_3$ 27, FeO 1·3, MnO 7·1, CaO 11·4, SrO 3·3, and $H_2O$ 5·9%.[397] The suggested formula is $(Ca,Sr,Mn)_3(Al,Fe,Mn)_6(PO_4,SiO_4)_{7-m}(OH)_{4m},3H_2O$.

*Barrandite* is an aluminian form of *strengite* (p. 756).

*Bialite*. This is a magnesian variety of *tavistockite*.[398] The latter name has priority (p. 906).

*Bolivarite*. The analysis, $Al_2O_3$ 44·1, $P_2O_5$ 34·9 and $H_2O$ 20·6%, agrees with $Al_2PO_4(OH)_3,H_2O$ approximately, but verification is required (p. 872).[302, 301]

*Borickite*. The analysis, $Fe_2O_3$ 52·3–53·0, CaO 7·3–8·2, $P_2O_5$ 19·4–20·5, $H_2O$ 19·1–20·0%, gives a formula approximating to $CaFe_5(PO_4)_2(OH)_{11},3H_2O$. The mineral, however, is ill-defined and is similar in many respects to *delvauxite* (p. 915).[367]

*Bosphorite* is a variety of *vivianite* (p. 744).

*Calcioferrite*. The analytical data are $Fe_2O_3$ 24·3, CaO 14·7, MgO 2·7, $Al_2O_3$ 2·9, $P_2O_5$ 34·0 and $H_2O$ 20·6%. Neglecting the small percentages of magnesium and aluminium, the data give the uncertain formula $Ca_3Fe_3(PO_4)_4(OH)_3,8H_2O$ (p. 976).

*Callainite* is very similar to *variscite* and has the analysis $Al_2O_3$ 29·6, $Fe_2O_3$ 1·8, CaO 0·7, $P_2O_5$ 42·6 and $H_2O$ 23·6% (p. 761).

*Cirrolite* approximates to $Ca_3Al_2(PO_4)_3(OH)_3$ from the analysis CaO 29·5, $Al_2O_3$ 20·5, MnO 2·2, FeO 0·9, $P_2O_5$ 41·2 and $H_2O$ 5·1%. On the other hand evidence as to the validity of the mineral as a species is lacking (p. 845).

*Coeruleolactite* is a hydrated basic aluminium phosphate of uncertain formula, probably $Al_3(PO_4)_2(OH)_3,4H_2O$, which, however, omits the copper found in the analysis: $Al_2O_3$ 35·1–38·7, CuO 1·4–4·3, CaO 0–2·4, $P_2O_5$ 36·3 and $H_2O$ 21·5% (p. 961).

*Dittmarite* has an analysis of MgO 25·7, $(NH_4)_2O$ 3·9, $P_2O_5$ 46·5 and $H_2O$ 23·4%, which is close to the formula $Mg_5(NH_4)H_4(PO_4)_5,8H_2O$. It is found in bat guano together with *struvite*, *newberyite* and *hannayite* (p. 699).

*Eguéite* is a hydrated ferric phosphate in which some iron is replaced by calcium and aluminium. The analysis, $Fe_2O_3$ 44·2, CaO 2·3, $Al_2O_3$ 1·5, $P_2O_5$ 30·3 and $H_2O$ 20·5%, gives the formula $(Ca,Al)Fe_{14}(PO_4)_{10}(OH)_4,21H_2O$ (p. 955).

*Ferrazite* is a hydrated lead, barium, aluminium phosphate. The analysis, which needs checking, gave PbO 45·6, BaO 8·9, $Al_2O_3$ 3·5, $SiO_2$ 2·4, $P_2O_5$ 26·2 and $H_2O$ 14·2% (p. 832).

*Fischerite*. An analysis gave $Al_2O_3$ 38·5, $Fe_2O_3$ 1·2, CuO 0·8, $P_2O_5$ 29·0 and $H_2O$ 27·5%. The mineral is, however, very similar to *wavellite* (p. 762). Both give the same *X*-ray powder diagram[303–4] but the optical and physical properties of the two minerals are different.[304] Wavellite has been formulated as $4AlPO_4,2Al(OH)_3,9H_2O$ and fischerite as $2AlPO_4,2Al(OH)_3,5H_2O$[304] or $2AlPO_4,Al(OH)_3,5H_2O$[303] (p. 762).

*Foucherite* contains $Fe_2O_3$ 38·5, CaO 7·7, $Al_2O_3$ 4·5, $P_2O_5$ 19·5 and $H_2O$ 28·5%, which corresponds to the formula $Ca(Fe,Al)_4(PO_4)_2(OH)_8,7H_2O$. Its characteristics are similar to those of *borickite* (p. 915).[367]

*Globosite* is very similar to *strengite*. Analysis gave $Fe_2O_3$ 40·9, MgO 2·4, CaO 2·4, $P_2O_5$ 28·9 and $H_2O$ 23·9% (p. 762).

*Harbortite* has the analysis $Al_2O_3$ 33·4, $Fe_2O_3$ 3·8, $Na_2O$ 3·7, CaO 1·2, $SnO_2$ 2·8, $TiO_2$ 1·0, $P_2O_5$ 35·7 and $H_2O$ 18·3%, approximating to $Al_3(PO_4)_2(OH)_3,3H_2O$. The validity of the mineral is doubtful and its *X*-ray pattern resembles that of turquoise (p. 951).

*Hibbenite*, with a composition corresponding to $Zn_7(PO_4)_4(OH)_2,7H_2O$, resembles *hopeite* and *spencerite* and may be a mixture of these (p. 737).

*Jezekite*. More recent *X*-ray examination[272, 361] suggests that this mineral is identical with *morinite*. The latter name has priority (p. 784).

*Kehoeite* needs verification (p. 944).

*Kolbeckite* is a hydrated aluminium, beryllium and calcium silicophosphate of uncertain formula. The analysis is $Al_2O_3$ 21·4, BeO 8·7, CaO 3·2, $SiO_2$ 9·3, $P_2O_5$ 33·8 and $H_2O$ 23·5% (p. 1015).

*Koninckite*, $FePO_4,3H_2O$, with an analysis of $Fe_2O_3$ 34·4, $Al_2O_3$ 4·6, $P_2O_5$ 34·8 and $H_2O$ 26·2% needs further study (p. 763). It appears to be derived from *heterosite* by simple hydration[373] (p. 763).

*Kribergite*. The approximate formula for this is $Al_{16}(PO_4)_8(SO_4)_3(OH)_{18},10H_2O$, corresponding to the analysis $Al_2O_3$ 38·5, $SO_3$ 13·1, $P_2O_5$ 31·3 and $H_2O$ 17·2% (p. 1011).

*Lacroixite*. The formula of this mineral is unknown. The analysis is CaO 19·5, $Al_2O_3$ 18·9, $Na_2O$ 14·9, MnO 8·4, $SiO_2$ 0·9, F 6·5, $P_2O_5$ 28·8 and $H_2O$ 5·46% (p. 783).

*Merrillite* has an analysis corresponding to $Na_2Ca_3O(PO_4)_2$[399] and may be a variety of *francolite*[400] (p. 797).

*Meyersite*, the analysis of which is given as 66·3% $AlPO_4$, 2·5% $FePO_4$ and 26·1% $H_2O$, is probably *ferrian variscite* (p. 761).

*Planerite* contains $Al_2O_3$ 37·5, CuO 3·7, FeO 3·5, $P_2O_5$ 33·9 and $H_2O$ 20·9%. It could be identical with *fischerite* or *coeruleolactite* (p. 762).

*Millisite* $(Na,K,Ca)Al_6(PO_4)_4(OH)_9,3H_2O$ is iso-structural with and is related to *wardite* (p. 941).

*Redondite*. The older analysis, $P_2O_5$ 43·2, $Al_2O_3$ 16·6, $Fe_2O_3$ 14·4, CaO 0·6 and $H_2O$ 24·0% indicated that the mineral was a ferrian variety of *variscite* (p. 756). A later analysis gave $P_2O_5$ 42·5, $Al_2O_3$ 29·25, $Fe_2O_3$ 3·5, $Cr_2O_3$ 1·11 and $H_2O$ 22·7%, corresponding to the formula $(Al,Fe,Cr)PO_4,2H_2O$.[401] A more recent analysis $P_2O_5$ 40·7, $Al_2O_3$ 34·65, $Fe_2O_3$ 0·34 and $H_2O$ 16·8%, and *X*-ray examination suggest that the mineral is distinct from *variscite*.[402] However, this view has been criticized[403] (pp. 756, 759).

*Richellite* has an uncertain formula, probably $Ca_3Fe_{10}(PO_4)_8(OH)_{12},nH_2O$ and an analysis of $Fe_2O_3$ 28·7–29·7, $Al_2O_3$ 1·8–3·6, CaO 5·5–7·2, F 1·0–6·0, $P_2O_5$ 25·5–28·8 and $H_2O$ 29·4–33·0 (p. 956).

*Richmondite* appears to be $AlPO_4,4H_2O$, with an analysis of $Al_2O_3$ 26·7, $P_2O_5$ 37·6 and $H_2O$ 35·7% (p. 762), but has been discredited as a separate species. The name is also used for a sulphide mineral[371] (p. 762).

*Rosieresite* is a hydrated copper aluminium lead phosphate, a specimen of which gave the analysis: $Al_2O_3$ 23·0, PbO 10·0, CuO 3·0, $P_2O_5$ 25·5 and $H_2O$ 38·0% (p. 924).

*Salmonsite* contains MnO 37·7, $Fe_2O_3$ 9·5, $P_2O_5$ 34·9 and $H_2O$ 15·7%, which could be formulated as $Mn_9Fe_7(PO_4)_8,14H_2O$. The mineral may, however, be an alteration product of *hureaulite* and its validity needs verification (p. 730).

*Sarcopside*. The formula of this is uncertain but may be $(Fe,Mn,Ca)_7(PO_4)_4F_2$ corresponding to the analysis of MnO 10·8–20·6, FeO 30·5–44·5, $Fe_2O_3$ 1·7–8·8, CaO 3·4–4·7, F 4·4–4·7, $P_2O_5$ 33·3–35·7 and $H_2O$ 1·5%. It might be an alteration product of *vivianite* (p. 858).[370] Another examination[404] indicated the formula $(Fe,Mn,Ca)_3(PO_4)_2$, but no calcium was found in a later analysis, the results being $P_2O_5$ 39·7, FeO 50–51·0, MnO 6·2–6·9 and MgO 2·7–3·5%. These results correspond to the formula $(Fe,Mn,Mg)_3(PO_4)_2$. The earlier confusion is attributed to contamination of the specimens with CaO derived from intergrowth with the similar mineral *graftonite*[405] (p. 858).

*Schertelite* is found in bat guano together with *struvite* and *newberyite*. The analysis, MgO 12·2, $(NH_4)_2O$ 16·2, $P_2O_5$ 43·9 and $H_2O$ 27·6% corresponds closely to $Mg(NH_4)_2H_2(PO_4)_2,4H_2O$ (p. 699). A synthetic product having this formula has been made[369] (p. 699).

*Spodiosite* may be analogous to *wagnerite*. The mineral is ill-defined, and the analysis, which is uncertain, is given as CaO 45·8–49·8, MgO 2·3–8·6, $Fe_2O_3$ 1·2–2·4, $SiO_2$ 1·2–8·7, $CO_2$ 0–3·9, F 2·9–4·7, $P_2O_5$ 29·6–32·2 and $H_2O$ 2·7–3·8% (p. 848).

*Stewartite* is a hydrated manganese phosphate of uncertain composition and is probably an alteration product of *lithiophilite* (p. 730). More recent examination indicates the probable formula $MnFe_2OHPO_4,8H_2O$.[374] Chemical analyses,[375–6, 368] physical and optical properties,[375, 368, 301] differential thermal analyses[368] and *X*-ray data have been reported.[301, 376] *Stewartite* is an alteration product of *triphylite* and has a unit cell very close to that of *laueite*[379] (p. 730).

*Tinticite*. The analysis is: $Fe_2O_3$ 48·8–49·2, $SO_3$ 0·7–1·1, $P_2O_5$ 28·4–30·2 and $H_2O$ 18·9–19·7% corresponding to $Fe_3(PO_4)_2(OH)_3,3\frac{1}{2}H_2O$ (p. 970). Infra-red analysis shows that it is distinct from *beraunite*[386] (p. 970).

*Trolleite* has the analysis $P_2O_5$ 46·7, $Al_2O_3$ 43·3, $Fe_2O_3$ 2·75, CaO 1·0 and $H_2O$ 6·2%, which is close to the formula $Al_4(PO_4)_3(OH)_3$. Validity of the species is lacking (p. 911).

*Vashegyite* has an analysis of $Al_2O_3$ 26·5–28·3, $Fe_2O_3$ 1·2–1·3, $P_2O_5$ 26·6–31·3 and $H_2O$ 39–44·7%, giving the somewhat uncertain formula $Al_4(PO_4)_3(OH)_3,nH_2O$ (p. 999).[373]

*Zepharovichite* is probably identical with *wavellite*, the analysis being: $Al_2O_3$ 28·4–29·8, CaO 0·5–1·4, $SiO_2$ 0·5–6·1, $P_2O_5$ 35·6–37·8 and $H_2O$ 26·6–29·0% (p. 964).[372]

Some of the more recently reported minerals have not been definitely established. The more important of these are commented on below.

*Chavesite* is a hydrated calcium manganese phosphate which is isostructural with and very similar to *monetite*.[417]

*Palermoite*. Examination of a purified specimen gave the analysis $P_2O_5$ 42·9–46·4, $Al_2O_3$ 30·8–33·9, SrO 9·2–12·9, CaO 0·9–1·4, $Na_2O$ 1·3–1·6 and $Li_2O$ 3·7–4·0%, corresponding to the formula $(Li,Na)_2(Ca,Sr)(Al,OH,PO_4)_4$.[406] This is stated to be in better agreement with the unit cell contents and the structure of the mineral than previous suggestions.[307–8]

*Tangaite*. This name has been suggested for a mineral similar to *variscite*.[401–2] However, it is reported to be superfluous because tangaite is identical with *redondite*.[403] The analysis is given as $P_2O_5$ 42·5, $Al_2O_3$ 29·3, $Fe_2O_3$ 3·5, $Cr_2O_3$ 1·1, CuO 0·9 and $H_2O$ 22·7%.[401]

*Rhabdophane minerals*. The only well-established members of this group are *rhabdophane* $(Ce,La)PO_4,H_2O$ and *ningyoite* $(Ca,Ce,U)PO_4,H_2O$. Minerals to which the names *silico-rhabdophane*, *titano-rhabdophane* and *silico-smirnovskite* have been given, are reported to have the following analyses:

| | Silico-rhabdophane | Titano-rhabdophane | Silico-smirnovskite |
|---|---|---|---|
| $P_2O_5$ | 18·8% | 3·6–6·8% | 3·1% |
| $SiO_2$ | 13·9 | 8·8–25·0 | 21·4 |
| $TiO_2$ | 0·4 | 12·3–13·1 | 2·9 |
| $Ce_2O_3$, etc. | 35·8 | 16·7–48·5 | 3·6 |
| $ThO_2$ | 0·3 | 0·8–6·0 | 45·3 |
| CaO | 3·4 | 3·1–3·2 | 2·9 |
| $Al_2O_3$ | 8·1 | 1·4–5·2 | — |
| $Fe_2O_3$ | 4·0 | 0·5–1·1 | 1·9 |
| $H_2O$ | 12·1 | 15·1–19·5 | 15·7 |
| $Nb_2O_5$ | 0·2 | 2·2–2·9 | — |

The separate names appear to be unnecessary because the minerals fit in well with *rhabdophane*, *monazite* or *smirnovskite*.[377] The name *tundrite* has been suggested for *titano-rhabdophane*, $Ce_2Ti(SiO_4,PO_4)(OH)_6,4H_2O$.[407]

*Hydrocerite.* Further examination and data are required to support the identity of this material. The analysis is very close to that of *smirnovskite* or *karnasurtite*.[378]

*Grayite.* The *X*-ray data would fit a mineral in either the *rhabdophane* or *monazite* group.[377]

*Karnasurtite* may be related to *monazite* or *rhabdophane*.[377]

*Erikite* with an analysis of $P_2O_5$ 20·1, $SiO_2$ 10·8, $Ce_2O_3$ 21·1, $La_2O_3$ 29·2, CaO 1·9, $Fe_2O_3$ 1·8, $ThO_2$ 1·2 and $H_2O$ 7·4% has been given the formula (La,Ce,Ca,Th,Fe) $(PO_4,SiO_4),H_2O$.[380] It seems, however, that the mineral belongs to either the *monazite* or *rhabdophane* group and the name is unnecessary.[381, 380]

*Fenghuangite.* The composition $(Ca,Ce,La,Th)_5(SiO_4,CO_4,PO_4)_3,O,OH,2{\cdot}5H_2O$ has been reported[382] for this mineral. This corresponds to the analysis: $P_2O_5$ 6·3, $SiO_2$ 13·8, $CO_2$ 2·6, $ThO_2$ 19·6, $CeO_2$ 13·0, $\Sigma\, Ce_2O_3$ 20·1, CaO 10·4 and $H_2O$ 5·5%, but the material is believed to be *thorian britholite*.[383]

*Jiningite.* This appears to be an unnecessary name for *thorite* or a variety of *thorogummite*.[384] The analysis is reported[384] to be: $P_2O_5$ 6·1, $SiO_2$ 7·1, $V_2O_5$ 1·0, $U_3O_8$ 0·5, $ThO_2$ 44·8, $ZrO_2$ 1·0, CaO 7·4, $Fe_2O_3$ 17·3, $Al_2O_3$ 1·5, $H_2O$ 9·9 and rare earth oxides $R_2O_3$ 1·8%.

*Shen-t'u shih.* Although the composition agrees with the formula

$$(Th,Fe,Ca,Ce)(SiO_4,PO_4,AsO_4)CO_3,OH,H_2O$$

the mineral appears to be a variety of *thorite* or *thorogummite*.[385] The reported analysis is: $P_2O_5$ 5·2, $SiO_2$ 15·8, $As_2O_5$ 3·6, $CO_2$ 1·85, $ThO_2$ 52·8, $Fe_2O_3$ 8·2, CaO 2·7, $\Sigma\, Ce_2O_3$ 2·1, $(NbTa)_2O_5$ 1·2 and $H_2O$ 3·4%.[385]

*Strontium-apatite.* It is suggested[391] that it would be better to use the name *belovite* for strontium-containing apatites.

*Pravdite.* This is an aluminium calcium silicate which contains a small percentage of phosphorus. The analysis is: $P_2O_5$ 3·1, $SiO_2$ 18·8, $Al_2O_3$ 35·7, CaO 15·8, $ThO_2$ 4·9, $Fe_2O_3$ 1·8 and rare earths 18·4%, corresponding to $Ca_4R.E._2Al_{10}Si_5O_{32}$.[392]

*Fornacite.* $(Pb,Cu,Fe)_3(CrO_4,AsO_4,PO_4)_2,OH$ is chemically and structurally related to *vauquelinite* (p. 652).

*Pseudo-autunite.* The formula derived from the analysis is given as

$$Ca_{0{\cdot}86}(UO_2)_{1{\cdot}14}(PO_4)_2(H_3O)_2,2{\cdot}5H_2O$$ [418]

This is valid only if $NH_4$ is known to be absent. The name has been criticized on the basis that chemical and *X*-ray examinations do not agree with the mineral being a member of the autunite or meta-autunite series.[419]

The minerals described since 1951 are given at the end of Table XVI, pages 46–55.

Further information on the occurrence, geochemistry and optical and other properties of most of the minerals in Table XVI is given by Gmelin.[408]

Table XVII lists the minerals in alphabetical order, together with the approximate $P_2O_5$ content, and the pages on which they are described. Where an analysis was not available, the $P_2O_5$ content, indicated by an asterisk, has been calculated from the formula.

## Table XVI.—Phosphorus Minerals

| Name | Formula | Percentage composition | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | $P_2O_5$ | $Li_2O$ | $Na_2O$ | $(NH_4)_2O$ | CaO | MgO | FeO | $Fe_2O_3$ | MnO | $Al_2O_3$ | F | $H_2O$ |
| Triphylite | $LiFePO_4$ | 41·1–46·4 | 7–8·9 | — | — | — | — | 21·7–35·1 | — | 3·1–21·1 | — | — | — |
| Lithiophylite | $LiMnPO_4$ | 43·4–45·1 | 5·5–9·2 | — | — | — | — | 3·0–12·6 | — | 30·5–42·6 | — | — | — |
| Sicklerite | $LiMnFe(PO_4)_2$ | 43·1–44·8 | 3·8–4·9 | — | — | — | — | — | 4·7–14·6 | 26·1–33·6 | — | — | — |
| Ferri-sicklerite | $LiFeMn(PO_4)_2$ | 44·7 | 3·3–3·7 | — | — | — | — | — | 27·2–29·1 | 15·2–19·1 | — | — | — |
| Amblygonite | $(LiNaAl)_4(PO_4.F.OH)_4,H_2O$ | 43·4–48·2 | 6·7–9·6 | 0·6–5·3 | — | — | — | — | — | — | 33·6–37·6 | 9–11·3 | 0–2·2 |
| Montebrasite | $(LiNaAl)_4(PO_4.F.OH)_4,H_2O$ | 46·7–47·8 | 8·8–9·7 | 0·4–2·2 | — | — | — | — | — | — | 33·9–35·8 | 0·6–5·5 | 3·3–6·0 |
| Natromontebrasite | $(LiNaAl)_4(PO_4.F.OH)_4,H_2O$ | 44·4 | 3·2 | 11·2 | — | — | — | — | — | — | 33·6 | 4·5 | 5·6 |
| Natrophylite | $NaMnPO_4$ | 41·0 | — | 17·9 | — | — | — | — | — | 41·1 | — | — | — |
| Huhnerkobelite | $(NaCa)(FeMn)_2(PO_4)_2$ | 39·4–41·9 | — | 3·7–9·7 | — | 1·4–9·7 | — | 7·1–18·2 | 14·5–26·5 | 6·4–9·8 | — | — | — |
| Varulite | $(NaCa)(FeMn)_2(PO_4)_2$ | 42·8–44·9 | — | 7·1–9·7 | — | 2·3–4·9 | — | 7·5–12·0 | 5·3–8·4 | 21·1–25·3 | — | — | — |
| Alluaudite | $NaMnFe(PO_4)_2$ | 41·3–42·5 | — | 5·5–8·2 | — | 0–2·7 | — | — | 20·6–25·6 | 20·7–23·1 | — | — | — |
| Mangan–alluaudite | $NaMnFe(PO_4)_2$ | 40·9–46·7 | — | 6·9–8·4 | — | 2·2–4·6 | — | — | 12·8–19·8 | 26·2–28·2 | — | — | — |
| Arrojadite | $Na_2(FeMn)_5(PO_4)_4$ | 34·3–40·0 | — | 4·7–6·4 | — | — | — | 19·8–28·2 | — | 12·3–15·8 | — | — | — |
| Dickinsonite | $Na_6H_2(MgCaFeMn)_{14}(PO_4)_{12},H_2O$ | 39·6–40·9 | — | 7·4 | — | 2·1 | 1·7 | 12·3–13·3 | — | 31·7 | — | — | 1·6–1·8 |
| Fillowite | $Na_6H_2(CaFeMn)_{14}(PO_4)_{12},H_2O$ | 39·1–39·7 | — | 5·4–5·7 | — | 3·6–4·1 | — | 9·3–9·7 | — | 39·4–39·6 | — | — | 1·6–1·7 |
| Lacroixite | $Na_4Mn(CaAlF)_3(PO_4)_3$ | 28·8 | — | 15·0 | — | 19·5 | — | — | — | 8·4 | 18·9 | 6·5 | — |
| Morinite | $Na_2(CaAl)_4(F_6O_2)(PO_4)_4,5H_2O$ | 33·0 | — | 5·1 | — | 13·6 | — | — | — | — | 17·5 | 13·0 | 17·6 |
| Jezekite | $Na_4CaAl_2(F.OH)_2(PO_4)_2.O$ | 30·3 | — | 18·7 | — | 13·5 | — | — | — | — | 21·9 | 8·2 | 7·3 |
| Brazilianite | $NaAl_3(OH)_4(PO_4)_2$ | 38·0–38·7 | — | 8·3 | — | — | — | — | — | — | 42·9–43·8 | — | 9·8 |
| Stercorite | $NaNH_4.H.PO_4,4H_2O$ | 34·4 | — | 3·1 | 7·7–8·5 | — | — | — | — | — | — | — | 42·3 |

| Name | Formula | Percentage composition | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | $P_2O_5$ | $Na_2O$ | $K_2O$ | MgO | CaO | FeO | $Fe_2O_3$ | MnO | $Al_2O_3$ | F | $CO_2$ | $H_2O$ |
| Bradleyite | $Na_3MgCO_3PO_4$ | 28·3 | 37·6 | — | 15·4 | — | — | 0·6 | — | 0·3 | — | 18·4 | 0·4 |
| Griphite | $(NaCaFeAl)_6(MnF.OH)_4(PO_4)_5$ | 38·5–39·7 | 3·3–5·5 | — | — | 6–7·5 | 2–10·7 | 2·4–7·0 | 18–29·6 | 8·7–10·1 | 0–3·0 | — | 2·6–4·3 |
| Dehrnite | $(NaKCa)_5(CO_3)_3(PO_4)_3.OH$ | 35·7–37·1 | 3·7–7·1 | 0·3–5·9 | — | 47·7–54·9 | — | — | — | — | — | 1·2–3·3 | 1·7–3·0 |
| Lewistonite | $(CaNaK)_5(PO_4)_3.OH$ | 32·3–37·9 | 0·5–4·3 | 1·4–3·7 | — | 41·4–46·8 | — | — | — | — | — | — | 7·7–8·6 |
| Wardite | $Na(OH)_4Al_3(PO_4)_2,2H_2O$ | 34·7 | 6–7 | — | — | 0–3 | — | — | — | 36·6–38·3 | — | — | 17·9 |
| Millisite | $NaKCaAl_6(OH)_9(PO_4)_4,3H_2O$ | 33·8 | 2·8 | 1·7 | — | 7·1 | — | — | — | 36·3 | — | — | 18·0 |
| Lehiite | $Na_2K_2Ca_5Al_8(OH)_{12}(PO_4)_8,6H_2O$ | 34·6 | 2·7 | 2·3 | — | 18·1 | — | — | — | 27·8 | — | — | 14·2 |
| Leucophosphite | $KFe_2.OH(PO_4)_2,2H_2O$ | 27–34·7 | — | 8–10·9 | — | — | — | 37–41·0 | — | — | — | — | 11·2 |
| Englishite | $K_2Ca_4Al_8(OH)_{10}(PO_4)_8,9H_2O$ | 37·8 | — | 5·4 | — | 14·1 | — | — | — | 24·7 | — | — | 16·5 |
| Minyulite | $K_2Al_4(OH)_2(PO_4)_4,7H_2O$ | 35·6 | — | 12·3 | — | — | — | — | — | 30·0 | — | — | 20·6 |
| Taranakite | $(K,NH_4)_3H_6Al_5(PO_4)_8,18H_2O$ | 35·1–38·9 | — | 4·2–8·9 | — | 0·4–0·6 | — | 0·8–1·7 | — | 17·0–22·9 | — | — | 28·2–34·9 |

*Table XVI.—(continued)*

| Name | Formula | Percentage composition | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | $P_2O_5$ | $Na_2O$ | $K_2O$ | BeO | CaO | FeO | $Fe_2O_3$ | MnO | $Al_2O_3$ | F | $CO_2$ | $H_2O$ |
| Beryllonite | $NaBePO_4$ | 55·6 | 23·5 | — | 19·4 | — | — | — | — | — | — | — | — |
| Monetite | $CaHPO_4$ | 52·2 | — | — | — | 41·0 | — | — | — | — | — | — | 6·6 |
| Brushite | $CaHPO_4.2H_2O$ | 38–42·7 | — | — | — | 30·8–33·0 | — | — | — | — | — | — | 23·3–30·9 |
| Whitlockite | $Ca_3(PO_4)_2$ | 45·7–45·9 | — | — | — | 46·8–48·2 | — | — | — | — | — | — | — |
| Isoclasite | $Ca_2.OH.PO_4,2H_2O$ | 29·9 | — | — | — | 49·5 | — | — | — | — | — | — | 20·6 |
| Graftonite | $(CaFeMn)_3(PO_4)_2$ | 38·9–41·7 | — | — | — | 4·5–12·8 | 27·8–32·6 | — | 15·7–25·5 | — | — | — | — |
| Francolite | $Ca_{10}(PO_4)_6F_2$ | 38·1–38·3 | — | — | — | 54·0–54·6 | — | — | — | — | 2·8–3·7 | 2·0–3·4 | — |
| Carbonate–apatite | $Ca_{10}(PO_4)_6CO_3,H_2O$ | 34·6–38·6 | — | — | — | 51·3–56·5 | — | — | — | — | 1·4–2·8 | 3·2–4·5 | 1·2–4·4 |
| Fluorapatite | $Ca_{10}(PO_4)_6F_2$ | 38·1–42·0 | — | — | — | 42·4–55·6 | — | — | — | — | 1·2–3·7 | 0–3·4 | 0–1·0 |

## SECTION II

# THE UTILIZATION OF PHOSPHORUS MINERALS

BY D. R. PECK

Numerous investigations have been made into methods of separating and extracting phosphorites which avoid the necessity of producing elemental phosphorus. The general aim has been to improve the quality of the phosphorite, or to convert it by relatively simple means into products of commercial value. The procedures used to achieve this involve physical, mechanical and chemical methods of separation.

## SEPARATION BY PHYSICAL AND MECHANICAL MEANS

The most general method of concentrating low-grade ores is some kind of flotation process. Under suitable conditions the $P_2O_5$ content of an ore may be increased from 10% to about 30% in this way.

In some of the earliest trials the phosphorite was pulped in the presence of shale oil fractions boiling at 170° to 250°C. and flotation carried out by adding 0·5 to 1·0% of a higher fatty acid. Neutral or slightly alkaline conditions favour the process, but impurities such as calcium carbonate, calcium fluoride and iron sulphide are also floated under these conditions.[1] A similar procedure using tar acids, sodium silicate (water glass) and petroleum sodium soaps (acidol) increases the $P_2O_5$ content of the phosphorite from 17% to about 30%.[2, 3] Carboxylic acids derived from the oxidation of paraffin or petroleum have been found to be more efficient flotation agents than oleic acid.[4] Naphthenic acid is useful as a gathering agent and pine oil as a froth producer.[5]

Physico-chemical investigations indicate that the nature of the surface of the mineral, as determined by its wettability, is the decisive factor in the efficiency of the flotation. Wettability isotherms of phosphorites are a useful means of determining their floatability and of evaluating the activity of flotation agents.[6]

Grain size should be adjusted to the type of phosphorite used, otherwise low yields are obtained due to excess mud carrying off large proportions of phosphorite.[7]

Studies of the effect of various gases on the flotation of phosphate ores, using sodium carbonate, sodium silicate and tallow soap as flotation agents, show that a nitrogen atmosphere decreases the $P_2O_5$ recovery and that oxygen gives a noticeable increase. This effect is thought to be due to the sorption of oxygen molecules which increase the hydrophobicity of the mineral surface, with a corresponding increase in the thickness of the sorption layer of the collector.[8] Measurement of the angle of contact between the mineral surface and the flotation medium confirmed that air and oxygen increase the hydrophobic nature of the phosphorite. Graphs have been given which show the relationship between the size of the contact angle and the length of the period of contact of the mineral surface with the collector.[9] Other data show the effect on the $P_2O_5$ recovery of particle size of the ore and the duration of the treatment of the pulp with the gas. The action of the gases did not appear to be related to any chemical action on the collector.[10]

The efficiency of flotation may be increased by preliminary roasting of the phosphorite. This removes organic matter and water of crystallization, causes partial dissociation of calcium carbonate and also results in some removal of fluorine.[11] With some ores this treatment increases the flotation speed by 50 to 100% and reduces the amount of flotation agent required to about one-third.[12, 13] A preliminary mild treatment of a phosphorite with acid also leaves a residue which may be more readily upgraded by flotation.[287]

Preliminary grinding of the phosphorite improves the $P_2O_5$ recovery, the best results being obtained with particles 0·15 mm. (approximately 150 mesh) in size.[14]

Some phosphorites contain gypsum and similar impurities which tend to be transferred from the ore into the phosphorite solution during flotation. In such instances a pre-flotation washing of the ore with sodium chloride solution shortens the flotation time and decreases the amount of carboxylic acid needed.[15]

Numerous flotation procedures have been worked out for enriching phosphorites on a commercial scale. These vary with the type of ore used and with its $P_2O_5$ content.[16–21]

Mechanical procedures for separating phosphate ores depend largely on the type of phosphorite and the nature of the impurities associated with it. For example, simple washing with water and screening may be sufficient to increase the $P_2O_5$ content from 16 to 18%.[22] Usually, however, more complicated procedures are necessary if ores containing about 10% $P_2O_5$ are to yield concentrates with a $P_2O_5$ content of 20 to 25%.[23] Iron-containing ores, for example, are improved by ignition and grinding followed by magnetic separation to remove the magnetite formed,[24] and air-separation to remove the gangue.[25]

A picking process has been devised for particles greater in size than 1·0 mm., which are not easily separated by flotation. The phosphorite is first treated with a 1% aqueous solution of sodium palmitate containing up to 2% of oil or petroleum. It is then brought into contact with a surface coated with a hydrophobic organic substance such as bitumen. After about two minutes the phosphorite grains adhere to the surface, whereas others, such as quartz, do not. If ice is used as the surface, the process is reversed and only the quartz grains are picked up. A 90 to 98% separation has been achieved in this process, using phosphorite particles 5 to 30 mm. in size.[26]

A combination of mechanical and flotation processes is most generally used in America. Florida pebble phosphate is screened to separate the $\frac{1}{16}$ to 1 in. pebbles, using water sprays and vibrating screens. The smaller particles are further separated to give a fraction which is retained on a 48-mesh screen and a second fraction which passes the latter but stays on a 150-mesh screen. The second fraction is then floated at pH 8·5, using sodium hydroxide, tall oil and fuel oil as flotation agents. The recovery is 92% and the product contains 5·5% silica. The latter is reduced to 3% and the $P_2O_5$ content increased to 36% by a second flotation stage using pine oil, sodium hydroxide and a cationic agent (usually an amine). The Tennessee deposits, which are generally of higher grade and contain 23 to 35% $P_2O_5$, are mostly separated mechanically by means of screens, hydro-separators, scrubbers, rakes and similar equipment.[27]

## SEPARATION BY CHEMICAL MEANS

Chemical treatment of phosphorites has been examined not only for extraction of the phosphorus but also for simultaneous production of other materials of commercial value.[29] The more common processes involve some form of acid treatment.[28] The type of treatment and the conditions under which the ore reacts are largely influenced by the variety and composition of the phosphorite, and by the nature of the desired end-product. The latter may not be a pure material and if the complete separation of a pure product, e.g. phosphoric acid, is required, further purification stages may be necessary.

### Decomposition with Hydrochloric Acid

Phosphorites are fairly easily decomposed by treating the ore, ground to 20-mesh size, with the theoretical amount of 10% aqueous hydrochloric acid. After filtration of the reaction mixture, the phosphoric acid may be precipitated as calcium phosphate by addition of ground limestone and allowing sufficient time for neutralization. In practice, however, it is an advantage to complete the reaction by using milk of lime.

The action of very dilute hydrochloric acid varies with the origin of the phosphorite, some ores being more easily decomposed than others. With 1% hydrochloric acid a 70 to 90% reaction is usually obtained at 18°C. This increases to 80 to 92% with 5% acid. In both instances the amount of acid used is sufficient to convert all the calcium in the ore into calcium chloride. For acid concentrations of 3% or less, part of the hydrochloric acid can be replaced by sulphuric acid.[30]

Pure phosphoric acid is claimed to result from the extraction of phosphate rock–hydrochloric acid mixtures with organic solvents such as ketones, butanol, pentanol or *iso*amyl alcohol which have a limited solubility in water.[31, 288–9] From the aqueous layer phosphoric acid of about 75% concentration is obtained. It is substantially free from metallic impurities except for calcium. The organic solvent is recovered by distillation.

When very low grade glauconitic ore is extracted with hydrochloric acid for 1 hr. at 80°C., the amount of iron removed is minimized by calcining the ore for 2 hr. at 1050°C. Increasing the time to 4 hr. doubles the amount of silica extracted.[32]

The distribution coefficient $K_d = c\,\underset{\text{aq.}}{\mathrm{H_3PO_4}} \Big/ c\,\underset{\text{org.}}{\mathrm{H_3PO_4}}$ for phosphoric acid between water and a series of straight-chain alcohols is found to obey the empirical relationship $K_d = 1/(an_c - b)$, where $a$ and $b$ are constants, and $n_c$ is the number of atoms in the $C_4 - C_{10}$ chain. The extractibility of the common mineral acids increases in the order $HNO_3 < HCl < H_2SO_4 < H_3PO_4$. 87·2% of the total phosphoric acid can be extracted by *n*-butanol from a native phosphorite treated with nitric acid.[290] Tributyl phosphate is also an excellent solvent for phosphoric acid.[291] Even more efficient purification is achieved by the use of solvents which:

(*a*) extract practically no phosphoric acid from aqueous solutions containing less than 35% $H_3PO_4$,
(*b*) extract significant amounts of acid at concentrations above 35% $H_3PO_4$, the amount increasing with increasing concentration,
(*c*) dissolve more phosphoric acid at low rather than at high temperatures.

Dibutyl ether is a particularly good solvent of this kind, and by using it to extract 86·5% phosphoric acid at low temperature, warming the extract and adding a small amount of water, an aqueous phosphoric acid is obtained of similar concentration to the original, but containing only a small proportion of the bases originally present.[292] An extensive review of earlier literature on the extraction of phosphoric acid has appeared.[288]

In some procedures the hydrochloric acid is generated *in situ* by using sulphuric acid and sodium, potassium, ammonium or magnesium chlorides. The amount of calcium extracted by this method varies with the salt used. If required for use as a fertilizer, the best product is said to result from treatment of the phosphorite with a mixture containing 2·5% $H_2SO_4$, 0·9% NaCl and 0·5% $MgCl_2$.[33] The rate of decomposition decreases when ammonium chloride is used in conjunction with hydrochloric and sulphuric acids.[34]

Hydrochloric acid and ammonium sulphate have been used to extract phosphate rock for fertilizer purposes. Calcium chloride and a mixture of mono- and dicalcium phosphates are obtained by an initial acid extraction. The product is then caused to react with ammonium sulphate to give a material containing 15% $P_2O_5$ and 7·4% nitrogen.[35]

A more unusual procedure involving treatment of phosphate rock with concentrated hydrochloric acid, ferric chloride, milk of lime, coke dust and chlorine has been described. Phosphorus oxychloride is distilled out as an intermediate product and is then hydrolyzed to phosphoric and hydrochloric acids. The latter is re-used.[36]

Phosphorites have been extracted by reaction with gaseous hydrogen chloride at 500° to 600°C.[37] Unground phosphate ores react very rapidly at 120° to 300°C. with gaseous nitric acid or hydrogen chloride to give a highly concentrated hot magma.

The latter is only slightly acid because of the low solubility of the gaseous reactants in the melt at the temperatures used. The product is non-hygroscopic and contains 15% $P_2O_5$ and 12% N. The process is suitable for continuous operation in towers.[38–9]

### Decomposition with Nitric Acid

The use of nitric acid may offer economic advantages over other acid processes when the product is used as a fertilizer. For example, the nitrogen value of the product can compensate for the higher cost of nitric acid as compared with that of sulphuric acid.[40, 293, 294] Numerous variations in processes involving nitric acid have been reported, of which the following are typical.

In one process a phosphorite containing 22% $P_2O_5$ and 39% CaO is ground to 150 to 200-mesh size and is then stirred for 1 to $1\frac{1}{2}$ hr. at room temperature with a 5% excess of 15 to 40% nitric acid. Maximum extraction (95%) of the $P_2O_5$ occurs when acid of 25% concentration is used. The extraction decreases to 60% if only 95% of the stoicheiometric amount of acid is added.[41] At 50°C. the maximum decomposition of phosphorite occurs with 14 to 25% nitric acid. Higher acid concentrations, increase in temperature and addition of sodium sulphate all tend to decrease the rate of decomposition.[42] Increasing both the temperature and the acid concentration increases the amount of base metals extracted from the ore.[43] Removal of fluorine is said to result from treating phosphorite with 43% nitric acid at 60°C. and then adding sericite (a sodium aluminium silicate mineral) and filtering.[44]

In order to obtain a less hygroscopic product, phosphorite is sometimes treated for 30 min. with only enough 25% nitric acid to decompose the calcium carbonate and tricalcium phosphate in the ore. Enough ammonia and ammonium carbonate are then added to precipitate the phosphorus and calcium as dicalcium phosphate and calcium carbonate.[45] Ammonium nitrate is obtained by evaporating the filtrate, but the product is hygroscopic owing to the presence of calcium nitrate. The latter is eliminated by carrying out the process in two stages and filtering off the calcium carbonate at 45° to 50°C.[46]

When ammonia is used in conjunction with nitric acid it is important to control the pH during the neutralization stage, otherwise complete recovery of the phosphorus does not take place. The optimum conditions for conversion into dicalcium phosphate of the monocalcium salt formed in the initial reaction of the phosphorite with nitric acid are a temperature of 60°C. and $P_2O_5$ and $N_2O_5$ concentrations in solution of not more than 6 and 21%, respectively.[47] Filtration of the precipitated calcium carbonate is improved if the ammonium carbonate is added at 40° to 45°C., using a 10 to 15% excess of a 25 to 30% solution. If the reaction is carried out with gaseous ammonia and carbon dioxide instead of ammonium carbonate, the rate of precipitation depends on the rate at which ammonium carbamate is hydrolyzed in solution.[48]

Phase diagrams relevant to the action of nitric acid on phosphorites have been studied by a number of authors. Diagrams for the $Ca(NO_3)_2$–$HNO_3$–$H_3PO_4$–$Ca_3(PO_4)_2$–$H_2O$ system at 5°, 25°, 50°, 75° and 100°C.[49] and for the solubility of calcium nitrate in the $Ca(NO_3)_2$–$H_3PO_4$–$HNO_3$–$H_2O$ system[50] have been given. Metastable equilibria in the $CaO$–$P_2O_5$–$H_2O$[51] and $Ca(NO_3)_2$–$HNO_3$–$H_2O$[52] systems have been studied. The influence of ammonium ions on these systems has been investigated in detail.[53–8] Some of the data[59–63] enable yields of mono- and dicalcium phosphate, obtainable by dissolving phosphorite in nitric acid of known concentration, to be calculated. The effect of adding ammonia to the system can also be determined.[64–6]

Phosphate ores of the fluorapatite type are less readily decomposed by nitric acid than are phosphorites. At 50°C. using 120% of the nitric acid required for the reaction:

$$3Ca_3(PO_4)_2{,}CaF_2 + 14HNO_3 = 3Ca(H_2PO_4)_2 + 7Ca(NO_3)_2 + 2HF$$

the decomposition is rapid during the first ten minutes, but decreases quickly as the CaO and $P_2O_5$ concentrations increase in the solution. At a later stage the soluble

$P_2O_5$ concentration decreases because monocalcium phosphate precipitates on the undecomposed fluorapatite and so reduces the decomposition rate. A diagram has been given which shows the optimum conditions for obtaining maximum yields of monocalcium phosphate and calcium nitrate in a cyclic process.[67] After filtering off the phosphate, the calcium nitrate is removed by crystallizing at 5°C. or at $-30$°C. At the latter temperature the equilibrium concentrations in solution are 29 to 39% $P_2O_5$, 2·3 to 3·9% CaO and 40 to 53% $H_3PO_4$.[68] A saving of 20 to 30% of the nitric acid used is said to occur when fluorapatite is treated at 60° to 100°C. with a 40 to 50% nitric acid solution containing 40% ammonium sulphate.[69] Iron and magnesium are reported to inhibit the conversion of the extracted phosphate into a citrate-insoluble form during the neutralization of nitric acid extracts of apatite with ammonia.[70]

Alternatively, after crystallization of calcium nitrate at low temperature, the residual nitric acid is removed as barium nitrate by the addition of barium carbonate. The residual phosphoric acid, after precipitation of calcium by sulphuric acid, is comparable in quality with gypsum process acid, while the nitric acid is recovered as ammonium nitrate for fertilizer use by treatment with carbon dioxide and ammonia.[294]

In most types of phosphate rock the $CaO:P_2O_5$ ratio is greater than that for dicalcium phosphate, so that invariably a product containing calcium nitrate is obtained when the ore reacts with nitric acid. The addition of ammonia in this process is assumed to give a mixture of dicalcium phosphate, calcium fluoride, calcium nitrate and ammonium nitrate, and the phosphates of any iron and aluminium present in the rock. For practical purposes the requirement of ammonia is calculated from the expression:

$$NH_3 = NO_3 + 0{\cdot}395P_2O_5 + 0{\cdot}737F - 0{\cdot}5CaO - 0{\cdot}55Al_2O_3 - 0{\cdot}35Fe_2O_3$$

where the symbols represent the weight in grams of each component in the system. The reaction mixture is often adjusted with sulphuric or phosphoric acid so as to avoid the presence of soluble calcium salts on subsequent neutralization with ammonia. The filtered solution then contains monoammonium phosphate instead of calcium nitrate, and for this the ammonia requirement is given by:

$$NH_3 = NO_3 + 0{\cdot}197P_2O_5 + 0{\cdot}368F - 0{\cdot}25CaO - 0{\cdot}275Al_2O_3 - 0{\cdot}175Fe_2O_3$$

The precipitation of dicalcium phosphate is assumed to take place according to the equation:

$$3Ca(H_2PO_4)_2 + 3Ca(NO_3)_2 + 6NH_3 = 6CaHPO_4 + 6NH_4NO_3$$

Under some conditions, however, the reaction is:

$$\begin{aligned}&3Ca(H_2PO_4)_2 + 7Ca(NO_3)_2 + 14NH_3 + 2H_2O\\&\qquad = 3Ca_3(PO_4)_2,Ca(OH)_2 + 14NH_4NO_3\end{aligned}$$

so that more than the calculated amount of ammonia is required.

Complete extraction of the rock occurs when the acid ratio (moles $N_2O_5$ to moles CaO) is 0·90 to 0·95. Fluorine in the ore, however, promotes the precipitation of an apatite. This can be avoided by removing most of the fluorine at the ammoniation stage. Neutralization of the acid extract at 30° to 40°C. with 40 to 50% of the required amount of ammonia, so as to bring the pH to 0·9 to 1·4, removes over 90% of the fluorine as calcium fluoride. The iron and aluminium are also removed as secondary phosphates, $R_2(HPO_4)_3$. Approximately 15% of the phosphorus in the extract is precipitated in this operation. After removal of the initial precipitate the phosphorus is recovered from the filtrate by addition of more ammonia so as to bring the total amount used to 110% of the calculated amount.[71]

Ammonia is used in processes based on the nitric acid extraction of phosphate ores so as to avoid the presence of calcium nitrate in the end product. In one procedure phosphate rock reacts with 53% nitric acid and the solution is partly neutralized with ammonia to form dicalcium phosphate which is filtered off. The filtrate is then treated with ammonia and carbon dioxide until the pH is 6 to 8. The main product is a carbonate apatite approximating to $Ca_{10}(PO_4)_6CO_3$ in composition.[72] A similar process uses ammonia and sulphur dioxide in the final stage. This gives a citrate-soluble material containing ammonium nitrate and a phosphate in which the molar ratio of CaO, $P_2O_5$ and $SO_2$ is 3·7:1:0·7.[73]

### USE OF SULPHURIC ACID AND NITRIC ACID

Sulphates and sulphuric acid have been used in conjunction with nitric acid and ammonia to produce materials which are both non-hygroscopic and non-caking. The composition of the products is often not known precisely, but it appears that calcium nitrate is eliminated and is replaced by calcium sulphate, calcium carbonate or dicalcium phosphate, together with an equivalent amount of ammonium nitrate. For example, Florida phosphate rock reacts with 42% nitric acid in proportions to give a molar $HNO_3/CaO$ ratio of 1·8. Ammonia is then added at 80°C. to give a molar $NH_3/NO_3$ ratio of 0·63, sufficient potassium sulphate also being present to give a $K_2O/P_2O_5$ weight ratio of unity. Ammonium sulphate can be used instead of the potassium salt and potash minerals, such as langbeinite ($K_2O$ 21·4, MgO 19·0, $SO_4$ 67%) and glaserite ($K_2O$ 41·6, $Na_2O$ 7·1, $SO_4$ 56·5%), are an alternative source of sulphate. The quantities of these minerals used are such as to give a $K_2O/P_2O_5$ weight ratio of 0·29 with langbeinite and 0·67 with glaserite. The products have a high citrate-solubility under the above conditions, but the $P_2O_5$ availability decreases sharply if the $HNO_3/CaO$ ratio is less than 1·8 or if the sulphate is added after the ammonia stage.[74] In a modification of this procedure, much smaller quantities of sulphate are used and the final stage is carried out with an equimolar mixture of carbon dioxide and gaseous ammonia until the $NH_3/NO_3$ molar ratio is 0·95. The product contains dicalcium phosphate, calcium carbonate and ammonium nitrate.[75]

With mixtures of nitric and sulphuric acids the efficiency of extraction of apatite is only slightly affected by the addition of up to 10% nitric acid. However, when the content of the nitric acid in the mixture is between 40 and 90%, over 96% of the phosphate is extracted in 15 min. at 50°C.[76]

A non-caking product is formed when Moroccan phosphate reacts with a mixture containing equal equivalents of nitric and sulphuric acids. The total acid concentration in this procedure is 66% and the amount used is 80% based on the CaO content of the rock. The reaction is vigorous and the product contains 23% of calcium nitrate, together with 90% of the fluorine originally present in the ore. If potassium chloride is added, the product becomes hygroscopic. In both cases the reaction mixture is adjusted to pH 6 with ammonia.[77]

In a similar procedure, ground Florida phosphate is caused to react at 70°C. with a mixture containing 15% $H_2SO_4$, 29% $HNO_3$ and 56% $H_2O$ in proportions corresponding to the equation:

$$Ca_{10}F_2(PO_4)_6 + 12HNO_3 + 4H_2SO_4 = 6H_3PO_4 + 6Ca(NO_3)_2 + 4CaSO_4 + 2HF$$

The mixture is then adjusted to pH 3·7 with gaseous ammonia to bring about the reaction:

$$\begin{aligned} &6H_3PO_4 + 6Ca(NO_3)_2 + 4CaSO_4 + 2HF \\ &\qquad = 12NH_4NO_3 + 5CaHPO_4 + NH_4H_2PO_4 + 4CaSO_4 + CaF_2 \end{aligned}$$

Under these conditions 98% of the phosphorus in the product is citrate-soluble.[78]

### USE OF PHOSPHORIC ACID AND NITRIC ACID

Phosphoric acid is frequently used, together with nitric acid and ammonia, for treating phosphorites, particularly where the product is used as a fertilizer. Many processes of this kind have been devised, of which the following is typical.

Florida rock of 30-mesh size is treated at 40° to 50°C. with a mixture of 42% nitric acid and 80% phosphoric acid in the proportions required by the equation:

$$Ca_{10}F_2(PO_4)_6 + 20HNO_3 + 4H_3PO_4 = 10Ca(NO_3)_2 + 10H_3PO_4 + 2HF$$

The amount of phosphoric acid used is such that the total $P_2O_5$ (i.e. the sum of the $P_2O_5$ in the rock and that in the added phosphoric acid) in the system is one mole for every two moles of CaO. Complete extraction occurs when the molar ratio $(HNO_3+H_3PO_4)/CaO$ is 2·1 or more. About 30% of the fluorine in the rock is volatilized at this stage.

The reaction mixture is now treated with gaseous ammonia at 90° to 110°C. in an amount required by the equation:

$$10Ca(NO_3)_2+10H_3PO_4+2HF+21NH_3 = 20NH_4NO_3+9CaHPO_4+NH_4H_2PO_4+CaF_2$$

The final pH is 3·7 to 4·0, the product is relatively non-hygroscopic and 98% of the phosphorus in it is available to plants.

The neutralization with ammonia in this process is carried out in four stages in which 57, 26, 13 and 4% of the total requirement is used. Single stage treatment, or neutralization to a higher pH than 4, considerably decreases the amount of available phosphorus in the product. This is due to the formation of fluorapatite, probably by a reaction such as the following[79]:

$$10Ca(NO_3)_2+10H_3PO_4+22{\cdot}8NH_3+1{\cdot}4HF = 0{\cdot}7Ca_{10}F_2(PO_4)_6+3CaHPO_4+2{\cdot}8NH_4H_2PO_4+20NH_4NO_3$$

This phenomenon has been observed in other extraction procedures.[71, 74–5]

In processes involving neutralization with ammonia, reversion of the phosphate to a citrate-insoluble or non-available form is a frequent occurrence. This happens when the ammonia addition is not controlled, or neutralization is carried to too high a pH value. There are conflicting reports as to how this may be avoided. Addition of salts of magnesium, aluminium, zinc, molybdenum, vanadium, manganese, iron, chromium, nickel and cobalt is said to enable the neutralization to be made up to pH 9.[80] The most effective salts appear to be magnesium, aluminium and manganese sulphates.[81] The sulphate ion alone seems to be equally effective because a similar action has been observed with sulphuric acid and alkali sulphates.[74–5] On the other hand the effect of these additions has been stated to be negligible and removal of 90% of the fluorine by controlled ammoniation is recommended.[71] It has also been proposed to remove the fluorine by adding silica to the acid extract, adjusting the $CaO:P_2O_5$ molar ratio to less than 2 and removing calcium nitrate by crystallization. Ammonium and sodium nitrates are then added and this precipitates 80% of the fluorine as sodium silicofluoride.[82]

### Decomposition with Sulphuric Acid

Sulphuric acid is the acid most generally used for extracting phosphorites. The methods and techniques adopted depend on whether the product is a fertilizer or wet-process phosphoric acid. For the latter it is important to have a pure material and the removal of trace impurities of fluorine, silica, iron and heavy metals is not easy to achieve.

Many investigations into the production of wet-process phosphoric acid have been made and this work has been well summarized and reviewed.[83] The following is a brief description of the procedure used when fluorapatite is the raw material.

The simplest representation of the reaction is given by the equation:

$$Ca_{10}F_2(PO_4)_6+10H_2SO_4+20H_2O = 10(CaSO_4,2H_2O)+6H_3PO_4+2HF$$

However, since phosphate rock is not pure calcium fluorapatite but contains impurities such as silica, iron, aluminium and carbonate, closer approximation to the reactions involved is given by the following series of equations:

$$(1)\quad Ca_3(PO_4)_2+3H_2SO_4+6H_2O = 3(CaSO_4,2H_2O)+2H_3PO_4$$
$$(2)\quad CaF_2+H_2SO_4+2H_2O = CaSO_4,2H_2O+2HF$$
$$(3)\quad 4HF+SiO_2 = SiF_4+2H_2O$$

$$2SiF_4+2H_2O = H_2SiF_6+SiO_2+2HF \tag{4}$$
$$6HF+SiO_2 = H_2SiF_6+2H_2O \tag{5}$$
$$H_2SiF_6 \rightleftharpoons SiF_4+2HF \tag{6}$$
$$CaF_2+H_3PO_4 = Ca(H_2PO_4)_2+2HF \tag{7}$$
$$H_2O+CaCO_3+H_2SO_4 = CaSO_4{,}2H_2O+CO_2 \tag{8}$$
$$Fe_2O_3+2H_3PO_4 = 2Fe^{3+}+2PO_4^{3-}+3H_2O \tag{9}$$
$$Al_2O_3+2H_3PO_4 = 2Al^{3+}+2PO_4^{3-}+3H_2O \tag{10}$$

In practice some weak re-cycled phosphoric acid is used to produce the initial slurry of phosphate rock.[84, 295–6] The following reaction then occurs:

$$Ca_3(PO_4)_2+4H_3PO_4+3H_2O = 3[Ca(H_2PO_4)_2{,}H_2O] \tag{11}$$

The monocalcium phosphate is later decomposed by sulphuric acid:

$$3[Ca(H_2PO_4)_2{,}H_2O]+3H_2SO_4+3H_2O = 6H_3PO_4+3(CaSO_4{,}2H_2O) \tag{12}$$

The last two equations represent the initial reaction of the phosphate rock more closely than does equation (1). This reaction involves dissolution of the rock according to (11) and the subsequent crystallization of gypsum. It is important to ensure that the rate of solution of the apatite does not exceed the rate of transfer of calcium ions from the rock to the gypsum surface. Excessive concentration of rock or of sulphate ion causes supersaturation near the rock surface and the formation of fine calcium sulphate crystals which may coat the rock particles and retard the reaction.[85]

Reactions (2) to (7) are not quantitative. Varying amounts of fluorine are found in the solid, liquid and gaseous phases of the reaction. The quantity volatilized as silicon tetrafluoride depends on the reaction conditions, but is largely influenced by the concentration of the sulphuric acid used and by the proportion of acid to phosphate. Various estimates state[83, 86–8] that 15 to 40% of the fluorine is removed by volatilization, 10 to 30% in the gypsum and that 50 to 60% remains in the filtered phosphoric acid. On concentrating this acid to 30–50% $P_2O_5$ further volatilization occurs, to give phosphoric acid containing about 30% of the fluorine which was originally present in the phosphate rock.

Carbonate in the ore is a disadvantage in that it consumes sulphuric acid to no purpose (reaction 8). It also causes practical difficulties with foaming of the reaction mixture.

Iron and aluminium are also objectionable in wasting sulphuric acid (reactions 9 and 10) and in decreasing the amount of phosphoric acid available, e.g. in the manufacture of superphosphate.[89]

Practical details of the wet-acid process are given in many references[77, 84, 86, 87, 90–6] and only the main features are referred to here. Other details are to be found below in the description of the reaction of phosphorites with sulphuric and phosphoric acids (see pages 81 to 90).

The efficiency of the wet-acid process is very dependent on the careful preparation of the correct size and shape of gypsum crystals.[97] Of the three forms of calcium sulphate—dihydrate, hemihydrate and anhydrite—only the last is stable in the range of acid concentration normally found in wet-acid procedures. Extensive studies have been made of the transitions of the crystal hydrates of calcium sulphate in the presence of phosphoric acid[98–9, 106] and on the $CaO–P_2O_5–H_2O$[100] and $CaO–P_2O_5–SO_3–H_2O$[101] systems. The effects of temperature and acid concentration on the degree of hydration of calcium sulphate are shown in Fig. 1. The data used in constructing this diagram are derived from the thermodynamic properties of gypsum,[102] investigations of the $CaSO_4–H_3PO_4–H_2O$ system[103, 99] and observations on wet-process phosphoric acid manufacture.[96] During the initial stages of the reaction of phosphate rock with sulphuric acid the system is in the region above the line AB.[104] In the region below this the rate of transformation of hemihydrate into anhydrite and dihydrate is delayed,[105] probably as the result of supersaturation.

The rate of transformation and the size and shape of the calcium sulphate crystals are affected by the metallic and organic impurities in the rock,[104] by the addition of surface active materials such as arylsulphonic acids,[297] and by the concentration of unreacted sulphuric acid. In supersaturated solutions nucleation occurs only above a threshold value and under practical conditions the rate of crystal growth is proportional to the supersaturation. The theory of this has been discussed.[105]

The ratio of acid to rock has a marked influence on the filterability of the reaction mixture and deviations from the optimum ratio considerably reduce the filtration rate. Similar effects are found with too high phosphoric acid concentrations. Control of the solids concentration in the system is also necessary, but this is rather less critical than are factors involving the acids.

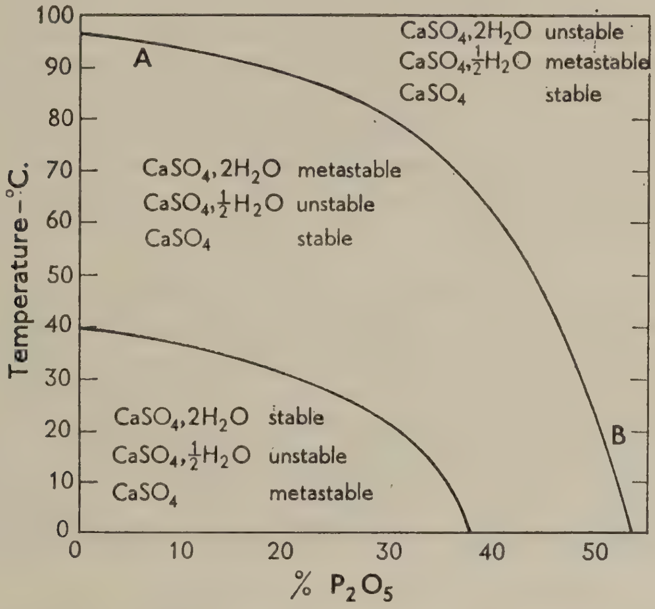

FIG. 1.—Effect of temperature and acid concentration on the form of calcium sulphate precipitated in the decomposition of phosphate rock

The kinetics of the reaction of sulphuric acid with phosphate rock have been extensively studied. Many of the data refer to the conditions used in production of superphosphate fertilizers rather than of wet-process acid. The following information is typical of that available in the literature.

### DECOMPOSITION OF PHOSPHATE ROCK

From a study of the reaction of Moroccan phosphate with 45 to 76% sulphuric acid at 80° to 105°C. it is concluded that for all acid/rock ratios the maximum conversion occurs with 70% sulphuric acid. In the initial stages, when free sulphuric acid is present, the main reaction is to form free phosphoric acid. This stops when the free sulphuric acid has disappeared and the reaction is then between phosphoric acid and unreacted phosphate to form monocalcium phosphate. After three weeks a stationary state is reached in which substantial proportions of free acid and unreacted phosphate remain. This is largely due to coating of the latter with calcium sulphate.[107] The effect of particle size of the ore on the time required for the free sulphuric acid to disappear from the reaction mixture is shown in Fig. 2.

Similar results were found with Florida pebble phosphate, the maximum conversion occurring with 60% to 70% sulphuric acid. The optimum acid concentration varied slightly with the time and temperature of the reaction. Addition of nitric acid or of sodium or ammonium nitrate increased the extraction rate, irrespective of variations in other factors. The acidulation ratio, i.e. the mole ratio of acid used to CaO in the ore, had an optimum value of 1·10 to 1·15. The optimum reaction temperature range, which depended on other reaction conditions, was 35° to 80°C. Empirical equations were derived which correlated the $P_2O_5$ extracted with acid concentration, reaction time and temperature, acidulation ratio, and the particle size of the rock.[108]

A linear relationship in which the percentage conversion of Florida phosphate varies from 90%, when using 76·5% sulphuric acid, to 98% with 52·5% acid has been found.[109] The only significant difference from the other observations[107–8] appears to be the higher reaction temperature of 120° to 130°C. The effect of acid ratio at this temperature when using 60% sulphuric acid is shown in Fig. 3.[109] The best practical sulphuric acid concentration is said to be 62%.[110]

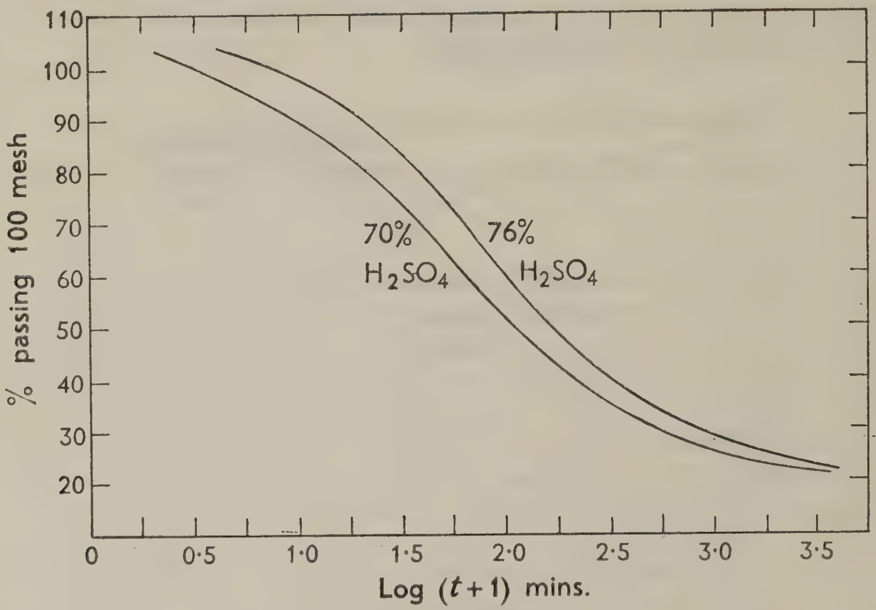

FIG. 2.—Rate of reaction of Moroccan phosphate with sulphuric acid

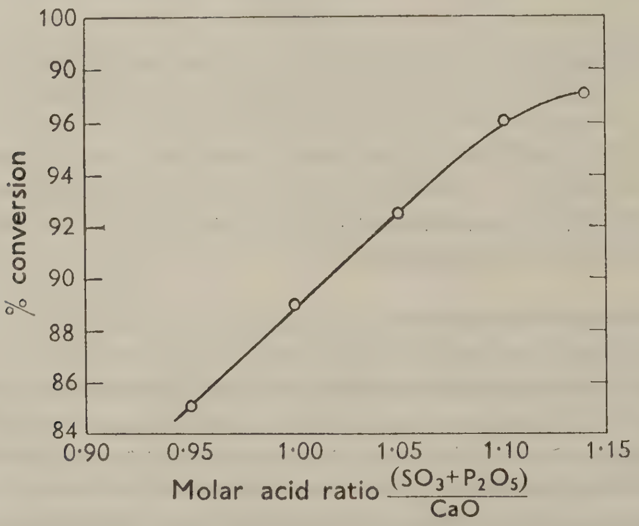

FIG. 3.—Effect of acid ratio on the reaction of Florida phosphate with sulphuric acid

During the mixing of sulphuric acid with apatite the amount of decomposition $K$ varies with the acid concentration and the weight ratio $R$ of acid to apatite according to the expression:

$$K = \frac{60R}{(1+0{\cdot}6A)\times 1{\cdot}38B}$$

where $A$ is percentage of phosphoric acid formed in the reaction mixture and $B$ is the percentage of $P_2O_5$ in the apatite. $K$ is maximal in 58% sulphuric acid when $R$ is 0·7.[111]

Too high a concentration of sulphuric acid inhibits the reaction with apatite and for a given temperature there is a concentration at which the reaction stops. As the temperature is raised so the concentration at which this occurs decreases.[112]

Several modifications of the wet-acid processes described above have been proposed, largely with the aim of making more concentrated phosphoric acid. In one of these the reaction temperature and sulphuric acid concentration are increased so as to precipitate calcium sulphate as the hemihydrate. This produces phosphoric acid containing 40 to 50% $P_2O_5$.[113–14, 298] More readily filterable hemihydrate crystals are obtained by carrying out the initial attack in a layer of foam on the surface of the reaction slurry.[299] Another modification involves the conversion of the hemihydrate into anhydrite at 100° to 110°C. in 45 to 50% $P_2O_5$ acid containing 1 to 4% free sulphuric acid.[115–16] In others the hemihydrate originally formed is recrystallized separately to give gypsum of low phosphate content.[300, 301] Acid of 50% $P_2O_5$ concentration is obtained by heating sulphuric acid (98%) to 90° to 105°C., mixing with phosphate rock to form a stiff paste and then heating for about an hour at 200° to 240°C. The resulting clinker is extracted with weak phosphoric acid or water. About 60% of the fluorine is volatilized during mixing and increases to 88% on heating.[117] Fuming sulphuric acid (104%) has been used in a similar process to give acid of 50–55% $P_2O_5$ concentration.[299] Submerged combustion has been used to concentrate phosphoric acid to 70% $P_2O_5$ content.[118] The polyphosphoric acids thus formed are claimed to hinder or prevent the formation of base precipitates during subsequent ammoniation.[302]

The reaction between sulphuric acid and phosphate ores to produce fertilizers has been studied in very great detail. Many of the procedures used involve a curing stage in which the reaction mixture is allowed to stand so as to increase the amount of $P_2O_5$ extracted. The effects of time, temperature, acid ratio and concentration, and the particle size of the ore on the process have been studied.[108] Attempts to avoid the curing stage by air-drying the reaction mixture at temperatures up to 540°C. have not been very successful.[119] Sulphuric acid of 40 to 60% concentration is best for this procedure, but the conversion is only 90% as compared with 98% for conventional processes.[120]

### DECOMPOSITION OF PHOSPHORITES

Phosphorites are easier to decompose with sulphuric acid than are ores having an apatite structure. With a phosphorite complete decomposition occurred in 3 to 5 hr. at 20° to 30°C. and about 80% of the reaction took place in the first 10 min. To achieve a 95% conversion of apatite with the same acid, a temperature of 80°C. was necessary. On the other hand the phosphorite consumed 50 to 100% more sulphuric acid per ton of $P_2O_5$ than did the apatite. This was largely due to impurities, particularly iron, in the phosphorite. Gypsum of uniform and large crystal size was obtained only when the $SO_3$ and CaO concentrations in the liquid phase were 1 to 2·5% and 0·35 to 0·75%, respectively.[121]

In order to increase the amount of $P_2O_5$ extracted from phosphorites containing up to 10% $Fe_2O_3$, it is an advantage to calcine the ore at 1000°C. and carry out the extraction with acid at 35° to 40°C. Stirring for 2 to 4 hr. with 93% of the theoretical requirement of sulphuric acid gives 87% conversion of the $P_2O_5$. Addition of 5% of sodium or potassium chloride increases this to 95%, but the corresponding sulphates decrease the amount of $P_2O_5$ extracted.[122]

Some data on the reaction of sulphuric acid with low-grade phosphorites are given in Table I. These were obtained under conditions where the liquid/solid ratio in the reaction mixture was 2·5:1 to 3:1 and the $SO_3$ and CaO concentrations in the liquid phase were 1·5 to 2% and 0·3 to 0·7% respectively. The amount of sulphuric acid used is shown as a percentage of that required to convert the CaO in the ore into calcium sulphate.[123]

Sulphuric acid corresponding in composition to $H_2SO_4,H_2O$ has been used to decompose phosphorite, followed by neutralization with ammonia or urea.[124] Low-grade phosphorites have been treated with 15 to 20% sulphuric acid, or a mixture of this and ammonium sulphate, to give monoammonium phosphate. The residue, which is mainly gypsum, is suspended in water and treated with ammonia and carbon dioxide to recover the phosphorus.[125–6] Addition of ammonium sulphate to the sulphuric acid decreases the amount of base metals extracted from the ore and also increases the filtration rate. The most effective mixture contains 16 to 22% of ammonium sulphate. Amounts greater than this decrease the extraction of $P_2O_5$ as compared with sulphuric acid alone.[127] In a variation of this procedure, 83% of the acid is added within 10 min. and the remainder is then added as ammonium sulphate.[128] If the base metals in the phosphorite are 10% or more, decreased extraction of these occurs when the conversion of $P_2O_5$ is limited to 80%.[129]

*Table I.—Extraction of Phosphorites with Sulphuric Acid*

| Phosphorite composition | | $H_2SO_4$ used | Reaction conditions | | $P_2O_5$ extracted | Composition of $H_3PO_4$ produced | | | |
|---|---|---|---|---|---|---|---|---|---|
| % $P_2O_5$ | % metal oxides | % on CaO | Time hr. | Temp. °C. | % | % $P_2O_5$ | % $SO_3$ | % $Fe_2O_3$ | % $Al_2O_3$ |
| 21–22 | 11–12 | 110 | 6 | 75 | 60–80 | 18·5 | 4·5 | 2·0 | 1·3 |
| 24–25 | 8 | 110 | 6·5 | 75–80 | 85–87 | 22·5 | 4·5 | 1·7 | 1·3 |
| 24–25 | 8 | 105 | 4·5 | 75–80 | — | 19·6 | 5·6 | 3·9 | 1·4 |
| 18–19 | 3–6 | 105 | 3·5 | 65–75 | 92 | 20·5 | 4·8 | 2·4 | 0·9 |
| 18–19 | 3–6 | 105 | 3·5 | 70 | 93 | 22·5 | 5·0 | 2·5 | 1·0 |
| 18–19 | 3–6 | 97–100 | 1·5 | 60 | 96 | 13·5 | 1·4 | 1·1 | 0·5 |
| 24–25 | 8 | 97–103 | 6 | 75–80 | 94–97 | 23·5 | 2·6 | 2·0 | 1·0 |

The effect of heating phosphorites on their rate of solution in 5% sulphuric acid has been determined by means of differential thermograms at temperatures up to 1400°C. The maximum rate of reaction with acid occurs when the phosphorite has been heated to a temperature at which thermal breakdown of the crystalline lattice takes place with molecular rearrangement into new solid phases. Pyritized phosphorites require heating to below 700°C., glauconite ores to about 800°C., and carbonate–apatites to 1200° to 1300°C.[130]

The rate of reaction of phosphorites containing magnesium with sulphuric acid is higher in dilute slurries than in thick pulps. Variations in the amount of $P_2O_5$ extracted when the amount and concentration of sulphuric acid are altered have been attributed to the removal at higher acid concentrations of calcium sulphate which is deposited on the unchanged particles of phosphorite.[131–2] Increase in temperature lowers the rate of decomposition in dilute slurries but increases it in concentrated ones. This has been explained by changes in the degree of supersaturation of complexes in the reaction mixture with reference to the phases present in the $MgO–P_2O_5$ and $MgO–CaO–P_2O_5$ systems.[133] Observations on the further reaction which occurs during drying have been reported.[134]

## Decomposition with Phosphoric Acid

Phosphoric acid was first used in Germany in 1872 to extract phosphate ores for the production of fertilizer materials, particularly triple superphosphate.[135] In the earlier procedures the phosphoric acid was obtained by treating phosphate rock with sulphuric acid on the basis of the simple equation:

$$Ca_3(PO_4)_2 + 3H_2SO_4 = 3CaSO_4 + 2H_3PO_4$$

This gave a dilute (20 to 30% $H_3PO_4$) phosphoric acid which was used to decompose a further quantity of the rock. One of the first developments of the process was to increase the acid concentration by drying the reaction mixture and allowing it to set. This was followed by a curing stage in which the mixture was allowed to stand, usually at room temperature. The effect of this was to improve the extraction and to make the $P_2O_5$ in the product more readily available to plants.[136]

More recently the trend has been towards the use of more concentrated sulphuric and phosphoric acids. In a typical procedure, Florida phosphate rock ($P_2O_5$ 31 to

33%, CaO 46 to 47%, F 3·5% and $Fe_2O_3 + Al_2O_3$ 1·7%) is treated with 93% sulphuric acid and the mixture cooled so as to maintain a temperature of 70° to 75°C. Calcium sulphate is removed by filtration and the phosphoric acid is concentrated by evaporation from 44 to 54% (32 to 39% $P_2O_5$). This acid is then treated at 80° to 100°C. with more phosphate rock of about 200 mesh-size, using an acid/rock weight ratio of 1·8. The water content is controlled to give a slurry which can be handled easily. In order to pass quickly through the plastic stage to the final free-flowing solid product, the reaction mixture is diluted with up to 20 times its weight of dust obtained from the later grinding stage. Successful operation depends largely on obtaining good crystals of gypsum in the sulphuric acid stage. This requires close control of the reaction time and temperature and of the acid concentration and the excess of acid used.[137]

Several processes have been worked out in which phosphorite or phosphate rock is caused to react in a single stage with a mixture of sulphuric and phosphoric acids. These give products varying in composition between that of ordinary and triple superphosphate. For any desired grade of product a suitable proportion of the two acids must be used. This complicates the selection of the best acid/phosphate ratio and raises the problem of the control of the amount of water in the reaction mixture. Graphs and other data enabling the appropriate acid composition to be calculated have been compiled.[138] Empirical equations have been derived which correlate the amount of acid with the phosphorus, calcium, iron, aluminium and fluorine contents of the rock.[139]

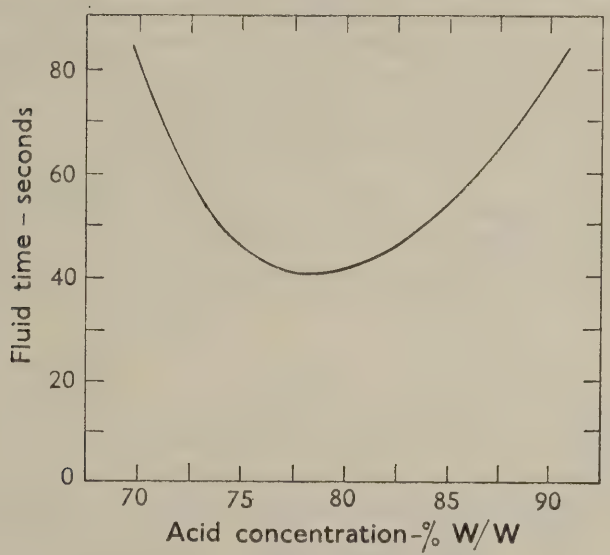

FIG. 4.—Effect of acid concentration on the fluid time in the reaction of phosphoric acid with Tennessee brown rock[143]

The duration of the curing stage is reduced from 4–6 weeks to 2–3 days by drying the reaction mixture at high temperatures.[119, 120, 140] If the acid reaction is carried out in an autoclave at 100° to 105°C. and the product then dried at 110° to 150°C., the curing time is as little as 10 hr.[141] The curing process is influenced by the acid concentration and the proportion of acid used.[142] These two variables are important in relation to several other factors involved in the phosphoric acid–phosphate rock reaction and many papers on the subject are to be found in the literature. Some of the more important data obtained in these studies are discussed below.

In the first stage of the reaction, immediately after mixing the rock with acid, the mixture is quite fluid. It then passes through a sticky, plastic stage, finally setting to a hard mass. The fluid time, as measured by determining the time for the reaction mixture to cease to flow in an inclined trough, is related to the phosphoric acid concentration as shown in Fig. 4. The data refer to Tennessee brown rock containing

33·4% $P_2O_5$, a reaction mixture having a $P_2O_5$/CaO molar ratio of 0·976, and the reactants initially at a temperature of 20°C. Somewhat different results are obtained with other types of rock and with different $P_2O_5$ contents, molar ratios and initial temperatures.[143, 142] The duration of the plastic stage is about 10% longer than the fluid time, and the time taken for the final solid to disintegrate to a powder is roughly equal to the plastic stage.[142, 144] If some of the phosphoric acid is replaced by an equivalent amount of sulphuric acid, the fluid time is shortened and the duration of the plastic stage increases.[144]

### EFFECTS OF CONCENTRATION OF PHOSPHORIC ACID

The most important effect of acid concentration is on the percentage conversion of the $P_2O_5$ in the rock to available $P_2O_5$. In the reaction of Tennessee brown rock (34·8% $P_2O_5$, 49·0% CaO) with phosphoric acid of concentrations between 60% and 80%, the percentage conversion varies as shown in Fig. 5. The theoretical requirement of acid is based on the $P_2O_5$ and CaO contents of the rock only and no allowance is made for the presence of iron, aluminium or other metals. The maxima in these curves are attributed to there being insufficient water in the system to enable complete conversion to occur during the 28 days' storage allowed in the experiments.[145, 142]

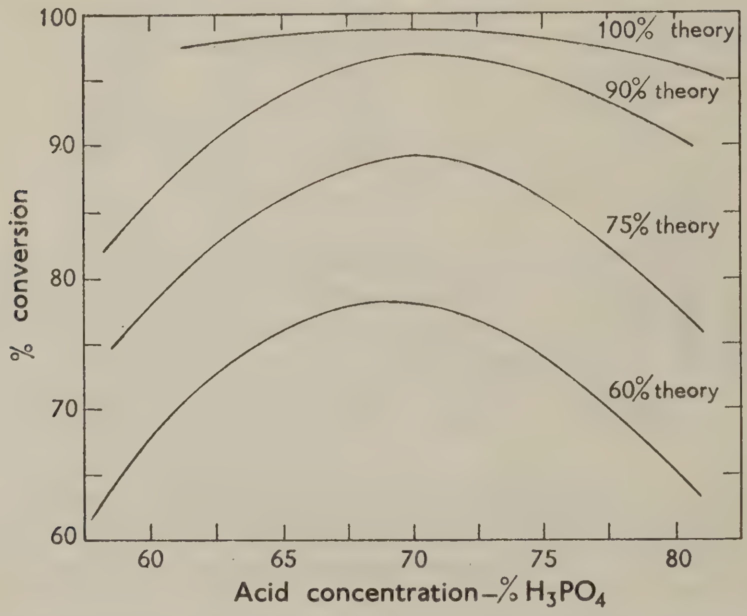

FIG. 5.—Effect of acid concentration on the reaction of Tennessee brown rock with phosphoric acid[145]

The behaviour of bone meal, bone ash, and Florida, Tennessee and Western States phosphate rock with phosphoric acid of various concentrations has been examined. So far as they can be compared, the results are substantially in agreement with those given above.[142–5] Florida rock is generally more reactive than other types of ore.[146]

The use of phosphoric acid of greater than 70% concentration has some practical advantages. The reaction with the rock becomes very rapid and sufficient heat is developed to dry the product during the curing period.[142, 144] If the reaction is carried out according to the equation:

$$3Ca_3(PO_4)_2,CaF_2 + 14H_3PO_4 + 10H_2O = 10Ca(H_2PO_4)_2,H_2O + 2HF$$

drying is not necessary because there is no excess of water in the system. This reaction corresponds to the use of 88% phosphoric acid.[144] Under these conditions a continuous mixing process is possible.[143, 142] On the other hand when acid of these high concentrations is used the influence of other factors such as temperature, particle size of rock and conditions of mixing becomes more marked. With acid containing less than 70% $H_3PO_4$ the temperature has only a minor effect on the percentage conversion of $P_2O_5$. At higher concentrations, however, low mixing and curing temperatures favour the conversion. Typical figures are increases in the percentage conversion from 62 to 74%, 76 to 92% and 83 to 96% when using 78% $H_3PO_4$ and the reactant temperature is decreased from 94° to 27°C. These improvements seem to be due to better mixing because of an increase in the duration of the fluid stage at the lower temperature. The lower temperature employed also decreases the amount of iron and aluminium extracted.[147] It is known that in the more concentrated acid systems aluminium, either alone or in the presence of iron, decreases the availability of the phosphorus in the product.[148–9] Iron alone, however, improves the citrate-solubility of the $P_2O_5$ because of the formation of complex calcium iron phosphates.[150, 151]

Phosphoric acid containing 76% $P_2O_5$ reacts rapidly with phosphate rock at about 100°C. and within 40 min. of mixing the temperature rises to 150° to 180°C. This volatilizes 60% of the fluorine in the rock as compared with 15% in conventional procedures. The product contains less than 1% of free water and the $P_2O_5$ is largely present as anhydrous monocalcium phosphate. The $P_2O_5$ content of the acid is equivalent to 105% $H_3PO_4$, but the actual composition is approximately 49% orthophosphoric acid, 42% pyrophosphoric acid and 9% of higher polyphosphoric acids. The percentage conversion of Florida rock (32% $P_2O_5$) with this acid is only 65% but this increases to 86% for 103% $H_3PO_4$, 92% for 102% $H_3PO_4$ and remains constant at 90% with 98 to 101% $H_3PO_4$.[152]

By dissolving phosphate rock with an excess of phosphoric acid in this way, a defluorinated solution can be obtained, from which solid monocalcium phosphate can be crystallized. The salt can be converted to phosphoric acid of good quality by treatment with ion exchange resin.[303]

### RATE OF THE REACTION

The rate of reaction of phosphoric acid with apatite and phosphorites under various conditions has been measured. At 40° to 100°C. apatite dissolves slowly in saturated solutions of dicalcium phosphate and the rate slows down to zero as the reaction products are deposited on the unreacted apatite. A similar phenomenon occurs in monocalcium phosphate solutions, but a thicker layer of deposit is required to inhibit the reaction. At 40°C. the rate of solution increases with the $P_2O_5$ content of the system, but the reverse occurs at 75°C.[153] The rate of solution is a function of the viscosity of the solution and the hydrogen ion activity.[154] The rate of decomposition of apatite by phosphoric acid is reported to be proportional to the hydrogen ion concentration and the surface area of the mineral and also to be a logarithmic function of the reciprocal of the absolute temperature.[155] Graphs and other data relating the decomposition rate with acid concentration have been given.[156]

Data for the rate of dissolution of apatite in aqueous mixtures of phosphoric acid (35–40%) and sulphuric acid (0–4%) suggest that slow dissolution results from nucleation of $CaSO_4,\frac{1}{2}H_2O$ on the surface of the rock particles. This was related to the degree of supersaturation, defined as the ratio of apparent to equilibrium solubility product constants. With a ratio close to 1, no nucleation of hemihydrate occurs; as the ratio approaches 2·5 hemihydrate precipitates but the apatite is completely dissolved. For ratios higher than 2·5 the coating of hemihydrate retards dissolution of the rock.[304]

In another investigation the rate of decomposition ($k$) of apatite by phosphoric acid was found to increase with the acid concentration and the temperature only during the first few minutes of the reaction. As the initial acid concentration increased, $k$ passed through a maximum, and by using sufficiently concentrated acid the reaction could be inhibited completely. It appears that a dense film of reaction products is formed on the surface of the undecomposed apatite and that in the later stages the reaction rate is controlled by the rate of diffusion of phosphoric acid through this film.[157] The rate of decomposition of apatite at 20° to 60°C. has been found to decrease from 66% conversion during the first hour to a 4% conversion in the second.[158] The optimum phosphoric acid concentration is 54 to 55% $P_2O_5$.[159, 158]

Similar phenomena have been observed in the reaction of magnesium-containing phosphorites ($P_2O_5$ 27%, CaO 43%, MgO 3% and $CO_2$ 8%) with phosphoric acid. A maximum decomposition rate at 20°C. occurs with acid containing 54% $P_2O_5$, and the initial high reaction rate falls off as the reaction products are deposited on the unreacted ore.[160] Phosphorites containing large proportions of carbonate give a porous, powdery material when they react at 50° to 55°C. with phosphoric acid. This differs from the dense, plastic mass obtained with apatite and is due to evolution of carbon dioxide during the acid treatment.[161] With glauconitic phosphorites the initial decomposition rate is proportional to the hydrogen ion concentration, but decreases as the reaction proceeds, owing to deposition of silica on the unchanged ore.[162] Other types of phosphorite are rapidly decomposed by 20% phosphoric acid at 20°C. and the rate does not seem to be affected by the geological characteristics of the phosphorite.[163]

### PERCENTAGE CONVERSION

For any given acid concentration the percentage conversion of $P_2O_5$ in phosphate rock is generally increased by using a greater proportion of acid. The effect is shown in Fig. 6 for three concentrations of acid, using a rock containing $P_2O_5$ 28%, CaO 39%, $SiO_2$ 13%, $Al_2O_3$ 6%, $Fe_2O_3$ 2%, F 3·2% and $CO_2$ 1·2%.

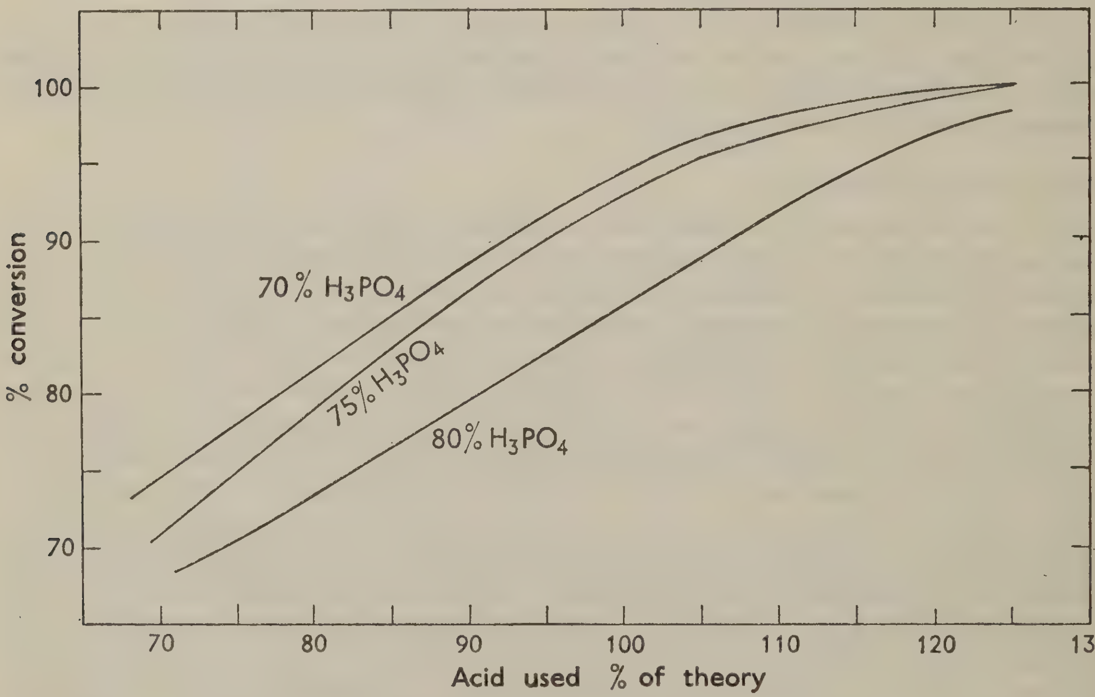

FIG. 6.—Effect of proportion of acid on the reaction of Tennessee brown rock with phosphoric acid[145]

The theoretical quantity of acid is calculated only on the $P_2O_5$ and CaO content of the rock and takes no account of the iron and aluminium present.[145] Similar results have been reported for Tennessee rock containing 35% $P_2O_5$ when reacted with 47% phosphoric acid.[146] The effect with Florida rock (32% $P_2O_5$, 46% CaO) and 102% phosphoric acid (74% $P_2O_5$) is shown in Fig. 7. The reactants were mixed at 65°C. and the $P_2O_5$/CaO ratio refers to the total $P_2O_5$ (i.e. that in the rock and in the added acid) to CaO in the reaction mixture.[152]

The ratio of acid to rock in the reaction mixture has a relatively minor influence on the fluid and setting times. Excess of acid increases these times and also improves the conversion slightly.[142–5]

Decrease in the particle size of the rock has a marked effect on the fluid time as shown in Fig. 8.[143]

There are somewhat conflicting reports on the influence of temperature on the reaction of phosphoric acid with phosphate rock, particularly as regards the percentage conversion to available $P_2O_5$. The initial temperature of the reactants affects the fluid time as shown in Fig. 9.

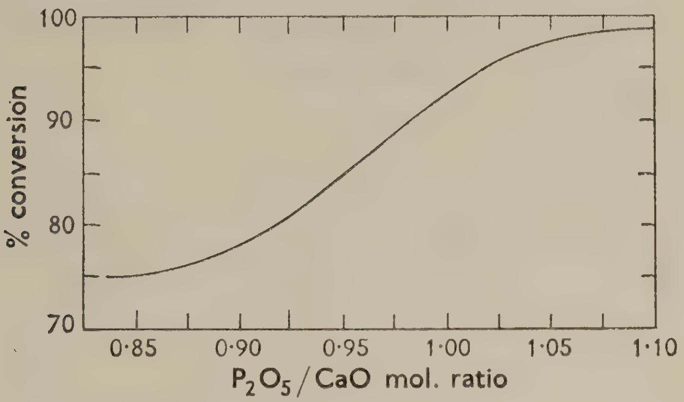

FIG. 7.—Effect of acid ratio on the reaction of Florida rock with 102% phosphoric acid

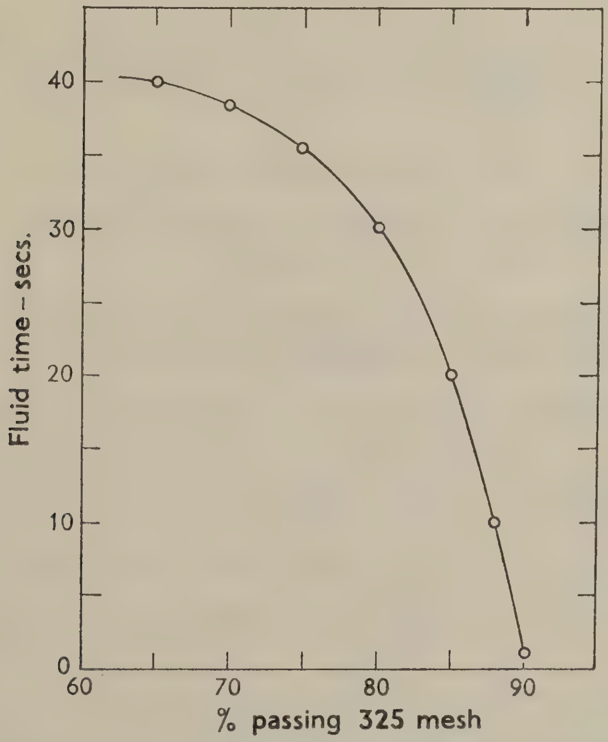

FIG. 8.—Effect of particle size on the fluid time in the reaction of Tennessee brown rock with 78% phosphoric acid[143]

Increasing the initial temperature of the reaction from 20° to 60°C. is said to improve the conversion by 2 to 12% when phosphoric acid of 21 to 64% concentration is used.[146] With 74 to 78% acid no effect on the conversion was found at 20° to 77°C.[144] Reaction of Florida rock with 102% phosphoric acid gave a conversion of 83% at 50°C., increasing to 90% at 90°C. and remaining constant at 90% for temperatures up to 150°C.[152]

It has also been reported[147] that the initial reaction temperature has little effect on the percentage conversion when the phosphoric acid concentration is 70% or less. At higher acid concentrations low reactant temperatures and low curing temperatures appear to favour the conversion. Some data illustrating this are shown in Fig. 10.

The contradictory nature of these results may be due to other factors having an influence on the experimental data. For example, calcium fluoride in the product can cause reversion of the phosphate to an unavailable form and this reaction is favoured by high curing temperatures. Evolution of fluorine and the extent of reaction of iron and aluminium in the rock are influenced by experimental conditions and these affect the citrate-solubility of the product.[145]

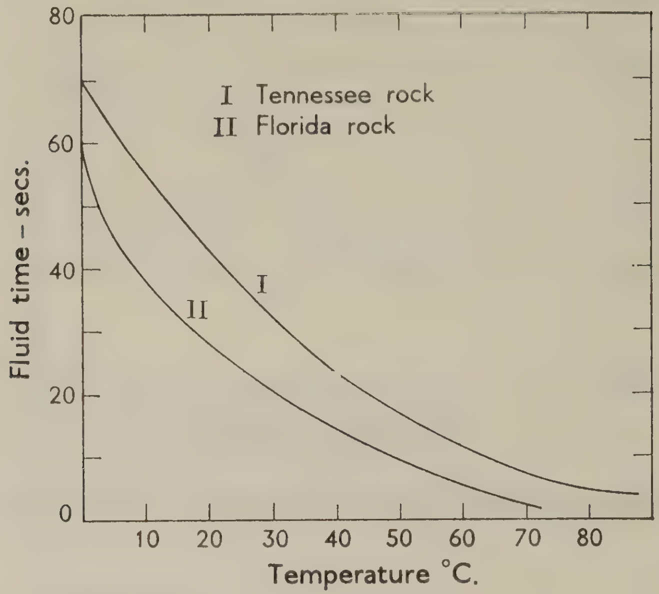

FIG. 9.—Effect of initial temperature on the fluid time in the reaction of Tennessee and Florida rock with phosphoric acid[143]

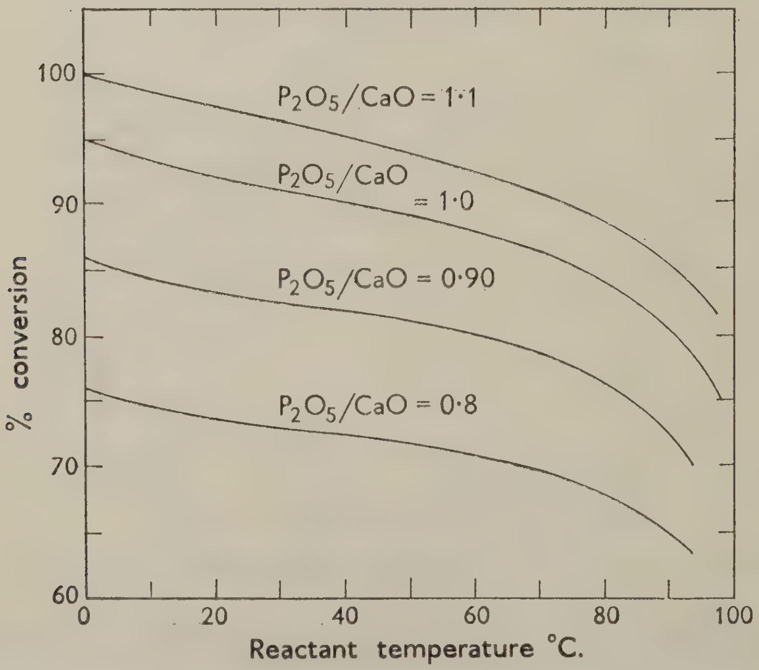

FIG. 10.—Effect of initial reactant temperature on the reaction of Tennessee brown rock with 78% phosphoric acid at various acidulation ratios[147]

A high $P_2O_5$ content in the phosphate rock favours the conversion to citrate-soluble phosphorus. The effect is shown in Fig. 11 for 70% phosphoric acid at five different acidulation ratios. The theoretical quantity of acid is based on the $P_2O_5$ and CaO in the rock, with no allowance for iron and aluminium. For the rock used an excess of about 20% of acid was sufficient to react with all the iron and aluminium present. This accounts for the difference between the results shown in Fig. 11 and Fig. 6 for the amounts of acid required for complete conversion of the rock. The higher grade ore contains less iron and aluminium, so that a smaller amount of acid is required for complete reaction.[145] For more precise details of the experimental conditions, type of rock used and other factors affecting the reaction, the original papers referred to above should be consulted.

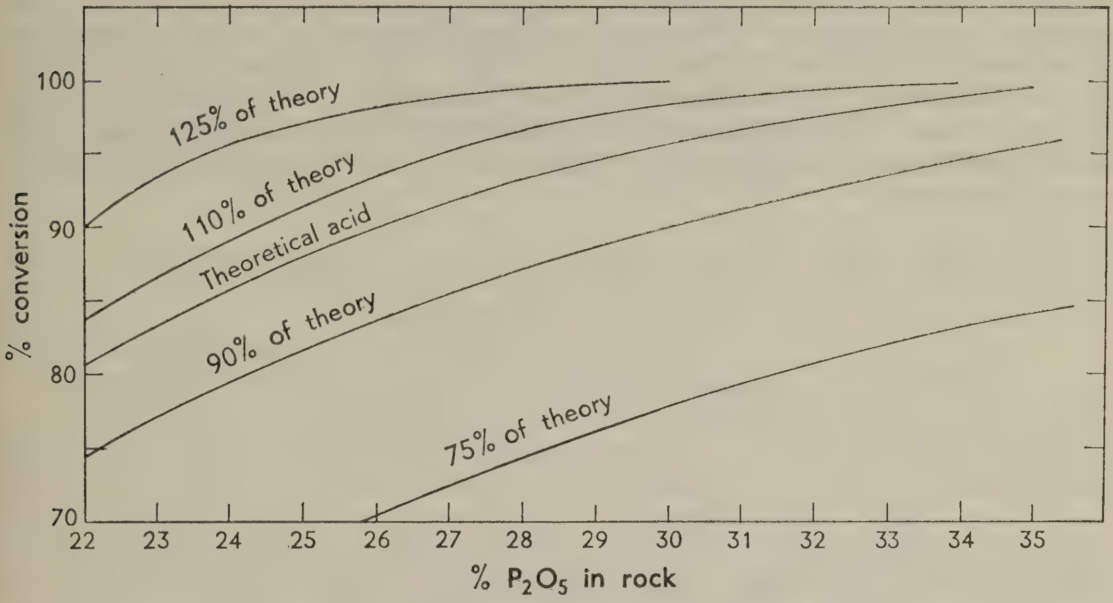

FIG. 11.—Influence of the $P_2O_5$ content of Tennessee brown rock on its reaction with 70% phosphoric acid[145]

In a common procedure for extracting phosphate rock and phosphorites, the ore is caused to react with sulphuric or phosphoric acid according to the equations:

$$3Ca_3(PO_4)_2,CaF_2 + 6H_2SO_4 = 3Ca(H_2PO_4)_2 + 6CaSO_4 + CaF_2$$
$$3Ca_3(PO_4)_2,CaF_2 + 12H_3PO_4 = 9Ca(H_2PO_4)_2 + CaF_2$$

If the extraction is carried out under conditions such that only dicalcium phosphate is formed, the amount of acid required per unit weight of ore is considerably reduced. The equations for these reactions are:

$$3Ca_3(PO_4)_2,CaF_2 + 3H_2SO_4 = 6CaHPO_4 + 3CaSO_4 + CaF_2$$
$$3Ca_3(PO_4)_2,CaF_2 + 3H_3PO_4 = 9CaHPO_4 + CaF_2$$

Earlier attempts[164] to carry out these reactions were unsuccessful because deposition of dicalcium phosphate on the unreacted rock inhibited the reaction. More recently, however, it has been found that under suitable conditions monocalcium phosphate reacts with water according to the equation[166]:

$$Ca(H_2PO_4)_2,H_2O + xH_2O = CaHPO_4 + H_3PO_4 + (x+1)H_2O$$

This reaction is dependent on the amount of water in the system and at 100°C., for example, 80% conversion to dicalcium phosphate occurs when there are 28 g. of water present per 100 g. of monocalcium phosphate monohydrate.

Formation of dicalcium phosphate occurs when sulphuric or phosphoric acid is added to phosphate rock in amounts sufficient to convert only part of it into monocalcium phosphate, and the reaction mixture is heated for a short time at 110°C. under reflux, and then at 185°C. without refluxing. The percentage conversion on heating phosphate rock with 1·77 times its weight of monocalcium phosphate monohydrate for 15 min. at 110°C., followed by 30 min. at a higher temperature, is shown in Fig. 12.

Heating for longer than 30 min. at 185°C. has no effect on the conversion, but under these conditions the ratio of monocalcium phosphate monohydrate to phosphate rock has a marked influence. The conversion decreases from 98% when the weight ratio is 1·77 to 60–70% when it is 0·6.[167]

In the extraction of phosphorites with phosphoric acid, all the phosphorus and a minimum amount of silica, iron and aluminium are removed if the ore is first heated for 2 hr. at 1050°C. and then reacts with the acid for 1 hr. at 80°C. Addition of sulphuric acid to the mixture decreases the amount of iron and silica extracted but increases the aluminium.[168] Magnesium in the phosphorite is also extracted by phosphoric acid, but the $MgO–P_2O_5–H_2SiF_6–H_2O$ phase diagram at 25°C. shows that the magnesium can be removed as the silicofluoride.[169] A practical application of this reaction has been described, in which $MgSiF_6,6H_2O$ is precipitated. It is removed and heated with phosphoric acid at 300° to 350°C. to recover $SiF_4$ and HF which are re-used.[170]

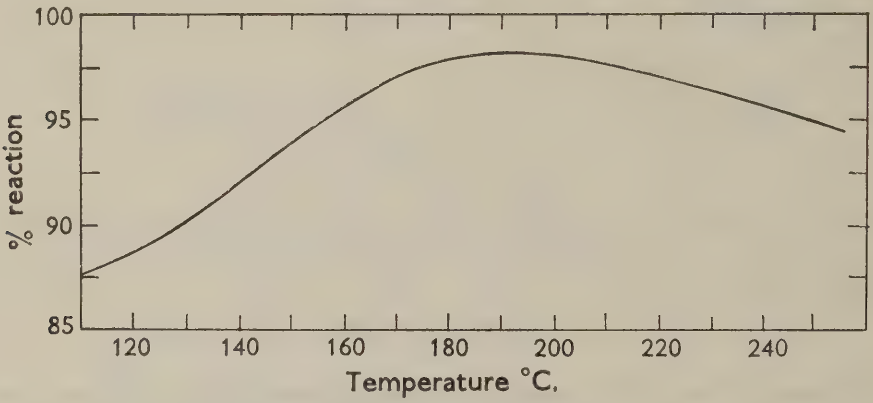

FIG. 12.—The effect of temperature on the reaction of monocalcium phosphate with Florida phosphate rock[167]

A study has been made of schemes for the preparation of concentrated phosphoric acid by decomposition of apatite with a mixture of hydrofluoric and hexafluorosilicic acid:

$$Ca_5F(PO_4)_3 + 9HF(+H_2O) \rightarrow 5CaF_2 + 3H_3PO_4(+H_2O)$$
$$Ca_5F(PO_4)_3 + 5H_2SiF_6(+3H_2O) \rightarrow 5CaSiF_6,2H_2O + 3H_3PO_4 + HF(+H_2O)$$

Phosphoric acid obtained by attacking apatite with technical HF (33% HF, 5% $H_2SiF_6$) for 30 min. at 100°, contained 45–48% $H_3PO_4$, 0·3–0·6% CaO and 5–8% F.[305]

A summary up to the year 1933 has been made of the various methods of decomposing phosphate ores with mineral acids and of processes for converting these into materials of commercial value.[171, 165]

### Decomposition with Alkalis

Several methods of extracting phosphate ores under alkaline conditions have been proposed, but these are generally much less efficient as commercial processes than the acid procedures described above.

In one method phosphate rock ground to pass 70-mesh is mixed with 50% aqueous sodium hydroxide in proportions to give a molar $NaOH/P_2O_5$ ratio of 5 and is then heated under pressure for 1 hr. at 200°C.[172] Similar results are obtained when part of the sodium hydroxide is replaced by sodium silicate in the proportion of 0·2 to 0·5 mols. $SiO_2$ per mol. of CaO in the rock.[173–4]

Other processes involving the use of alkalis at higher temperatures are described below (see page 93).

## Decomposition by Chlorination

Low-grade phosphorites can be decomposed by heating a mixture of three parts of ore and one part of wood charcoal for 2 hr. at 700° to 800°C. in a rapid stream of chlorine, the gaseous products being absorbed in water. About 97% of the phosphorus is recovered, together with about half of the iron and aluminium in the phosphorite.[175] Absorption of the gases in ammonia solution increases the yield.[176] Addition of 5% of nickel chloride or copper sulphate to the reactant mixture decreases the reaction time from 10 to 3 hr. and lowers the temperature from 800°C. to 650–700°C.[177] The presence of a small percentage of water in the mixture increases the reaction.[178]

Chlorination more than doubles the fertilizing action of ground phosphorite, making it at least as effective as superphosphate in this respect. The improvement over untreated, ground phosphorite is attributed to the decomposition by the chlorine of the calcium carbonate present in the ore.[179] As a result the pH of aqueous extracts of treated material is 3 to 3·5 whereas extracts of the original phosphorite have pH 6·5 to 7·0. This increase in acidity favours the assimilation of $P_2O_5$ by plants.[180] Treatment of phosphorites with chlorine or hydrogen chloride at high temperature removes all of the carbon dioxide, some of the fluorine and most of the base metal oxides. Chlorinated phosphorites are generally more effective as fertilizers than those treated with hydrogen chloride,[181] perhaps because their $P_2O_5$ content is higher as well as being more available to plants.[306]

Phosphorus pentachloride has been obtained by complete chlorination of low-grade phosphorite in the temperature range 600° to 1200°C. in the presence of carbon. The extent of the reaction depends on the temperature, the rate of flow of chlorine, the amount of carbon used and the moisture content of the system. Under the best conditions 85% of the phosphorus in the ore is extracted.[182] In the presence of salt and carbon, phosphorites are chlorinated to phosphorus oxychloride and phosphorus trichloride in the temperature range 600° to 800°C.[183] Phosphorus oxychloride only is said to result from the chlorination at 600° to 650°C. of a mixture of phosphate rock and carbon with 0·5 to 1·0 parts of sodium chloride.[184] The yield from this reaction is very variable and is influenced by the composition of the phosphate rock. For example, 80 to 90% of the phosphorus is extracted when chlorine at 650° to 670°C. is passed over briquets made from tar, charcoal and fluorapatite, but only 65% can be recovered as phosphorus oxychloride. The low yield may be due to hydrolysis of the phosphorus oxychloride by moisture in the system, according to the equation:

$$POCl_3 + 3H_2O = H_3PO_4 + 3HCl$$

Phosphorus oxyfluoride may be formed, and Van Wazer,[83] considers that under the above conditions the reaction approximates to the equation:

$$3[3Ca_3(PO_4)_2,CaF_2] + 27C + 54Cl_2 = 16POCl_3 + 2POF_3 + 30CaCl_2 + 27CO_2$$

The chlorine efficiency of this process is low because of wastage through its conversion into calcium chloride and chlorides of the base metals present in the phosphate rock, e.g. iron and aluminium.[185]

In a variation of the above procedure, a mixture of equal parts of finely-ground phosphate rock and ground coal is heated at 500°C. in sufficient chlorine for complete conversion of the rock to calcium metaphosphate. The product is then heated for a further period at 600° to 750°C., in a lower concentration of chlorine, to yield phosphorus oxychloride as the final product.[186]

A more complicated and less practical procedure has been described. This involves the formation of phosphoric acid from phosphate rock and sulphuric acid followed by reduction and chlorination.[187]

Chlorine has been used in conjunction with sulphur dioxide by passing the gas into a suspension of phosphorite in a solution containing 7 to 8% $SO_2$. An 85% decomposition of the phosphorite is obtained at ordinary temperature and pressure.[188]

This is essentially a reaction of the phosphorite with sulphuric and hydrochloric acids formed according to the equation:

$$SO_2+Cl_2+2H_2O = H_2SO_4+2HCl$$

The same two gases may be passed into a slurry of phosphate rock in a solution of sodium sulphate to give phosphoric acid, sodium chloride and calcium sulphate.[189] A suspension of ground phosphate rock in 46% phosphoric acid has also been subjected to the action of chlorine and sulphur dioxide for 3½ hr. at 95°C.[190]

Sulphur monochloride reacts exothermically with phosphorites at room temperature. On average, 75% of the sulphur in the monochloride is reduced to elemental sulphur and the remainder is oxidized to sulphuric acid. After reaction for 24 hr. over 95% of the phosphorus is recovered. The mechanism proposed for the reaction is:

$$\begin{aligned} 2Ca_3(PO_4)_2+6S_2Cl_2 &= 6CaCl_2+2P_2O_5+3SO_2+9S \\ SO_2+Cl_2+2H_2O &= H_2SO_4+2HCl \end{aligned}$$

In the presence of excess of sulphur monochloride the phosphorus pentoxide formed is converted into phosphorus oxychloride.[191]

Phosphorites react with a mixture of chlorine and carbon monoxide in the presence of carbon as a catalyst. The reaction starts at 180°C. and is rapid at 350°C.; the overall equation is:

$$Ca_3(PO_4)_2+6CO+6Cl_2 = 2POCl_3+6CO_2+3CaCl_2$$

The evidence is, however, that two stages are involved; calcium metaphosphate is formed at the lower temperatures:

$$Ca_3(PO_4)_2+2CO+2Cl_2 = Ca(PO_3)_2+2CO_2+2CaCl_2$$

further reaction at higher temperatures then converts this into phosphorus oxychloride[192]:

$$Ca(PO_3)_2+4CO+4Cl_2 = 2POCl_3+4CO_2+CaCl_2$$

Similar reactions occur at 350° to 500°C. when minerals such as vivianite and pyromorphite are heated in a stream of phosgene. This reaction may be written as[193–4]:

$$3MO,P_2O_5+6COCl_2 = 2POCl_3+6CO_2+3MCl_2$$

At 800°C. uranium can be separated as uranium tetrachloride from uranite by the reaction[194]:

$$CaO,2UO_2,P_2O_5+8COCl_2 = 2POCl_3+2UCl_4+8CO_2+CaCl_2$$

The treatment of phosphorites with chlorine, hydrogen chloride, sulphur chlorides and carbon tetrachloride has been discussed.[195]

### Decomposition by Thermochemical Methods

Many investigations have been made into thermal methods of improving apatites and phosphorites. These processes are usually carried out at temperatures above 1000°C. and give rise to so-called thermophosphates. The latter are generally used as fertilizers and the aim of the thermal treatment is to render the phosphate available to plants and to increase the agricultural value of the product by incorporating in it elements which enhance the fertilizing action. This applies particularly to phosphorus ores which are of too low a grade to be worth converting to phosphoric acid or extracting by the methods described above. Some ores, even though they have a reasonably high content of phosphorus, also contain quantities of silica, base metals and other impurities which are difficult to remove chemically from the final product. In some instances it is possible to combine thermal and other processes to give phosphates and other products of commercial value.

Direct application to the soil of ground phosphate minerals is not always very successful as regards crop response. The action as a fertilizer depends largely on the mineralogical composition of the ore. In general, phosphates with a fluorapatite structure are more difficult for plants to assimilate than phosphorites or minerals of mixed composition such as kurskite, $2Ca_3(PO_4)_2,CaCO_3,CaF_2$.[196] Fine grinding may increase the amount of phosphate assimilated,[197] but the degree of fineness is chiefly determined by the petrographic composition of the ore.[197] The solubility of the phosphate in water is usually of importance in determining crop response, which is much less marked in calcareous soils[198] and those having a low moisture content. This effect is often measured by determining the solubility of the phosphate in solutions of citric acid or ammonium citrate. The latter gives low results, indicating poor availability of phosphorus to the soil, and for this reason a 2% solution of citric acid is more often used as a standard test. Even though fluorapatite is almost insoluble in 2% citric acid, the test is not always satisfactory. In some instances plant growth tests show that less phosphate is available than is indicated by the citric acid solubility of the phosphate. The concentration of the citric acid, time of contact of phosphate with it and the proportion of solid to liquid have been shown to be relevant factors in the results given by the test.[199]

Heat treatment of phosphate rock at temperatures below 1000°C. is usually carried out to improve the grade of the mineral and its ease of grinding, and to remove organic matter and carbonate which adversely affect its behaviour on acidulation. The response to calcination depends on the variety of rock treated. Thus Moroccan phosphate showed a sharp collapse of the internal structure of its particles between 500° and 700°C. which was less evident in Utah phosphate. Solubility of phosphorus decreased in the Moroccan rock, but reached a maximum at 850° in the Utah rock. The reactivity of both rocks was somewhat decreased by calcination.[307] A Florida rock phosphate after heating at 1000° showed a similar decrease in acid solubility, accompanied by an increase in apatite crystal size, and a disappearance of crystalline quartz.[308]

Phosphorites are quite reactive towards a number of substances at temperatures above 1000°C., the reactivity being increased in the molten state. Fusion processes usually convert the phosphate into a metastable state. If the structure of the high-temperature form can be preserved at ordinary temperatures the product generally becomes more reactive than it was before melting. To achieve this, quenching or rapid cooling is necessary and the rate of cooling depends on the nature of the product being made. Quenching of the product may be more important than its actual chemical composition. The latter may be varied over a wide range with only gradual changes occurring in the physical and chemical properties of the thermophosphate. The three most important methods of heating phosphates are sintering in a rotary kiln, melting in a cyclone furnace and sintering in a fluidized bed.[309–10]

It has been shown that if apatite or phosphorite is fused with quartz sand and magnesium oxide or serpentine and the product is cooled slowly, less than 4% is soluble in 2% citric acid. The material is essentially crystalline with a structure similar to that of fluorapatite. Rapid cooling produces a material which is a glass and is completely soluble in citric acid.[200]

Thermal methods of decomposing phosphorites may be divided into acid and basic processes. In the acid process phosphorite is mixed with up to 37% of its weight of silica in the form of sand and is then heated to over 1400°C. and cooled rapidly. Over 98% of the $P_2O_5$ is soluble in citric acid. In the basic processes alkaline materials are mixed with the phosphorite. This method is generally more efficient than the acid procedure and the reaction temperature is lower. With potassium minerals such as feldspar and phonolith the reaction occurs at 1100° to 1200°C. and can be represented by the equation:

$$Ca_3(PO_4)_2 + K_2O = K_2Ca_2(PO_4)_2 + CaO$$

The amount of alkali used should be approximately one mol. of $K_2O$ for one mol. of $P_2O_5$ in the phosphorite.[201] Mixtures of phosphorite and calcium carbonate with sodium carbonate or sodium sulphate may also be sintered at 1200°C. in a current of steam.[202] Processes in which coal is added and the alkali is replaced by magnesium oxide have been used.[203] Substitution of sodium chloride for sodium carbonate is successful only if coal is also added. With some types of phosphorite sodium carbonate is reactive at temperatures as low as 700° to 800°C.[204]

Sintering of phosphate ores rather than fusion has been developed as a commercial process to give the so-called Rhenania phosphates. In this process the ore is mixed with sodium carbonate to give a molar $Na_2CO_3:P_2O_5$ ratio of unity and sufficient silica is added to form calcium silicate with the calcium oxide in the phosphate. The materials are finely ground, 10% of water is added and the mixture is heated for about 2 hr. in a rotary kiln at 1000° to 1200°C. Very little fluorine is volatilized in the process.[205]

The reaction of sodium carbonate with phosphorites has been studied for three different phosphorus contents, the extent of decomposition being measured by the amount of the product which was soluble in citric acid. The results are summarized in Table II.

*Table II.—The Reaction of Phosphorites with Sodium Carbonate at* 900° *to* 1300°*C.*[206]

| Temp. °C. | % $P_2O_5$ in ore | Parts $Na_2CO_3$ per 100 ore | % decomposition |
|---|---|---|---|
| 900–1200 | 40 | 30 | 70 |
| | 40 | 37·5 | ~85 |
| | 40 | 45 | ~85 |
| 1100 | 40 | 45 | 61 |
| 1200 | 40 | 45 | 93 |
| 1300 | 40 | 45 | 93 |
| 900 | 27 | 25 | 82 |
| 1100 | 27 | 20 | 75 |
| 1100 | 27 | 25 | 100 |
| 1100 | 19·5 | 22 | 100 |

The maximum solubility in citric acid is achieved by fusing the ore for 30 min. at 1100° to 1200°C. with a weight of sodium carbonate equal to 110% of the $P_2O_5$ in the ore.[206]

Sintering at 800° to 1300°C. of a mixture of apatite with 1 to 6 mol. of sodium carbonate per mol. of $P_2O_5$ has been proposed. The product is extracted at 80°C. with a solution saturated with sodium carbonate at 65° to 70°C. and containing a small proportion of sodium hydroxide.[207] According to Van Wazer,[83] the leaching stage is critical in this process. If the solution contains more than 4% $P_2O_5$ then the forward reaction:

$$(CaO)_{3-x}(Na_2O)_xP_2O_5 + (3-x)Na_2CO_3 \rightarrow 3CaCO_3 + 2Na_3PO_4$$

is opposed by the reverse one between calcium carbonate and trisodium phosphate:

$$3CaCO_3 + 2Na_3PO_4 = Ca_3(PO_4)_2 + 3Na_2CO_3$$

A similar process using sodium hydroxide alone and operating at 400°C. has been described.[208]

Sulphates have been used in the thermal decomposition of phosphate ores. Apatite, mixed with silica, carbon and sodium sulphate is fused at 1250°C. in an atmosphere of carbon dioxide or nitrogen. A product containing $Ca_2SiO_4$, $Na_2SiO_3$ and $CaNaPO_4$ is obtained.[209] In another procedure a mixture of phosphate rock and ammonium sulphate is heated at 450° to 515°C. and the product is leached with water. The calcium sulphate residue is treated with carbon dioxide, ammonia and water to recover ammonium sulphate which is re-used.[210]

If apatite is sintered at 1100° to 1200°C. with potassium sulphate and charcoal the product has all its phosphorus in an available form. In the presence of air the reaction may be represented by the equation:

$$3Ca_3(PO_4)_2,CaF_2 + 4K_2SO_4 + 8C + 6O_2 = 6CaKPO_4 + 2KF + 4CaO + 8CO_2 + 4SO_2$$

Less sulphate is required, and the $P_2O_5$ content of the product is increased, if water vapour is passed over the mixture. Under these conditions the reaction is:

$$3Ca_3(PO_4)_2,CaF_2 + 3K_2SO_4 + 6C + 4H_2O = 6CaKPO_4 + 2HF + 4CaO + 3H_2S + 6CO_2$$

The most favourable conditions, which give a 96% decomposition of the phosphorite, are sintering for 30 min. at 1100°C. in the presence of water vapour, using a mixture of four parts of phosphorite, two of potassium sulphate and one of charcoal.[211]

In a similar procedure[212] a mixture of equal parts of phosphorite and astrakhanite ($Na_2SO_4,MgSO_4,4H_2O$) and 40% of coal is heated at 1250°C., or is melted at 1400°C. in a reducing atmosphere and is then quenched.[213]

Potassium sulphate alone does not react with apatite under these conditions. Since carbon is necessary for the reaction it is assumed that the intermediate formation of potassium sulphide is involved.[214] A similar mechanism is postulated for the reaction with sodium sulphate and carbon at 800°C. according to the equation[215]:

$$Ca_3(PO_4)_2 + 2Na_2SO_4 + 8C = CaNaPO_4 + Na_3PO_4 + 2CaS + 8CO$$

Magnesium sulphate on the other hand reacts only in the absence of carbon according to the equation[214]:

$$3Ca_3(PO_4)_2,CaF_2 + 9MgSO_4 + H_2O = 3Mg_3(PO_4)_2 + CaO + 9CaSO_4 + 2HF$$

When carbon is present in this reaction an unstable magnesium sulphide is formed and this rapidly decomposes into the oxide, sulphur dioxide and hydrogen sulphide.

The reactions between Florida phosphate rock and magnesium and potassium sulphates and the minerals langbeinite ($K_2SO_4,2MgSO_4$) and polyhalite ($K_2SO_4, MgSO_4,2CaSO_4,2H_2O$) have been examined in some detail. Mixtures of these were melted at 1150°C. and were then quenched, the extent of the reaction being determined by citric acid solubility of the product. The results, shown in Fig. 13, indicate that potassium sulphate is much less reactive than the magnesium salt, while polyhalite occupies an intermediate position.[216]

The reaction between phosphate rock, magnesium oxide and silica has also been studied carefully. Quenching of melts prepared at 1450° to 1550°C. gives products containing up to 99% of citrate-soluble phosphorus. The mineral olivine ($SiO_2$ 44%, MgO 45%, $Fe_2O_3$ 8%) may be substituted for the magnesium oxide–silica mixture.[217]

At 1500°C. apatite and the mineral serpentine ($Mg_3H_4Si_2O_9$) react to form magnesium pyrophosphate, with complete elimination of fluorine from the rock.[218]

Other magnesium minerals, such as dolomite and magnesite, have been considered as reagents for producing thermophosphates from phosphorites.[219] The fertilizing value of magnesium thermophosphates has been shown to be comparable with that of superphosphate, particularly on acid soils.[220] On the other hand there is evidence that this is related to the fluorine content of the product and the conditions of treatment of the phosphate. The reaction between apatite and magnesium oxide in the absence of silica at high temperature does not remove the fluorine. In the presence of both, the magnesium oxide gives readily fusible compounds, and the silica assists diffusion in the melt and aids the elimination of fluorine as silicon tetrafluoride.

Slow cooling of the melt when fluorine is present causes reversion to fluorapatite and reduction in the availability of phosphorus in the product. Quenching of the material from the molten state largely avoids this. It also prevents the transformation, which occurs at 1100°C., of tricalcium phosphate into a modification in which the phosphorus is not biologically available. In the presence of excess of calcium, together with silica, no quenching is necessary because the resulting calcium silicophosphate does not undergo polymorphic transformation on cooling. Citrate-soluble products are obtained by simple fusion and quenching if the apatite contains the correct proportions of magnesium oxide and silica.[221]

The effects of temperature and the amount and nature of the materials added to the reaction mixture on the available phosphate have been studied for apatite and a phosphorite. Only 30% of the phosphorus becomes available when apatite ($P_2O_5$ 40%, CaO 52%, F 3·2%) is fused at 1800°C. with lime and/or silica and is not quenched. Almost complete availability occurs when the melt is quenched, even though only 10% of the fluorine is volatilized. Similar results were found with an apatite–nepheline ore ($P_2O_5$ 27%, CaO 38%, $SiO_2$ 15%, Cl 5%, F 2·2%) except that the optimum temperature is 1550°C. This also applies to a phosphorite ($P_2O_5$ 25%, CaO 40%, $H_2O$ 13%, $CO_2$ 4·5%, F 2·6%), but in addition fusion with lime and the mineral serpentine (39% MgO) and quenching were equally effective. In every instance an optical and *X*-ray examination showed that the quenched material was vitreous, whereas the slowly-cooled product was crystalline and had a fluorapatite structure.[222]

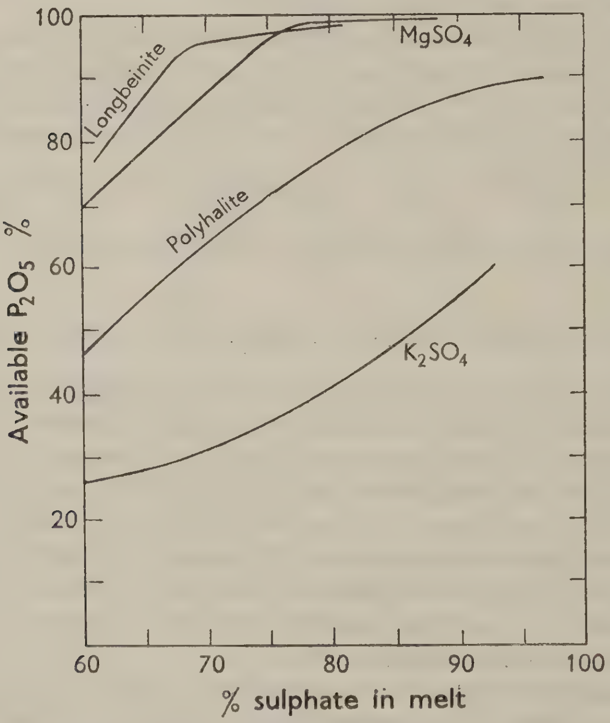

FIG. 13.—The reaction of Florida phosphate with sulphates at 1150°C.[216]

Mixtures of leucite, $KAl(SiO_3)_2$, and phosphate ore react with lime, dolomite, bauxite and calcium or sodium carbonates at temperatures above 750°C.[223]

Fusion of phosphate rock and a manganese silicate ore, followed by quenching from 1350°C. with a water-spray, is claimed to give a citrate-soluble product.[224]

A material which contains 70% of citrate-soluble $P_2O_5$ is said to result from calcining a mixture of phosphorite and monoammonium phosphate at 600°C.[225]

Phosphate rock reacts at 1000°C. with phosphoric acid and sodium chloride to give a material having good fertilizing properties.[226] A similar reaction occurs with aluminium phosphate ores at 800°C. in the presence of steam. The mechanism here seems to be the formation of sodium hydroxide from sodium chloride and steam at 700°C. or above, followed by reaction of the alkali to form complex sodium, calcium and aluminium phosphates.[227] Compounds of the type $CaNa_2(PO_4)_2$, $AlNa_6(PO_4)_3$ or $Na_3PO_4$ decompose phosphate rock at 1000°C.[228]

Phosphorus pentoxide in the vapour state reacts very readily with phosphate rock to form calcium metaphosphate. This fact has been used to produce high-grade phosphate fertilizers.[229] The large-scale manufacture of these from apatite has been described.[230] The process consists essentially in causing phosphorus pentoxide vapour to react with phosphate rock at 1100° (i.e. about 120°C. above the melting point of calcium metaphosphate) and then quenching to prevent crystallization. A product of low citrate-solubility and poor fertilizer value is obtained if the reaction is carried out below 1000°C. or the melt is not quenched.[231] Calcium metaphosphate does not absorb ammonia and must be hydrolyzed, e.g. with steam, if it is to be used for making ammoniated superphosphates.[232]

In a modification of the above process phosphorus is burned in air in the presence of water vapour and the combustion products are passed through phosphate rock at an optimum temperature of 1000°C. The main reaction is[233]:

$$3Ca_3(PO_4)_2,CaF_2+6P_2O_5+2HPO_3 = 10Ca(PO_3)_2+2HF$$

Potassium chloride may be used in the reaction to give a mixed calcium–potassium fertilizer. As a source of potassium the latter is somewhat better than potassium chloride for plant growth.[234] The composition and chemical and physical properties of calcium metaphosphate have been discussed in relation to its manufacture and use as a fertilizer.[235]

A study of the reaction of phosphorus pentoxide with Tennessee brown rock at 900°C. shows that in the initial stages the rate is governed by the transfer of phosphorus pentoxide through the gas surrounding the rock particles and is proportional to the $P_2O_5$ concentration in the gas phase. A coating of liquid products then begins to form on the particles and when this is complete the rate-determining factor is the transfer through the liquid layer. As the absorption of phosphorus pentoxide proceeds the absorption rate diminishes rapidly and there is no proportionality between this and the $P_2O_5$ concentration in the final stages of the reaction. At temperatures above 1000°C. resistance in the liquid phase becomes predominant only at high $P_2O_5$ concentrations. The absorption rate is very dependent on temperature and a temperature of at least 1000°C. in the absorption zone is required to maintain absorption rates high enough for production purposes.[236]

## Decomposition by Miscellaneous Methods

Many relatively simple methods have been proposed either for completely decomposing phosphorites or for improving their suitability for agricultural purposes.

About half of the phosphorus in phosphorites containing 12 to 30% $P_2O_5$ is said to become water-soluble on grinding with potassium sulphate and then extracting with hot water. Calcium carbonate retards this action and apatite gives only about 5% of soluble $P_2O_5$.[237]

Apatite and phosphorites are decomposed to the extent of about 70% when heated with sodium bisulphate solutions at an optimum temperature of 200°C. under pressure.[238] By a multi-stage treatment of apatite with sulphuric acid and sodium sulphate with recycle at each stage, a monosodium phosphate can be separated which is sufficiently pure for use in beverages.[311] Carbon dioxide solutions at about 50 atmospheres pressure react slightly with phosphorite to form calcium bicarbonate.[239]

Suspensions of ground phosphorite in water or dilute sulphuric or phosphoric acids are decomposed at 80° to 90°C. by treatment with air containing 3 to 5% each of nitric oxide and sulphur dioxide.[240] The amount of sulphur dioxide used should be equivalent to the phosphoric acid produced.[241]

Gaseous sulphur dioxide reacts only slowly with phosphate rock, even at high temperatures, but almost complete reaction occurs with aqueous solutions at pressures up to 3 atmospheres.[188] Finely-ground Florida rock is almost completely soluble in saturated aqueous solutions of sulphur dioxide under 3 to 10 atmospheres pressure and at temperatures of 25° to 100°C. The products of the reaction are elemental sulphur, calcium sulphate and sulphite and mono- and dicalcium phosphates.[242]

Phosphate rock reacts with aqueous solutions of lead chloride at room temperature according to the equation:

$$3Ca_3(PO_4)_2+10PbCl_2 = 3Pb_3(PO_4)_2,PbCl_2+9CaCl_2$$

If the product is dissolved in nitric acid so as to give a solution containing 145 g. $NO_3$ and 330 g. $P_2O_5$ per litre, most of the lead nitrate remains insoluble and can be filtered off and recovered as lead chloride by reaction with potassium chloride and ammonia.[243]

Phosphorites have been converted into soluble calcium and phosphorus compounds by an electrodialysis procedure.[244] Separation by high-voltage electrolysis is also possible.[245] In this method lime is precipitated at the cathode and phosphoric acid is concentrated in the anode compartment.[246]

### Decomposition of Aluminium Phosphates

Large deposits of aluminium phosphate ores occur in the Senegal region of North Africa and minerals such as wavellite, $Al_3(PO_4)_2,5H_2O$, crandallite, $CaAl_3(PO_4)_2,(OH)_5,H_2O$, and millisite, $(Na,K)CaAl_6(PO_4)_4(OH)_9,3H_2O$, are associated with the Florida phosphates. Chemical treatment of these phosphates is difficult, particularly with low-grade ores and on a commercial scale filtration and purification problems are involved. Some of the ores can be dissolved in sodium hydroxide to form trisodium phosphate and sodium aluminate. Some of the former can be crystallized if the sodium content of the solution is controlled so as to minimize the saturation with aluminate. The phosphorus may also be precipitated with lime and the aluminium then recovered.

It has been proposed to heat aluminium phosphate ores with carbon and sodium sulphate at 800°C. and then extract the trisodium phosphate with hot water.[247] If this process is carried out in the presence of steam, the extract contains trisodium phosphate, sodium aluminate and sodium hydroxide.[248]

In another procedure the phosphate is mixed with clay, carbon and siliceous material and is calcined in a rotary kiln. Phosphorus is recovered by condensing the vapour and the clinker is leached to give soluble calcium aluminate. The residue from this is treated to give an hydraulic cement.[249] Alternatively, a pelletized mixture of lime, alumina, carbon and defluorinated[312] phosphate rock can be heated at 1325–1425° in a rotary kiln. Most of the phosphorus is evolved[313–14] leaving a clinker suitable for Portland cement manufacture.[313]

An acid extraction has been used in which the ore is first calcined at 1000° to 1150°C. and is then treated with 42% nitric acid and 50% sulphuric acid, using 2·2 moles of each acid per mole of $P_2O_5$. About 90% of the $P_2O_5$ and 60% of the $Al_2O_3$ in the ore is extracted by this procedure.[250] Filtration rates are at a maximum and the amount of $Al_2O_3$ extracted is at a minimum (55%) when the calcining temperature is about 1000°C.[251]

## THE REMOVAL OF FLUORINE FROM PHOSPHATE ORES

Fluorapatite is a potential major source of fluorine. Although they are not at present exploited for their fluorine content, the quantity of phosphate ores used for commercial and industrial purposes is equivalent to a considerable tonnage of fluorine. It has been estimated[252] that the fluorine in the phosphate rock processed in the United States during 1958 was more than double that in the fluorspar which was mined in that year.

The fluorine/phosphorus ratio[253] and the fluorine content,[254] which may be as high as 5% or more but is usually about 3·5%, vary with the source of the phosphate. Typical analyses of different types of ore are given in Table III.[252–8]

The extraction of fluorine from phosphate ores does not compete economically with processes using high-grade fluorine minerals. On the other hand the removal of fluorine from phosphates is an important consideration in the utilization of the phosphorus. The use of phosphates as animal food supplements and as fertilizers requires a product having a low fluorine content.

In the conversion of phosphate rock to phosphoric acid by the wet-acid process as much as 30% of the fluorine in the rock may be present in the final acid.[83] Removal of the fluorine from the phosphoric acid is difficult, but can be achieved if the acid is converted into phosphates. Treatment with sodium carbonate to pH ~ 2 causes most of the fluorine to precipitate as sodium silicofluoride. The latter is least soluble at pH 5 and filtration of concentrated solutions at this stage gives monosodium phosphate which contains 0·1% or less of fluorine.[83]

*Table III.—Fluorine and Phosphorus Content of Some Phosphate Ores*[252–8]

| Source of phosphate | % F | % $P_2O_5$ |
|---|---|---|
| Florida hard rock | 3·4–4·0 | 31–36 |
| Florida land pebble | 3·2–4·1 | 30–36 |
| Florida soft rock | 0·2–3·8 | 15–35 |
| Tennessee brown rock | 2·6–4·1 | 25–38 |
| Tennessee blue rock | 3·3–4·0 | 28–34 |
| Tennessee white rock | 3·1–3·8 | 30–36 |
| Tennessee limestone | 1·0–2·3 | 10–19 |
| Montana, U.S.A. | 2·9–7·0 | 27–38 |
| Western States, U.S.A. | 3·1–3·8 | 26–35 |
| S. Carolina, U.S.A. | 2·2–3·8 | 16–29 |
| Curacao, West Indies | 0·3–0·9 | 38–41 |
| Algeria | 3·3–4·2 | 23–32 |
| Morocco | 4·1–4·3 | 33–35 |
| Tunisia | 3·5–3·8 | 26–29 |
| Egypt | ~3·5 | ~30 |
| Congo and Ruanda | 2·3–4·2 | 40–43 |
| Esthonia | 1·5–2·4 | 16–27 |
| Kola peninsula, U.S.S.R. | 3·2 | 39 |
| Nauru and Ocean Islands | 2·0–3·3 | 38–41 |
| Christmas Island | 1·0–1·5 | 39 |
| Pelew Islands | ~3·0 | ~40 |
| Vietnam | 3·0–3·5 | 38–40 |
| S. Australia | 3·3–3·6 | 30–34 |

Under certain conditions, a compound containing fluoride can precipitate with the gypsum during the initial attack of apatite by sulphuric acid. The compound has a unique *X*-ray pattern and forms regular octahedral crystals containing F, Ca, $SO_4$, Al, Si, and $H_2O$. Its formula is complex and has been variously reported as

$2{\cdot}5CaSO_4,3CaSiF_6,3CaAlF_5,2{\cdot}2CaF_2,25H_2O,$[315]
$4CaNa_mH_n(Al_xSi_{(1-x)})F_6,6CaF_2,3CaSO_4,44H_2O,$[316]
$Ca_3Al_2(R.E.)SO_4F_{13},12H_2O$[319] and
$CaSO_4,1{\cdot}5CaSiF_6,CaF_2,12H_2O$[317]

The addition of fluoride[315] or lime[318, 320] to the phosphoric acid will often assist its formation. Attention has been drawn to its isomorphism with the rare earth mineral chukhrovite, $Ca_3Al_2(R.E.)SO_4F_{13},10H_2O$.[319]

When phosphate rock reacts with sulphuric or phosphoric acids to give superphosphate most of the fluorine is transferred to the product. Under the best conditions only 10 to 40% of the fluorine is volatilized and the superphosphate generally contains 1·5 to 2·7%.[86] When it is mixed with lime or treated with ammonia, fluorapatite is formed with reversion of the phosphate to an unavailable form.[259] Several of the factors which influence the removal of fluorine in the superphosphate process have been studied using Florida pebble phosphate. The proportion of fluorine volatilized is increased by increasing the acid concentration, raising the acid/rock ratio, and by adding the concentrated acid to a mixture of the rock and water. Less fluorine is removed when mixtures of 70% sulphuric acid and 85% phosphoric acid are used than by either acid alone. The effect is shown in Fig. 14. With phosphoric acid alone there is a sharp increase in the volatilization of fluorine when the acid concentration is greater than 72% $H_3PO_4$.[260]

The action of sulphuric acid on phosphate rock may be considered to occur in two stages, in the first of which the main reaction is to form phosphoric acid which then reacts with undecomposed rock to give monocalcium phosphate. The mechanism of the volatilization of fluorine during these reactions has been variously interpreted. According to the early views calcium fluoride reacts with the sulphuric acid to form hydrogen fluoride. The latter then reacts with the silica in the rock to give silicon tetrafluoride, which is then partly hydrolyzed to fluosilicic acid. This is converted to hydrogen fluoride and silicon tetrafluoride by the action of heat in the presence of acid.[261] The reaction scheme is represented by the equations:

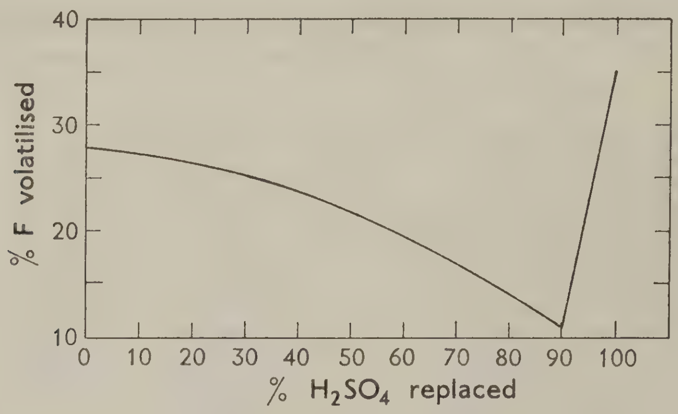

FIG. 14.—Effect of replacing sulphuric acid by phosphoric acid on the volatilization of fluorine from phosphate rock[260]

$$\begin{aligned} CaF_2+H_2SO_4 &= CaSO_4+2HF \\ 4HF+SiO_2 &= SiF_4+2H_2O \\ 3SiF_4+2H_2O &= SiO_2+2H_2SiF_6 \\ H_2SiF_6 &\rightleftharpoons SiF_4+2HF \end{aligned}$$

A later interpretation explains the mechanism by the equations[84]:

$$\begin{aligned} CaF_2+H_2SO_4+2H_2O &= CaSO_4{,}2H_2O+2HF \\ CaF_2+2H_3PO_4 &= Ca(H_2PO_4)_2+2HF \\ 6HF+SiO_2 &= H_2SiF_6+2H_2O \\ H_2SiF_6 &\rightleftharpoons SiF_4+2HF \end{aligned}$$

More recently[260] the above mechanisms have been questioned, mainly on the ground of the observation that on contact of phosphate rock with acid the major proportion of the fluorine is evolved as silicon tetrafluoride and not as hydrogen fluoride. There is also some evidence that hydrogen fluoride reacts more readily with phosphate rock than it does with silica. Fluorine evolution is increased much more by the addition of calcium fluosilicate to the reaction mixture[260] than by adding silica.[262] These facts are explained by assuming that the fluorine is present in phosphate rock as calcium fluosilicate.[263] Under anhydrous conditions, i.e. when sulphuric acid of concentration greater than 95% is used, the main reaction in the volatilization of fluorine is[264, 260]:

$$CaSiF_6+H_2SO_4 = CaSO_4+2HF+SiF_4$$

In the presence of water fluosilicic acid is formed:

$$CaSiF_6+H_2SO_4 = H_2SiF_6+CaSO_4$$

and its concentration in solution increases until it reaches the composition corresponding to the invariant complex $H_4SiF_8,12H_2O$.[265] This hydrate is formed by the reaction[260]:

$$2H_2SiF_6,6H_2O \rightleftharpoons H_4SiF_8,12H_2O + SiF_4$$

Various procedures have been devised for removing fluorine from superphosphate. Almost complete defluorination is achieved by heating the material for up to 30 min. at 700° to 900°C. The presence of water assists the reaction and also prevents reversion to fluorapatite.[266] Other calcination procedures[267] and the influence of various factors on the defluorination[268] have been reported. A large-scale manufacturing process based on these observations has been described in detail.[142]

Many investigations have also been made into the removal of fluorine from phosphate rock. Early observations indicated the importance of silica and of water in the defluorination process, but the necessity of having both present in the system was not clearly recognized. Consequently many of the methods proposed before about 1945 were not completely satisfactory when used on an industrial scale.

In one of the first systematic investigations of the problem it was found that 95 to 100% of the fluorine was removed by adding sand to the phosphate rock so as to make the total silica content about 45%. The mixture was then heated in an atmosphere of steam for up to 60 min. at 1400°C.[269] With closer control of the operation similar results were achieved with only 5 to 10% of silica in the mixture.[270] With ores such as Moroccan phosphate (which contains less than 1% $SiO_2$) only 50 to 60% of the fluorine is removed unless extra silica is added.[271–2] Vanadium and similar impurities are reported[252] to inhibit the defluorination of phosphate rock at 1450°C.

A product containing less than 0·1% F is obtained by mixing finely-ground phosphate rock with 45% of its weight of silica and then adding 40% of water to the mixture. The material is then calcined at 1350° to 1450°C. and quenched.[273] In a similar procedure more than 95% of the fluorine is removed by steaming a Kola apatite/silica mixture at 1450° to 1475°C. without chilling the product.[274]

The removal of fluorine by hydrothermal methods is said to take place in two stages. In the first of these isomorphous replacement of fluorine with hydroxyl ions occurs and this is followed by breakdown of the hydroxy-apatite into tri- and tetracalcium phosphates. Steam is necessary only in the first stage. Addition of silica, which reacts with the hydroxyapatite, results in the formation of a phase which has a variable composition and which is isomorphous with tricalcium phosphate.[275]

The addition of 2 to 3% of silica to phosphorites followed by steaming at 1370° to 1400°C. is reported to remove only 90% of the fluorine. The product is not soluble in 2% citric acid. Similar treatment of apatite completely removes the fluorine and gives a citrate-soluble product.[276]

One of the difficulties in operating the above procedures on a large scale is that it is not easy to control the temperature of the rock near its softening point. For this reason the defluorination of molten phosphate rock has been proposed. A detailed examination of this process in the temperature range of 1450° to 1600°C. shows that temperatures above 1500°C. have relatively little effect on the defluorination rate $R$. For shallow charges of molten rock the rate is given by

$$R = k\,\frac{w^{0\cdot 45}\,v^{0\cdot 30}}{d}$$

where $k$ is a constant and $d$, $w$, $v$ are respectively the charge depth, concentration of water vapour in the reaction atmosphere and the gas velocity over the charge. In deep charges the rate is governed by diffusion through the melt and $R$ increases with temperature and varies inversely with the square of the depth. Addition of iron and aluminium oxides and silica assists the defluorination. The theory of the process, velocity equations and graphical data have been given.[277]

Defluorination of phosphate rock on a commercial scale has been achieved by the melt-process, using either an arc electrode furnace[278] or an oil-fired furnace in which the water vapour is provided by the combustion products of the oil.[279] Products containing less than 0·1% F are obtained, but the furnace linings (refractory silica) are rapidly attacked by the melt.

### Recovery of Volatilized Fluorine

Various methods of absorbing and collecting the fluorine-containing gases evolved in defluorinating processes have been described.

Hydrogen fluoride can be absorbed in a tower containing limestone but the absorption slows down as the limestone becomes coated with calcium fluoride. A recovery of 87% has been achieved.[280] Partial pressures in the HF–$H_2O$ system,[281] and vapour pressure data for the HF–$H_2SiF_6$–$H_2O$[265] and HF–$H_2O$[282] systems have been reported. Hydrogen fluoride has been recovered from gases by absorbing it on solid sodium fluoride at 100°C. It is then recovered in a pure state by heating the solid at 275° to 350°C.[283–4] The equilibrium involved is[285]

$$HF + NaF \underset{>250°C.}{\overset{<200°C.}{\rightleftharpoons}} NaHF_2$$

Silicon tetrafluoride is absorbed as $Na_2SiF_6$ in this method, but is not decomposed when heated to 350°C.

The fluorine gases evolved from the treatment of phosphate rock with phosphoric acid containing 74% $P_2O_5$[152] contain 6% of the fluorine as hydrogen fluoride, the remainder being silicon tetrafluoride. These gases are absorbed by solutions containing ammonium fluosilicate and ammonium fluoride at pH 5·5 to 6. The solution is maintained at a constant pH by addition of an ammonia/ammonium fluoride solution having pH 8·5 to 9·0. The reactions involved are:

$$SiF_4 + 2NH_4F = (NH_4)_2SiF_6$$
$$2HF + NH_4OH = NH_4HF_2 + H_2O$$

Silica in an easily filtered form is then precipitated by neutralizing the solution to pH 8·5 to 9·0 with ammonia[286]:

$$(NH_4)_2SiF_6 + 4NH_3 + 2H_2O = 6NH_4F + SiO_2$$
$$NH_4HF_2 + NH_3 = 2NH_4F$$

The ammonium fluoride obtained from the above procedure can be converted into cryolite by reaction with an alkaline solution of sodium aluminate[283]:

$$6NH_4F + NaAlO_2 + 2NaOH = Na_3AlF_6 + 6NH_3 + 4H_2O$$

An alternative method is to use a solution of aluminium and sodium sulphates at pH 5·5:

$$12NH_4F + 3Na_2SO_4 + Al_2(SO_4)_3 = 2Na_3AlF_6 + 6(NH_4)_2SO_4$$

To avoid contamination of the cryolite with phosphate in these methods only 95% of the stoicheiometric amounts of sodium sulphate and aluminium compounds should be used. The F/$P_2O_5$ weight ratio in the solution must not be allowed to increase above 100.[283]

Ammonium hexafluoroaluminate can be precipitated at pH 5 to 7 from solutions containing ammonium fluoride and phosphate by addition of an aluminium salt. Heating the product at 500° to 550°C. causes the following decomposition:

$$(NH_4)_3AlF_6 = AlF_3 + NH_3 + NH_4HF_2 + NH_4F$$

The ammonia and ammonium fluorides are recycled in the process.[283]

### SECTION III

# THE PREPARATION OF PHOSPHORUS

### BY D. R. PECK

## WHITE PHOSPHORUS

Most of the methods of preparing phosphorus have already been described (Mellor, VIII, 740), and an historical account has been given of the development of phosphorus manufacture.[272] With one or two exceptions much of the later work has been concerned with improving the earlier methods and applying them to commercial processes. These procedures, which usually involve the reduction of a phosphate by carbon in the presence of silica, require temperatures in the range of 1000° to 1500°C. if high yields of phosphorus are to be obtained. It has been found, however, that many phosphates can be reduced by hydrogen at temperatures between 300° and 750°C. Metals which do not form phosphides, or give phosphides which are easily dissociated by heat, are most susceptible to this reduction. In these reactions the metal is formed and the oxygen of the phosphate is quantitatively converted to water. Lead phosphates are particularly easy to reduce by hydrogen. For example, pyromorphite, $3Pb_3(PO_4)_2,PbCl_2$, starts to react at 300°C. and is completely reduced at 850°C.[1] The alkali metal and alkaline earth phosphates are not reduced under these conditions.

Phosphorus, however, can be prepared from tricalcium phosphate by first converting it into pyromorphite. The latter is formed by stirring the phosphate or a phosphorite in suspension in aqueous lead chloride at room temperature[2]:

$$3Ca_3(PO_4)_2 + 10PbCl_2 = 3Pb_3(PO_4)_2,PbCl_2 + 9CaCl_2$$

The pyromorphite is then reduced by hydrogen at 500° to 600°C.:

$$2[3Pb_3(PO_4)_2,PbCl_2] + 50H_2 = 20Pb + 3P_4 + 4HCl + 48H_2O$$

Phosphorus is also formed by reducing the ortho-, meta- or pyro-phosphates of tin, bismuth and lead in a stream of hydrogen at temperatures between 400° and 800°C.[3] The reduction of phosphates by hydrogen has been studied at temperatures up to 1000°C. and at pressures slightly above atmospheric. Water vapour formed in the reaction is continuously removed to prevent equilibrium being established. By plotting the pressure in the system against the temperature, the point at which each reaction becomes rapid can be determined. The results showed that the phosphates can be classified according to the type of reaction which occurs. Table I gives the decomposition temperatures for those phosphates which form phosphorus and the metal only.

Antimony phosphate forms a small quantity of antimony phosphide. Silver phosphate is reduced to silver and orthophosphoric acid at 140°C., and at 425°C. the acid is reduced to phosphorus. Between 300° and 350°C. the mercury phosphates form mercury and metaphosphoric acid which is reduced to phosphorus at 600°C. Stannic phosphate reacts slowly at 300° to 450°C., being reduced to stannous phosphate, which rapidly forms the metal and phosphorus at 600°C.

From a second group of phosphates metal phosphides are formed, usually

*Table I.—Decomposition Temperatures for Phosphates which are Reduced to the Metal and Phosphorus by Hydrogen*

| Phosphate | Decomposition temperature °C. |
|---|---|
| $BiPO_4$ | 425 |
| $Ag_3PO_4$ | 425 |
| $SbPO_4$ | 450 |
| $Pb_3(PO_4)_2$ | 575 |
| $3Pb_3(PO_4)_2,PbCl_2$ | 600 |
| $Hg_3PO_4$ | 600 |
| $Hg_3(PO_4)_2$ | 600 |
| $SnO_2,P_2O_5$* | 600 |

* Stannic phosphate of uncertain composition, containing some excess of $SnO_2$.

together with phosphorus. Decomposition temperatures and products for this group are given in Table II.

Cupric phosphates were reduced to metaphosphoric acid and cuprous metaphosphate at 300°C. On cooling from this temperature, cupric metaphosphate and metallic copper resulted:

$$2CuPO_3 = Cu(PO_3)_2 + Cu$$

The remainder of the phosphates studied gave various products. Phosphides were not major products and phosphorus was obtained only under certain conditions.

*Table II.—Decomposition Temperatures of Phosphates which give Phosphides, but no Metal, on Reduction by Hydrogen*

| Phosphate | Decomposition temperature °C. | Products |
|---|---|---|
| $Ni_3(PO_4)_2$ | 450 | $P+Ni_2P$ |
| $Ni_2P_2O_7$ | 550 | $P+Ni_2P$ |
| $Ni(PO_3)_2$ | 600 | $P+Ni_2P$ |
| $CuPO_3$ | 600 | $P+Cu_3P+CuP_2$ |
| $CrPO_4$ | 650 | $P+CrP+Cr_2P$ |
| $Co(PO_3)_2$ | 675 | $P+Co_2P$ |
| $Mn_3(PO_4)_2$ | 850 | $P+Mn_2P$ |
| $Fe_2P_2O_7$ | 600 | $FeP$ |
| $Co_3(PO_4)_2$ | 600 | $CoP+Co_2P$ |
| $Co_2P_2O_7$ | 600 | $CoP$ |
| $Zn_3(PO_4)_2$ | 600 | $Zn_3P_2$ |

Table III summarizes the data.[4] The reduction by hydrogen at 1000° of a crude aluminium phosphate from Senegal, predominantly crandallite and millisite, yielded 59% of the phosphorus. The residue contained alumina, $\beta$-tricalcium phosphate and ferrophosphorus.[263]

Many of the earlier reactions (Mellor, VIII, 740–3) in which phosphorus is formed have been applied to commercial processes in which the object is the maximum utilization of phosphate ores. In these procedures phosphorus manufacture is combined with that of by-products of industrial value. Such processes have been devised for phosphate ores which are not generally suitable for the electrothermal production of phosphorus.

In some of the methods the main by-product is an aluminous cement or similar material. Naturally-occurring aluminium phosphates may be mixed with lime, silica and charcoal and smelted to give a calcium aluminate cement, and the phosphorus recovered as phosphoric acid.[5] Mixtures of calcium and aluminium phosphates[6] or of calcium phosphate and aluminous materials[7] can be used, and the process may be used for the simultaneous production of yellow phosphorus and aluminous cement.[264–5] Addition of bauxite[8] and the use of bauxite instead of silica[9] have been proposed. If relatively pure phosphate is available the slag may be used as a raw material for the manufacture of aluminium.[10] A hydraulic cement is obtained if the proportions of the reactants are chosen so as to produce a slag with a composition in the range: $Al_2O_3$ 12–35%, CaO 40–55% and $SiO_2$ 18–38%.[11] Phosphorus and cements may also be obtained by smelting phosphates with carbon and potash minerals such as feldspar or leucite in the presence of alumina,[12] or by using bauxite containing iron.[13] Fluorine in the phosphate is eliminated by adding alkali metals and melting in the presence of water vapour.[14]

*Table III.—Reduction by Hydrogen of Phosphates which do not form Phosphides as Major Products*

| Phosphate | Decomposition temperature °C. | Products |
|---|---|---|
| $Cu_3(PO_4)_2$ | 300 | $CuPO_3+HPO_3$ |
| $Cu_3(PO_4)_2$ | 600 | $CuPO_3+$ some $Cu_3P$ |
| $Cu_2P_2O_7$ | 300 | $CuPO_3+HPO_3$ |
| $FePO_4$ | 460 | $Fe_2P_2O_7$ |
| $(UO_2)_3(PO_4)_2$ | 550 | $3UO_2,P_2O_5$ |
| $(UO_2)_3(PO_4)_2$ | 750 | $P+UO_2$ |
| $H_3PO_4+SiO_2$ | 550 | P |

It has been proposed to manufacture phosphorus and pure alumina by heating aluminium phosphate minerals with carbon at temperatures above the melting point of alumina.[15] In a variation of this process iron sulphides,[16] or iron and sulphur compounds,[17] are melted with carbon and aluminium phosphate. If silica is also added, phosphorus and aluminium–silicon alloys are obtained.[18]

Phosphorus and lithium compounds can be obtained from lithium-containing phosphorites, e.g. amblygonite and triphyllite, by heating them with silicon. Phosphorus is volatilized and lithium silicates remain.[19]

Smelting of phosphorite and potassium silicate minerals with carbon in an electric furnace,[20] or in a blast furnace,[21] volatilizes both the phosphorus and potassium. Phosphorus and potassium hydroxide can be recovered by heating a mixture of charcoal, phosphorite and a potassium aluminium silicate such as feldspar.[22] Chlorination of phosphate rock with excess of chlorine in the presence of carbon yields the trichlorides of phosphorus, aluminium and iron as gaseous products. If the gases are then passed over a heated mixture of carbon and orthoclase, phosphorus and potassium chloride are also formed.[23]

The combined manufacture of phosphorus and calcium compounds has been suggested in a number of processes. In one of these Moroccan phosphate, kaolin and coal are heated to 1600°C. and phosphorus, alumina and calcium oxide are recovered.[24] A slag which readily disintegrates and is easily soluble in acid is obtained from this procedure by adjusting the proportions of the reactants so as to form a product containing 45–60% CaO, 10–30% $SiO_2$ and 10–40% of iron and aluminium oxides.[25] Reduction of tricalcium phosphate, phosphorite or other tertiary calcium phosphate with charcoal at 1600° to 1750°C. in an atmosphere of carbon monoxide volatilizes the phosphorus, leaving a mixture of calcium oxide and charcoal. Further heating in the presence of carbon monoxide forms calcium carbide.[26] The procedure may be carried out in a kiln-type electric furnace.[27] The calcium carbide obtained in this way often contains traces of phosphorus which are eliminated by heating at 900°C. in a stream of nitrogen to convert the carbide into calcium cyanamide.[28] Simultaneous production of the latter and of phosphorus is achieved by heating phosphorites and coal, anthracite or peat at 1000° to 1600°C. in the absence of silica, the last traces of phosphorus being removed by heating to 1600–1900°C. The residue is then heated in nitrogen at 1000–1200°C.[29] Phosphorite and calcium carbide in the presence of a little calcium fluoride are said to form phosphorus and cyanamide at 1000°C. in a nitrogen atmosphere.[30]

Active carbon and phosphorus have been made from phosphoric acid by kneading the latter with organic material, e.g. sawdust or peat, and carbonizing at 300°C. The residue is then heated for 8–9 hr. at 900° to 1200°C.[31] Monocalcium phosphate may be used in this procedure instead of phosphoric acid.[32] Phosphine and carbon monoxide are also products of this reaction.[33]

Hydrogen is obtained as a by-product of the reduction of phosphates to phosphorus, by heating the phosphate with silica at 1200° to 1300°C. in an atmosphere of methane,[34] or by blowing hydrocarbons into the melt.[35] The reaction occurs at 1000°C. in the presence of silicates, when carbon monoxide is also formed.[36]

At electric furnace temperatures silicon replaces the phosphorus in ferrophosphorus.[37] Ferrosilicon or mixtures which produce silicon at high temperatures may be used in this reaction.[38] A similar method using sulphur has been proposed.[39] Carbon and silica behave in a similar way.[40] An alternative procedure is to cause the ferrophosphorus to react at 500° to 700°C. with insufficient chlorine to chlorinate it completely. This yields phosphorus and ferrous chloride which is recovered by decantation from the residue at 700–1250°C.[41]

Mixtures of crude phosphate, chromium ore, coke and silica yield phosphorus in the electric furnace, together with a chromium–iron–phosphorus alloy. Heating the latter with sodium hydroxide in the presence of oxygen converts it into dichromate.[42]

In one of the more direct procedures for preparing phosphorus, phosphate is heated with carbon and silica at 1400°C. in the presence of a molten chloride such as sodium chloride.[43] Another method uses 100 parts of tricalcium phosphate, 100 parts of aluminium phosphate and 48 parts of charcoal. At 1500–1600°C. the reaction is[44]:

$$2AlPO_4 + Ca_3(PO_4)_2 + 10C = Al_2O_3 + 3CaO + P_4 + 10CO$$

Lower reduction temperatures (about 1200°C.) are said to be required if the source of carbon is pitch, asphalt or a similar material which is absorbed by the phosphate.[45] Tricalcium phosphate is reduced to phosphorus when heated with coke, heavy metal sulphides, e.g. those of iron, lead, copper or zinc, and an easily fusible sulphide such as potassium, magnesium or aluminium sulphide. The temperature is kept high enough to decompose the heavy metal sulphide, but below the dissociation point of calcium sulphide.[46]

### Production of Phosphorus by Blast Furnace and Similar Methods

As an alternative to the electrothermal process for the manufacture of phosphorus, many procedures have been examined in which blast or shaft furnaces or similar types of equipment have been used. Most of these were designed for phosphorus ores such as apatite or tricalcium phosphate, or for phosphorites containing mainly calcium phosphates. They can, however, be used with ores having a lower phosphorus content than that normally required for the satisfactory operation of the electrothermal process.

Although the method of operating these furnaces varies with the type of equipment used and is also dependent on the composition of the phosphate ore, the basic procedure is to mix the ore with carbon and silica in some suitable form and then heat to a high temperature.

The very early processes for the manufacture of phosphorus by furnace or retort procedures were essentially commercial developments of the methods previously described (Mellor, VIII, 740–1). The possibility of reducing tricalcium phosphate by carbon and silica in a furnace at high temperature was first demonstrated by Berthier in 1826.[47] He observed that the ease of reduction increased with the proportion of silica used, that calcium phosphide was not formed, but that any iron phosphate present formed only iron phosphide. Three years later Wöhler repeated this and obtained phosphorus and carbon monoxide by heating in a retort a mixture of calcined bone with half its weight of sand and a little lampblack.[48] Schloesing showed that all the phosphorus could not be extracted by heating calcium, magnesium or aluminium phosphates with carbon only, because of poor contact between the reactants.[49] Addition of silica gave complete reduction because a melt was obtained.[50–1] Brisson[52] in 1868 was the first to propose the large scale manufacture using mineral phosphate, coke and a flux in a blast furnace operation. A vertical furnace has been suggested.[53] Readman examined the problems of the blast furnace procedure in an experimental manner.[54]

The operation of a blast furnace process on a commercial scale has been described.[55] Phosphate rock was briquetted with half of the amount of carbon required to reduce it to phosphorus, a larger proportion causing serious blocking of the furnace by the slag formed. The furnace was charged with the briquets, silica and coke in proportions to give a slag having a $CaO:SiO_2$ weight ratio of 1·2. The phosphorus could be burned to phosphorus pentoxide and then hydrated to phosphoric acid. However, a purer acid was obtained by separating the phosphorus and burning and hydrating it in a further stage. In order to improve the thermal efficiency of the process it was necessary to burn part of the exit gases in heat exchangers and use the heat to pre-heat the air blast. The remainder of the gas was used for steam raising. From calculations of the heat balance of a small experimental blast furnace it has been estimated that the thermal efficiency of the reduction is 5–10%.[56]

Various ways of utilizing the exhaust gases from the blast furnace have been studied. The carbon monoxide present may be oxidized, caused to react with steam and the resulting gases used for ammonia or methanol synthesis.[57] The phosphorus in the gas can be recovered by oxidation to phosphoric acid with steam and air and then passed over lime at 600–750°C. Alternatively the phosphorus can be oxidized to phosphorus pentoxide so as to recover the heat of combustion, with simultaneous formation of superphosphate.[58] The rate of oxidation of the phosphorus-containing gases in the presence of air, steam and lime at 550–950°C. has been found to be very high, even at high velocities of the gas stream. Sodium chloride may be used instead of lime so as to recover the phosphorus as sodium phosphates. Under these conditions the temperature must be limited to 400–500°C. to prevent volatilization of salt.[59] It has been proposed to oxidize the phosphorus and phosphine in the gases by scrubbing with nitric acid. The oxidation of the phosphine is largely due to the oxygen in the air, but nitric acid catalyzes the reaction.[60]

Methods of operating[61] a blast furnace, and the preparation,[62] size,[63] and physical form[64] of the charge have been described. Retaining the slag in the furnace for 2–4 hr. and operating at 1450°C. with an oxygenated air blast containing 30–45 wt.-% of oxygen is said to improve the volatilization of phosphorus.[65] The amount of carbon used in the reaction appears to be decreased by dehydrating the incoming air.[66] Improved efficiency of operation is claimed to result from maintaining the reaction zone in the furnace at above 1400°C., keeping the temperature of the exit gases below 400°C. and heating the air blast to at least 700°C.[67] The use of aluminium silicate as flux[68] and of silicon or silicon–iron alloys[69] has been suggested. Other variations,[70] modifications in furnace design,[71] and alternative methods of charging the furnace,[72] have been proposed.

Shaft furnaces have been used as an alternative to the blast furnace. In one of the earliest of these the shaft acted as a melting zone for a mixture of phosphate rock, sand and coke. The melt was then transferred to a slag chamber where phosphorus was volatilized, and withdrawn via the shaft.[73] Similar processes have been described in which the charge is fritted,[74] or sintered,[75] rather than melted. Variations of the procedure have been proposed.[76] A furnace having two reaction chambers has been used in an attempt to improve the thermal efficiency of the process.[77] Most of these procedures do not seem to offer any advantage over the blast furnace process.

More recently fluidized beds have been applied to phosphorus production. In one case finely ground phosphate rock was fluidized with hydrocarbon, and carbon cracked on to it at 950–1000°C. The coated rock was heated with silica for 1–8 hours at 1000–1300°C. in a second fluidized bed, when it evolved most of its phosphorus.[278] A similar procedure has been adopted for phosphate–shale mixtures,[279] and the electrical resistive heating of fluidized carbon-coated particles of phosphate has been proposed.[280]

### FACTORS WHICH AFFECT PHOSPHORUS YIELDS

Investigations carried out with shaft or blast furnaces have yielded information on the reactions occurring during the high temperature reduction of phosphate ores. Thus both carbon and silica were shown to be necessary for high extraction of the phosphorus from fluorapatite ore heated in a shaft furnace. The effects of time and temperature on the extraction are shown in Table IV for two mixtures.

*Table IV.—Volatilization of Phosphorus from Phosphate Rock*

| 50% rock + 50% carbon | | | 63% rock + 21% carbon + 16% sand | | |
|---|---|---|---|---|---|
| Time min. | Temp. °C. | Extraction % | Time min. | Temp. °C. | Extraction % |
| 78 | 1300 | 61 | 75 | 1400 | 73 |
| 78 | 1300 | 42 | 75 | 1450 | 91 |
| 85 | 1400 | 27 | 75 | 1500 | 94 |
| 80 | 1450 | 40 | 15 | 1550 | 78 |
| 96 | 1500 | 38 | 75 | 1550 | 96 |
| 15 | 1550 | 37 | 90 | 1550 | 98 |
| 85 | 1550 | 53 | | | |
| 105 | 1550 | 70 | | | |
| 85 | 1600 | 67 | | | |
| 120 | 1650 | 92 | | | |

The effect of varying the lime: silica ratio was determined by heating at 1500°C. for 45 min. mixtures which contained a 50% excess of carbon over that required for the reaction:

$$Ca_3(PO_4)_2 + 3SiO_2 + 5C = 3CaSiO_3 + 2P + 5CO$$

The results, shown in Table V, indicate that high ratios decrease the amount of phosphorus extracted.

*Table V.—Effect of Lime: Silica Ratio on the Volatilization of Phosphorus from Phosphate Rock and 50% Excess of Carbon*

| $CaO:SiO_2$ wt. ratio | Phosphorus extracted % |
|---|---|
| 2:3 | 96·8 |
| 1:1 | 98·4 |
| 3:2 | 96·5 |
| 2:1 | 85·0 |
| 3:1 | 68·0 |

For mixtures ground to a fineness of 200 mesh or smaller it was observed that in the absence of carbon melts were obtained at 1300° to 1400°C. Addition of carbon raised the melting temperature and with sufficient present the temperature could be raised to 1650°C. without fusion occurring.[78]

A detailed study of the behaviour of an experimental blast furnace using an enriched blast (41% $O_2$ or 2·2 lb. of oxygen per lb. of $P_2O_5$ in the mixture charged to the furnace) showed that it is necessary to maintain strongly reducing conditions in the shaft of the furnace. For successful operation of the furnace it is essential to adjust the proportions of the ingredients in the charge to give a slag which is very fluid in the molten state. The best temperature for removal of the slag is 1500°C. Use of pure oxygen in the blast causes excessive volatilization of silica, but if the oxygen content in the inlet air is less than 40%, coke consumption is increased and the amount of phosphorus extracted decreased.[79]

The amount of phosphorus which can be extracted from phosphorites at a given temperature in the presence of carbon and alkali metal is greatest when the mixture contains, per mole of phosphorite, 3 moles of silica, 0·5 mole of aluminium oxide and 1 mole of sodium sulphate. Lower yields occur if the sodium sulphate is replaced by sodium carbonate or chloride.[80–1]

Sublimation of phosphorus from a mixture of fluorapatite and wood charcoal, without added silica, is complete in 1 hr. at 1600°C. No calcium phosphide was observed at this temperature but considerable quantities were formed at 1700° to 1800°C. At 1250° to 1450°C. only insignificant volatilization of fluorine occurred, but this increased when silica was added. For a silica : lime ratio of 1·07 about 52% of the fluorine was evolved in 1 hr. at 1450°C.[82]

Measurements of the rate of reduction of phosphorus ores by carbon at 1300°C. have shown significant differences in the behaviour of tricalcium phosphate, hydroxy-apatite and fluorapatite.[83]

Some observations have been reported on the operation of a blast furnace in a process designed for the production of phosphoric acid. Coke containing 87% of carbon was used and the consumption of this was measured in terms of the weight of coke per unit of phosphorus pentoxide reduced to phosphorus. The coke consumed was not affected by varying the air blast between 334 and 466 cu. ft. per minute. The furnace temperature was related to the coke consumption in a linear manner, as shown in Table VI.

*Table VI.—Effect of Furnace Temperature on the Coke Consumed in a Phosphorus Blast Furnace*

| Temp. °C. | lb. coke used per lb. $P_2O_5$ in charge |
|---|---|
| 650 | 4·5 |
| 805 | 3·7 |
| 865 | 3·5 |
| 940 | 3·2 |
| 965 | 3·1 |
| 1000 | 3·0 |

A reduction in coke usage was also found when the particle size was ½ in. or less, and the furnace was easier to operate when the phosphate rock feed contained not more than 20% of material smaller in size than 10 mesh. Thermochemical and heat balance calculations indicated that the thermal efficiency could vary between 38 and 75%. This depended on the heat insulation of the furnace, the type of filling and the method of operation.[84]

In place of coke, it has also been proposed to use methane as a reducing agent.[256] In the presence of silica, sodium sulphate and magnesium sulphate, 99% of the phosphorus in a phosphorite ore was recovered in 5 minutes at 1400° using a methane oxygen mixture.[256] At temperatures greater than 1300° the reduction is primarily by hydrogen.[257–9] The process has not found application commercially.[258–60]

The production of phosphorus by the blast furnace and similar procedures has not attained the industrial prominence of the electrothermal process. Apart from being less competitive as regards the purity of the end products, there are difficulties in preparing the furnace charge, in the construction of equipment and in the collection of the products, particularly the recovery of phosphorus from the outlet gases. Fuel economies and the recovery and distribution of waste heat in the process are generally less favourable than in the electrothermal procedure. The relative merits of the two methods have been discussed[85] and assessed.[86–7] The use of a nuclear reactor for phosphorus manufacture has also been suggested.[282]

### Production of Phosphorus by the Electrothermal Process

The use of electrical energy for the production of phosphorus on a commercial scale was first achieved by Readman, who obtained a patent for the process in 1888. A similar procedure was independently patented later in the same year by Parker and Robinson.[88] The earlier history of the industrial development of the electrothermal method has been variously described by Van Wazer[85] and others.[86, 89–91, 272] Descriptions have also been given of the equipment, and methods of operating in England,[92] America,[93] France,[94] Germany[95] and the U.S.S.R.[96]

The electrothermal method of preparing phosphorus differs from many other industrial electrical processes in that only the thermal effect of the electric current is used. Electrolytic effects, such as occur in the production of magnesium or aluminium for example, are not involved. In a phosphorus furnace the current passes through the charge and heat is developed partly by arc and partly by resistance phenomena. The operation of the furnace is essentially a reduction process and this distinguishes it from the resistance, induction or direct-arc furnaces commonly used in the melting and refining of metals.

Many investigations have been made into the design,[97–103] operation[104–11] and performance[112–14] of phosphorus furnaces. Experience has shown that it is easier to supply the large amount of electric power required by using alternating rather than direct current. This also makes it easier to control the current and voltage. In single-phase furnaces a greater concentration of heat under the electrode can be achieved if, instead of using two electrodes, only one is used and the bottom of the furnace or crucible serves for the other connection. However, single-phase operation has the disadvantage of unbalancing the power supply and a three-phase furnace is to be preferred. Two arrangements of the latter are possible. Three electrodes can be mounted in a line, giving a rectangular furnace which is fairly easy to construct. On the other hand this arrangement makes it difficult to maintain an electrical balance between the three electrodes. This can be avoided by fixing them at the corners of a triangle and constructing a cylindrical furnace.

The electrodes are cylinders up to 40 inches in diameter and may be made of graphite or baked carbon. The Soderberg electrode, made by packing a paste of coke and tar into a steel cylinder, has been proposed. This bakes into a rigid electrode under the heat developed in the furnace and can be replaced at the top so as to give continuous operation as the lower part is worn away. In phosphorus furnaces, however, the Soderberg electrode is not widely used, partly because of mechanical difficulties involved in adapting the system to enclosed furnaces. In addition the low consumption of carbon or graphite electrodes usually does not justify the extra cost of installing the Soderberg electrodes.[115]

The furnace consists of a mild-steel casing which can be water-cooled if necessary. It has a lining of firebrick, within which is another lining of carbon bricks up to the level of the molten slag. Two tap-holes are usually provided, one near the bottom of the furnace for removing ferrophosphorus and the other just above it for discharging the silicate slag. The roof of the furnace is lined with firebrick or similar material and is provided with a gas take-off, electrode holders, cleaning and poke holes, and closed chutes for feeding in the raw materials. The equipment is made air-tight and is operated under a slight positive pressure. The operation of furnaces at internal pressures of up to 50 kg./cm.$^2$ has been claimed[281] to give shorter reaction times and smoother operation, but no commercial use of this is known in phosphorus manufacture.

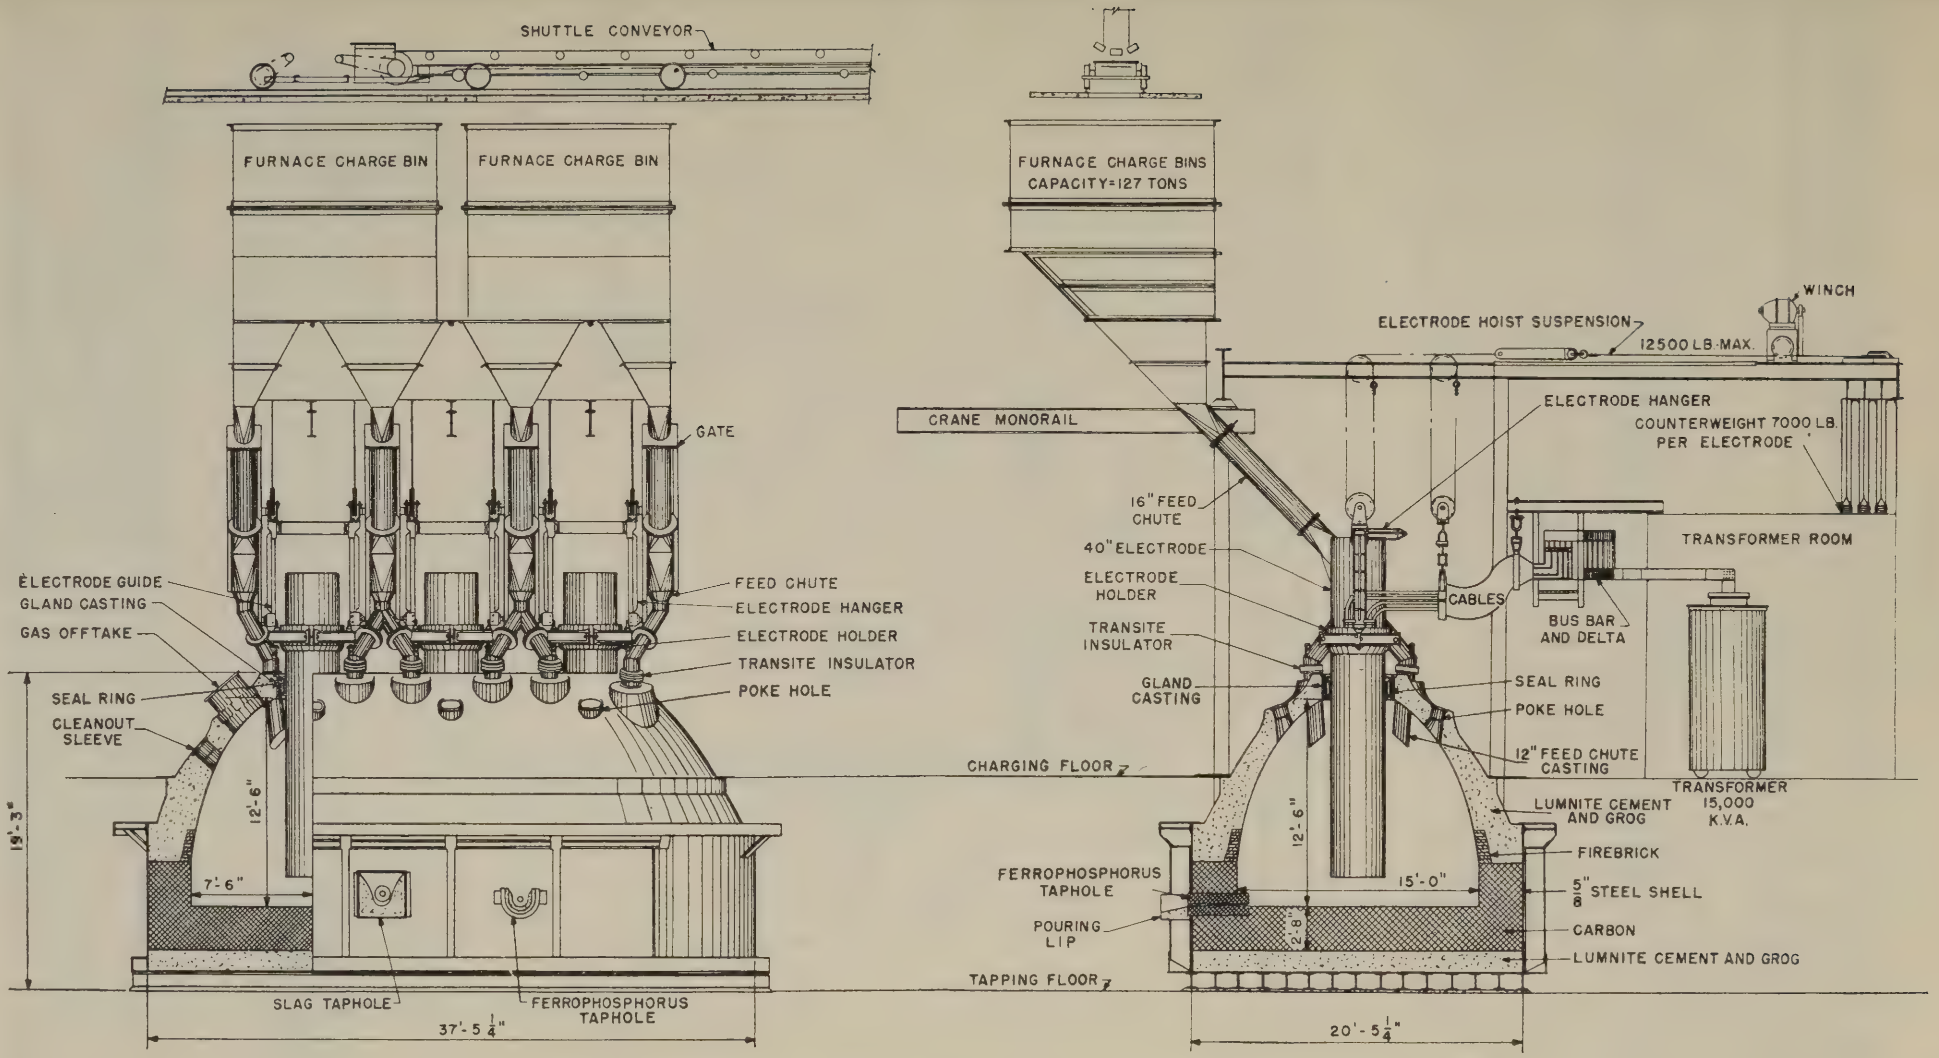

FIG. 1.—General arrangement of T.V.A. No. 6 phosphorus furnace

The current used by a three-phase furnace depends on its size and varies between 5000 and 50,000 amps. The potential difference between the electrodes is usually between 170 and 300 volts. The largest furnace in operation in 1960 had an electrical energy consumption of 50,000 kilowatts.[85]

### A RECTANGULAR FURNACE

A furnace operated by the Tennessee Valley Authority[116] is shown in Fig. 1.

This is a rectangular-type furnace of 13,400 kilowatts capacity with three in-line electrodes operating at a potential of 300 volts. Under normal conditions 14 lb. of electrode are consumed per ton of $P_2O_5$ in the furnace charge and 97% of the $P_2O_5$ is reduced to phosphorus. 87% of the phosphorus in the charge is recovered as the element. The electricity consumption is 6·1 kwh. per lb. of phosphorus recovered. This figure depends on the size of the furnace and on the quality of the raw materials used. Other values of 6·5–7[85] and 5·8–7[86] kwh. per lb. of phosphorus have been given.

### A ROTATING FURNACE

A rotating furnace, originally designed for producing calcium carbide and iron alloys[117] has been adapted for producing phosphorus.[118] This is shown diagrammatically in Fig. 2. The furnace is of cylindrical type, 3-phase, with a triangular

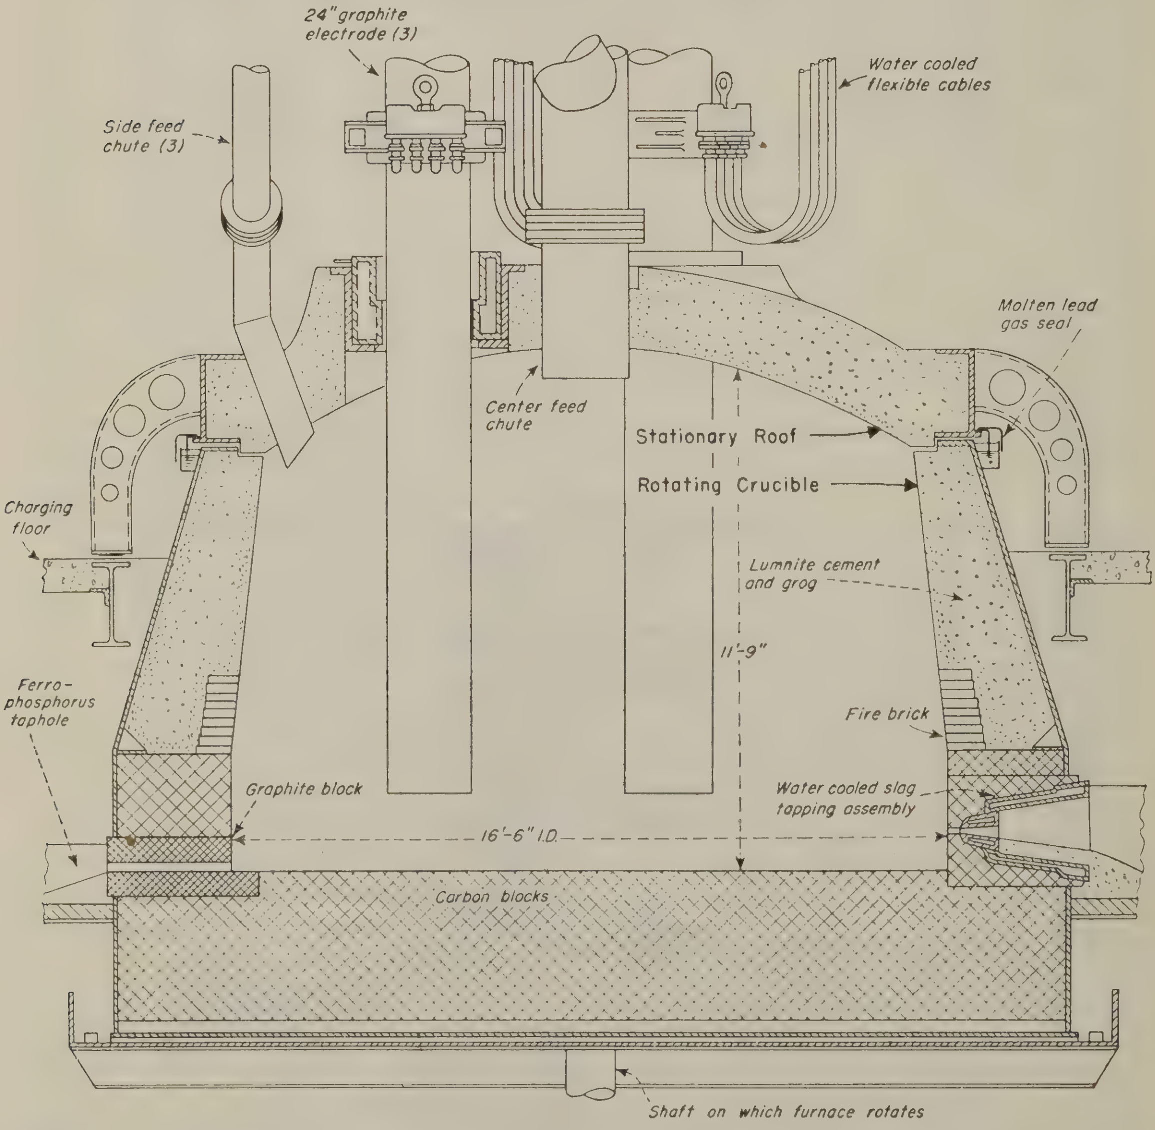

FIG. 2.—A rotating phosphorus furnace with stationary roof, electrodes, cables and feed chutes

arrangement of electrodes operating at a phase voltage of 300–350 volts. The capacity is 7500 kilowatts. The electrodes are stationary and the bottom of the furnace can be rotated at a speed of between 20 and 100 hr. per revolution. Consumption of electrodes varies between 7 and 12 lb. per ton of $P_2O_5$ in the charge. For short periods of operation the electricity consumption is 5·5 kwh. per lb. of phosphorus produced. This decreases to 5·1 for continuous operation.[119] Other advantages of the rotating furnace are increased life of the lining and the use of cheaper phosphate fines instead of lump material. A similar furnace of 25,000 kw. capacity has been described,[269] as has the design and operation of a plant based on the rotating furnace.[270]

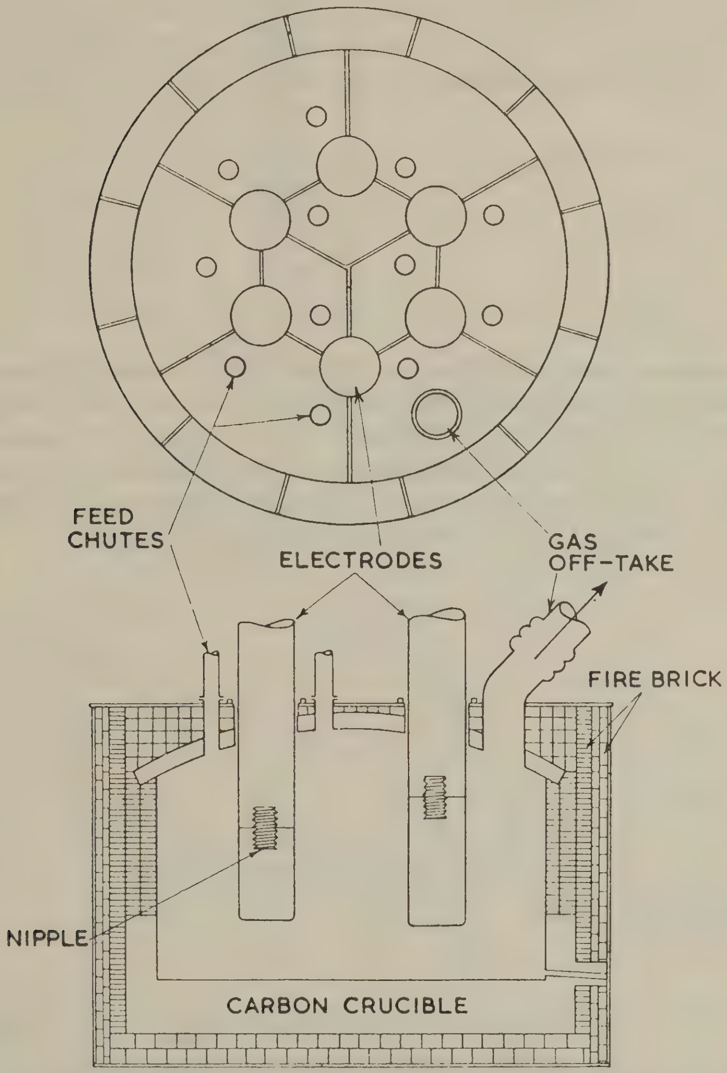

FIG. 3.—Diagrammatic sketch of a circular six-phase electric furnace

A six-phase furnace of cylindrical construction has been described[120] and is shown in Fig. 3. Observations[121] and data[122] on other furnaces have been reported. The principles to be followed in the design and construction of high efficiency phosphorus furnaces have been discussed in terms of the nature of the feed, furnace dimensions and other parameters.[271]

### THE CHARGE

In the operation of an electric furnace a phosphate ore with a minimum $P_2O_5$ content of 25% is generally required.[123] The charge must be maintained in a sufficiently porous state to allow the gaseous products to escape freely. The most suitable size for the raw materials is 0·5 to 2 in. If the phosphate rock has a small particle size, it must be agglomerated in some way. This may be done by briquetting,[124] nodulizing,[125] sintering with coal or by pellet formation in some suitable way.[126] Poor quality rock, especially if high in calcium carbonate, can be improved for electric furnace use by a preliminary heat treatment at 950–1050°.[261]

*Table VII.—Reduction of Fluorapatite by Various Forms of Carbon*

| Reducing agent | Temp. °C. | % $P_2O_5$ reduced |
|---|---|---|
| Lampblack | 1400 | 26 |
| | 1450 | 45 |
| | 1500 | 62 |
| Metallurgical coke | 1400 | 55 |
| | 1450 | 65 |
| | 1500 | 70 |
| Petroleum coke | 1400 | 31 |
| | 1450 | 49 |
| | 1500 | — |
| Pitch | 1450 | 76 |
| | 1500 | 90 |

The carbon used is generally in the form of coke or anthracite. Some differences in the relative reducing efficiencies of various forms of carbon have been noted,[127] but this effect seems to be dependent on the reaction temperature.[128] Some data are given in Table VII for the reduction of fluorapatite with the theoretical amount of carbon to reduce all the $P_2O_5$, in the presence of sufficient silica to give a $SiO_2:CaO$ weight ratio of 0·85 in the mixture,[116] the reaction time being 10 min.

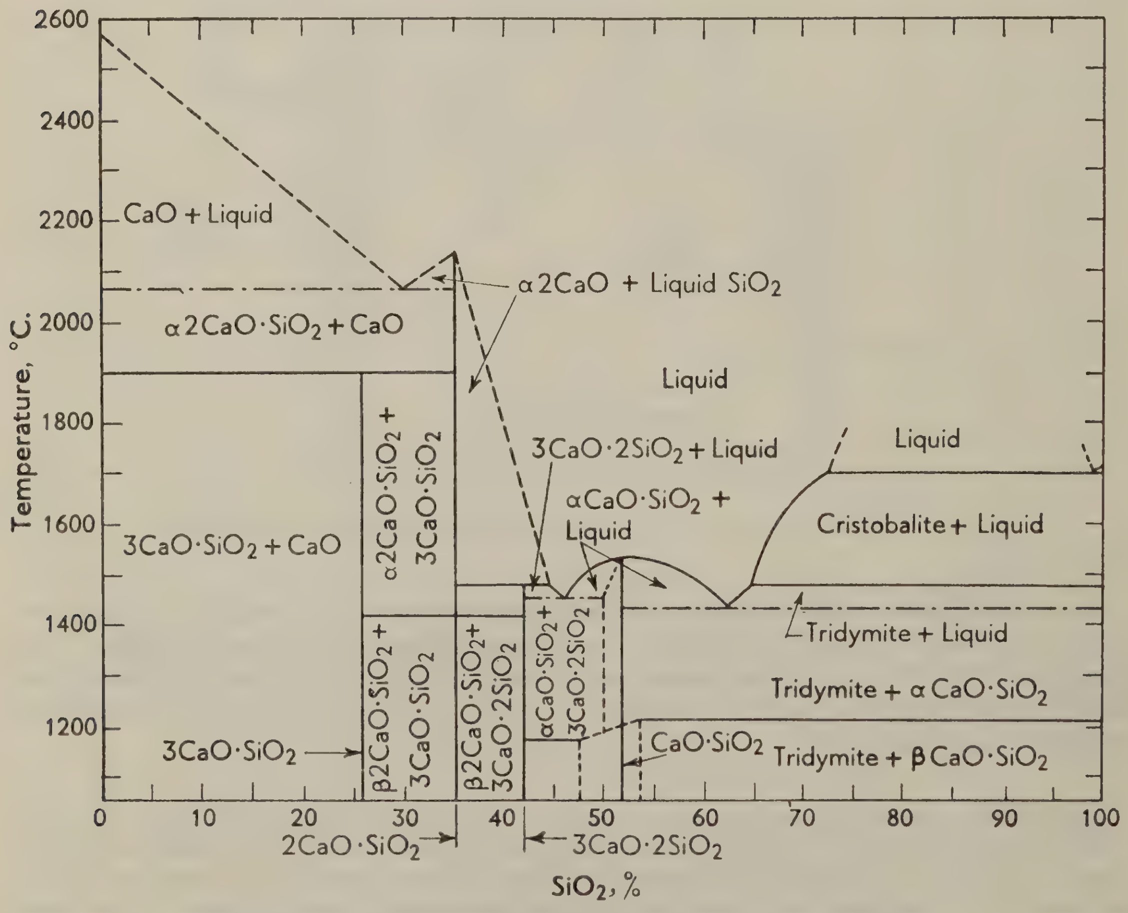

FIG. 4.—Equilibrium diagram for the system CaO–SiO₂

The composition of the charge has an important bearing on the operation of a phosphorus furnace. The properties of the slag and the amount of it produced are determined by the lime:silica ratio. Experimental furnaces have been operated with $CaO:SiO_2$ weight ratios varying between 0·70 and 2·00 (reference 116, p. 245), but for commercial production it is considered that for smooth operation of the furnace the ratio should be unity[86] or between 1·1 and 1·25.[129] With ratios of 0·6–0·9, more easily fusible slags are obtained and the yield of phosphorus increases somewhat, but more electrical energy is required and the attack on furnace linings is increased. With more basic compositions, i.e. $CaO:SiO_2$ ratios between 1·30 and 2·0, increasing quantities of silica are volatilized with the phosphorus. This appears to be a consequence of an increase in the fusion temperature of the charge. Any silica coming in contact with a melt at high temperature tends to be volatilized before slag formation occurs.[130] The $CaO–SiO_2$ equilibrium diagram[131] is shown in Fig. 4.

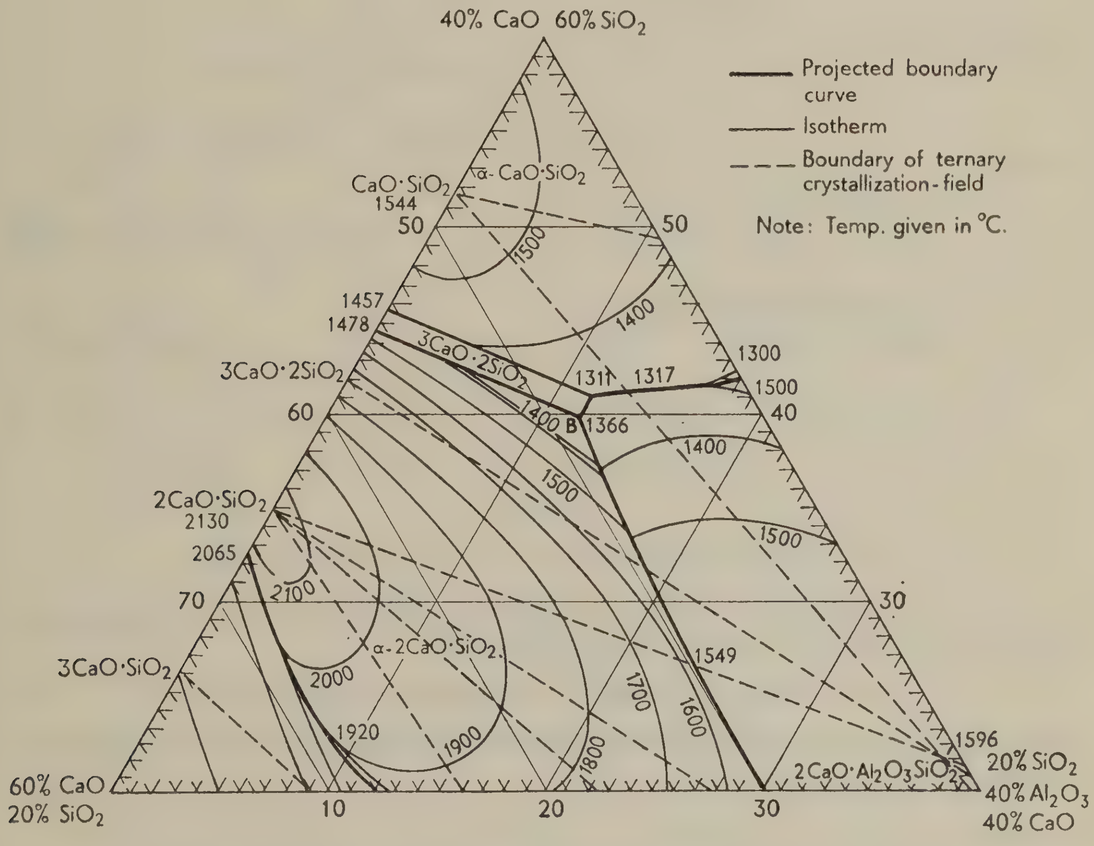

FIG. 5.—Equilibrium diagram for the system $CaO–Al_2O_3–SiO_2$

Any alumina which is present in the charge enters the slag and forms compounds with the lime and silica in the latter. An alumina content of up to 10% in the slag lowers the fusion temperature and causes difficulty in operating the furnace. On the other hand alumina acts as a fluxing agent and can be used to replace part of the silica in the charge. Experimental observations are reported.[116] Phase diagrams of the $CaO–Al_2O_3–SiO_2$ and $CaO–Al_2O_3$ systems[132] are shown in Figs. 5 and 6. The $Ca_3(PO_4)_2–SiO_2$ system has also been investigated.[133]

The presence of iron in the furnace charge is detrimental. Large amounts of ferric oxide lower the m.p. and melting usually starts in the upper part of the furnace. This causes the electrodes to rise, increases the temperature of the furnace gases and also the dust concentration. The ferric oxide is reduced to iron, which combines with the gaseous phosphorus to form ferro-phosphorus. These reactions increase the electrical energy consumption and also result in a lower thermal efficiency. The reduction of iron compounds occurs at much lower temperatures than are required for the phosphate in the charge. Carbon monoxide reduces $Fe_2O_3$ at above 200°C. to form FeO and the latter is reduced by carbon to form iron at 950°C. Iron phosphate is reduced to $Fe_3P_2$ at temperatures above 600°C.[134] Formation of iron–phosphorus alloys is therefore largely unavoidable in phosphorus furnaces. These alloys usually contain 20–28% of phosphorus, which, from the phase diagram[135] shown in Fig. 7, corresponds to a mixture of $Fe_2P$ and FeP. The quantity of phosphorus discharged from the furnace as ferrophosphorus is about 2–8% of the phosphorus present in the initial feed. It has been proposed to recover this by converting the ferrophosphorus into trisodium phosphate according to the equation[136]:

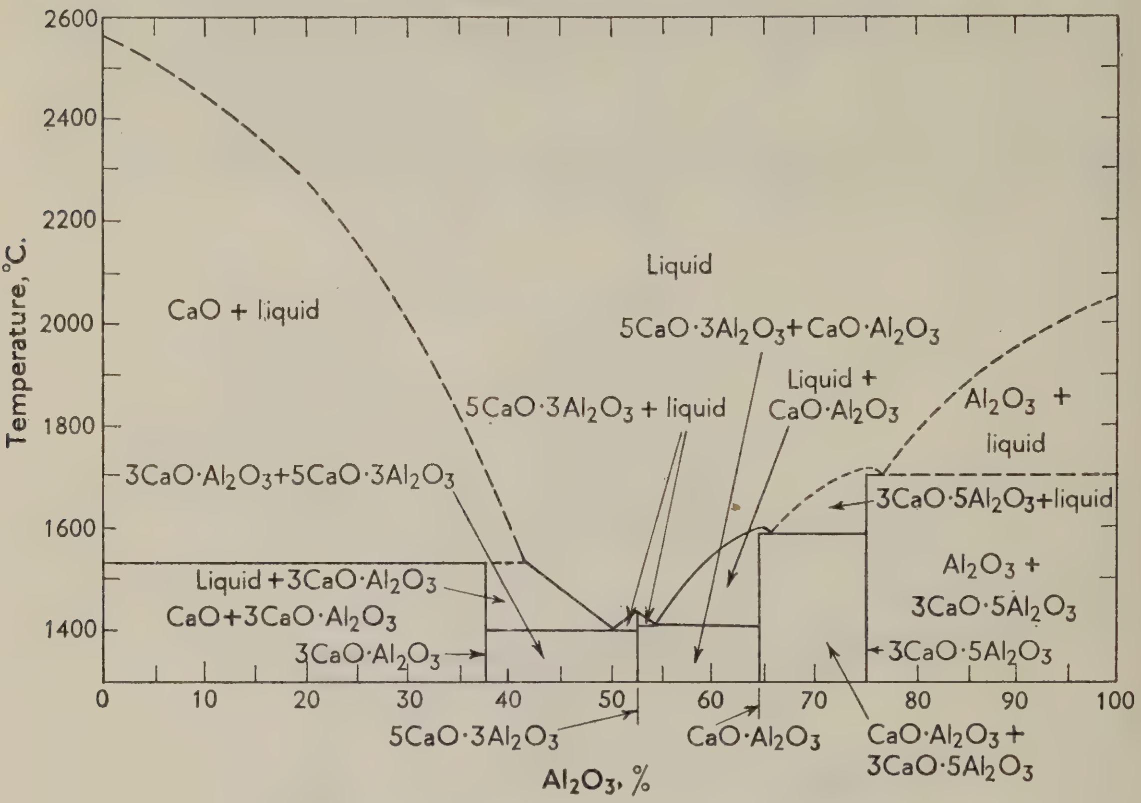

FIG. 6.—Equilibrium diagram for the system CaO–$Al_2O_3$

$$2FeP + 3Na_2CO_3 + 4O_2 = 2Na_3PO_4 + Fe_2O_3 + 3CO_2$$

Alternatively a portion of the phosphorus may be vaporized from ferrophosphorus by melting it in a vacuum.[262]

### THE SLAG

The calcium silicate slag usually contains 3–7% of the phosphorus originally charged into the furnace. The analysis of this material varies with the quality and composition of the raw materials and the method of operation of the furnace. Some typical data are given in Table VIII for plants in operation in England,[86, 137] America[116, 111, 129] and Germany.[95]

*Table VIII.—Typical Percentage Analyses of Phosphorus Furnace Slags*

| | England | U.S.A. | Germany |
|---|---|---|---|
| $P_2O_5$ | 0·5–2·0 | 1·0 | 0·6 |
| $SiO_2$ | 39–43 | 38–40 | 47 |
| CaO | 47–51 | 48–50 | 43 |
| $Fe_2O_3$ | 0·1 | 0·1–0·3 | 0·3 |
| $Al_2O_3$ | 3–5 | 5·9–6·2 | — |
| F | 3–4 | 2–3 | — |

Most slags contain up to 3% of fluorine which may be present as cuspidine, $3CaO,2SiO_2,CaF_2$.[138] About 90% of the fluorine in the furnace comes out in the slag. If the phosphate ore is nodulized or sintered, 30–50% of the fluorine may be volatilized in the process.[86]

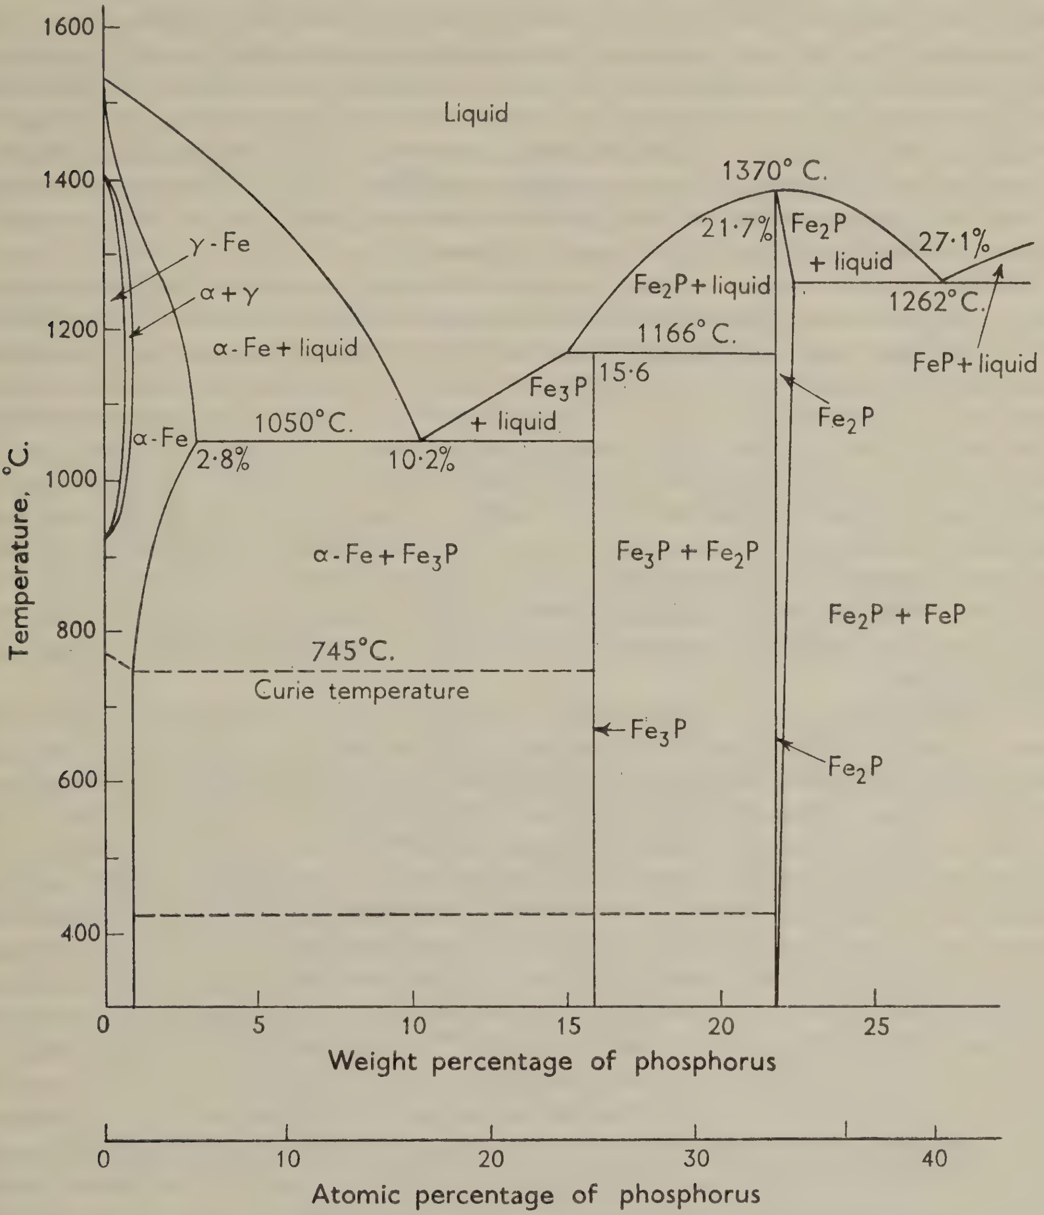

FIG. 7.—Phase diagram of the iron–phosphorus system

### THE FURNACE GASES

The gases leave the furnace at temperatures between 200° and 400°C. A typical composition by volume is: 7–8·5% P, 70–85% CO, 3% $H_2$, 1% $CH_4$, 1% $C_2H_4$, 0·5% $SiF_4$ and 0·5% $CO_2$.[111, 120] A variable amount of dust is also present and this is removed by passing the gases through electrostatic precipitators which operate at discharge potentials as high as 60,000 volts.[120] The partial pressure of the phosphorus vapour in the gases is between 50 and 60 mm. From the vapour pressure equation[139]:

$$\log p_{\text{mm.}} = 18{\cdot}8192 + 1{\cdot}074 \times 10^3 T - 3{\cdot}906 \log T - (3{\cdot}2167 \times 10^3)/T$$

this corresponds to a dewpoint of 170° to 176°C. The furnace gases have therefore to be kept above this temperature in the precipitator unit so as to prevent condensation of phosphorus. The dust which is collected contains some phosphoric acid formed by oxidation and hydration of phosphorus by traces of oxygen and moisture in the equipment. A typical analysis of the dust is[111, 116]: $P_2O_5$ 28–38%, CaO 10–16%, $SiO_2$ 18–20%, $K_2O$ 13–16%, $Na_2O$ 3%, $Al_2O_3$ 3·4%, $Fe_2O_3$ 1·5% and F 6%. The design, construction and operation of precipitator equipment have been described in detail.[116]

After leaving the precipitator the furnace gases are passed through equipment for condensing the phosphorus. This is usually a wet, spray-type condenser or a dry, surface condenser. In both cases they are operated at above the m.p. of phosphorus (44°C.) and molten phosphorus is run to storage under water. For technical details and a discussion of the relative merits of phosphorus condenser systems, reference 116 should be consulted. It has been proposed to recover the phosphorus by means of active charcoal, followed by steam treatment at 200° to 350°C.[140] Aqueous solutions of ammonia and ammonium fluoride have been suggested instead of water as a means of reducing scaling in condenser equipment.[141]

Some of the dust in the furnace gases persists after passing through the precipitators, and becomes emulsified with the phosphorus in the condensers. This forms a mud which contains a significant proportion of the phosphorus in the original raw materials. For example, the mud from the T.V.A. No. 6 furnace described above contained 69% P, 7·6% $P_2O_5$, 3% CaO, 9% F and 1·8% $Fe_2O_3$. This represented 13% of the phosphorus charged to the furnace (see reference 116, page 167). Phosphorus mud appears to be a dispersion of water and colloidal silica or carbon in molten yellow phosphorus. It does not have a sharp melting point, but slowly separates phosphorus when heated below 100° to give a viscous residue containing about 50% P.[255] The phosphorus may be recovered from the mud by vacuum,[142] flash[143] or steam[144] distillation, by centrifugation[254] or by volatilization in a mud furnace. The most convenient method, however, seems to be incorporation with a subsequent furnace charge.

The exhaust gas from the condensers contains about 20% by weight of water when spray-type equipment is used. The volume composition on a dry basis is approximately: 92% carbon monoxide, 5% hydrogen and 2% nitrogen, with minor amounts of carbon dioxide, phosphine and methane. The phosphorus content is about 0·5 lb. per 1000 cu. ft. The calorific value averages 300 B.Th.U. per cu. ft. and the gas may be used as a fuel in other parts of the process,[145] e.g. in kilns for nodulizing the phosphate ore. The use of the gas for synthetic processes, e.g. ammonia or methanol production,[146] has been considered. For this, some purification is necessary in order to remove traces of phosphorus, phosphine, hydrogen sulphide and other unwanted impurities. Several methods have been proposed for removing phosphorus, including absorption in high boiling oils or salt solutions[147] or reaction with phosphate rock[148] or silicofluorides.[149] Phosphorus and phosphine may be removed by catalytic reaction with metals such as copper, iron, titanium or cerium.[150] Oxidation with mixtures of oxygen and nitrogen has been suggested, but this carries with it an explosion hazard. Mixtures of nitric oxide and nitrogen dioxide are safer to use.[151] Chlorine and hypochlorite are alternative oxidizing agents[152] and passing the gas over ferric oxide at temperatures above 250°C. is claimed to be satisfactory.[153] Hydrogen sulphide is removed by washing the gas with a suspension of ferric hydroxide.[147] A product suitable for use in the synthesis of methanol is obtained by mixing a gas containing: CO 75–85%, $CO_2$ 2–5%, $H_2$ 5–7·5%, $N_2$ 10–20%, $CH_4$ 0–2%, $PH_3$ 0·05–0·8% and $H_2S$ 0·04% with half its volume of steam and reacting with siderite ($FeCO_3$) at 350°C. Activation of the latter with CuO is an advantage.[154] Another catalyst which has been used consists of: $Al_2O_3$ 60%, $Fe_2O_3$ 30%, $Cr_2O_3$ 8% and $ThO_2$ 2%.[155] Details have been given (reference 116, page 285) of the oxidation of phosphorus and sulphur by nitric and sulphuric acids, followed by absorption in a packed tower or in a limestone bed. The theory of the condensation of phosphorus in inert gases has been discussed.[156]

### RECOVERY OF BY-PRODUCTS

Recovery and utilization of the various by-products from the electrothermal production of phosphorus have been considered by a number of investigators. The possibility of doing this, however, is limited in most instances by economic considerations. Fluorine is present in the silicate slag, in the precipitator dust and in the phosphorus condensers. Silicofluorides or pure fluorine could be recovered by relatively simple procedures, but this does not appear to be worthwhile.[157] Any vanadium present in the phosphate ore is mostly concentrated in the ferrophosphorus, the concentration in the latter being as high as 5%.[158] One method of recovering this is to roast the ferrophosphorus with sodium carbonate and sodium chloride and then extract the phosphorus and vanadium by leaching with water. Phosphorus is crystallized as trisodium phosphate and the solution hydrolyzed to precipitate vanadium pentoxide. A 95% recovery of both elements is claimed.[159] Vanadium and chromium have been recovered by a three-stage crystallization and hydrolysis process.[160] Attempts have been made to recover uranium from the silicate slag. The best recovery (about 50% of the uranium) was achieved with a high temperature liquid–liquid extraction procedure.[161]

Up to 8 or 9 tons of calcium silicate slag are produced per ton of phosphorus recovered from an electric furnace. Numerous attempts have been made to find an economic outlet for this material. Some of the more important of these are summarized below:

(1) The use of slag for road making is limited by the expense of handling and crushing the material. Its properties as an aggregate for concrete compare well with those of gravel.[108]
(2) Granulated slag as a raw material in the manufacture of Portland cement is satisfactory so far as tensile strength, setting time and other physical properties are concerned. Replacement of some of the $SiO_2$ in the furnace charge by $Al_2O_3$ gives slags which can be converted into aluminous cements. However, the compressive strength of concrete made from these cements may be much lower than that made from commercial products.[116]
(3) As an agricultural material quenched slag has some value as a liming agent, being as effective in this respect as dolomite or limestone.[162] The phosphate present in it has a slight fertilizing action.[163–4]
(4) An expanded slag formed by quenching the molten material with water and steam, and having a cellular structure, can be produced at low cost and is suitable for the construction of concrete blocks.[165]
(5) The production of slag wool as a thermal insulation material has been examined, but does not seem to be competitive with conventional materials.
(6) The manufacture of ceramic bodies and glazes from slag is possible, but the use of the products is limited by the slight radioactivity of the slag.

The main outlet for ferrophosphorus is for the manufacture of special steels. This may necessitate decreasing the proportion of coke in the furnace charge so as to produce a ferrophosphorus of the required quality. Because all the ferrophosphorus produced is not used in steel-making, several alternative uses have been investigated. Roasting with 1·2 parts of limestone for 30–60 min. at 1000° to 1200°C. converts it into a material containing 19–20% $P_2O_5$ which is suitable as an animal feed supplement. The product also has some action as a fertilizer, but is less effective in this respect than superphosphate.[166] The results of animal-feeding tests have been reported.[167] Electrolysis of ferrophosphorus anodes under acid, alkaline or neutral conditions yields soluble iron phosphate, ferric oxide or insoluble iron phosphates, respectively. These products find some application as pigments for anticorrosive paints.[168–9] Alloys containing 3–12% P and 6–20% Si, which are resistant to corrosion by phosphoric, sulphuric and hydrochloric acids, have been made from ferrophosphorus.[116]

The dust recovered from the electrostatic precipitators is valuable as a potash–phosphate type fertilizer.

The technology of the production of phosphorus by the electrothermal process, the selection and composition of raw materials, furnace construction and operation and

**Refs. p. 143**

furnace burden calculations have been discussed in detail.[85, 129] The Tennessee Valley Authority Report No. 3[116] gives a very full account of the chemical engineering involved in the design, operation and development of various types of furnace, and includes many useful data and diagrams.

Typical data, taken from various sources, for weights of raw materials used and products obtained in normal furnace operation are given in Table IX. The figures refer to weight of material per ton of phosphorus produced. For the composition of the materials and other information, the original references should be consulted. The amount of silica used by the T.V.A.[116] is lower than that for other processes because of the very high silica content (24% $SiO_2$) of the T.V.A. phosphate ore. Other data have been reported.[170–1]

THERMAL EFFICIENCY

The thermal efficiency of the process depends on a number of factors such as the size of the furnace, method of operation, composition of the charge and the amount and composition of the slag. It has been estimated,[102] for example, that a decrease in the $P_2O_5$ content of the phosphate ore from 26 to 25% increases the electrical energy requirement by about 340 kwh. per ton of $P_2O_5$ charged to the furnace. A calculation[116] of the heat balance in a furnace shows that of the electrical energy put in 49%

*Table X.—Thermal Data in Phosphorus Furnace Operation*[116]

is used in the reaction, 33% is lost as sensible heat and 10% by radiation, conduction and convection. About 8% of the heat could not be accounted for. This was attributed to uncertainty in the thermochemical data, undetermined electrical losses and to the assumptions made as to the composition of the slag and its heat of formation. The sensible heat lost in tapping the slag from the furnace at 1450°C. accounts for about 29% of the electrical energy input, and 58% is required to reduce the phosphate ore. Another estimate[102] gives the distribution of the energy input as 51% for chemical reactions, 35% for sensible heat losses and 9% for radiation, conduction and convection, leaving 5% of the energy unaccounted for. Some useful thermal data are given in Table X, exothermic reactions being indicated by a negative sign.

Some modifications of the electrothermal method of producing phosphorus have been described.[172–3] Operation at temperatures as low as 500°C.[174] and the use of high-frequency current[175] are said to be successful. A high-pressure pump[176] and metering apparatus[177] for use with molten phosphorus have been described. Precautions to be taken to ensure the safe handling of white phosphorus have been outlined,[267] and a sampling technique for molten phosphorus has been suggested.[268]

In many instances the production of phosphorus is coupled with that of phosphoric acid. The development of a continuous process of this type has been reported in detail.[178] The production technology[179–80] and corrosion problems[181] have been discussed. Alternative methods of burning,[182] vaporizing[183] or oxidizing[184] phosphorus have been given.

## Purification of Phosphorus

Phosphorus made by the electrothermal process usually has a purity of 99·8% or more.[86] An American specification for good quality material is[85]:

| | |
|---|---|
| Insoluble in benzene | 0·006–0·025% |
| Oil | 0·001–0·020% |
| Arsenic as $As_2O_3$ | 50–180 p.p.m. |
| Iron as Fe | 1–8 p.p.m. |
| Fluorine as F | 1–4 p.p.m. |

Technical grade yellow phosphorus is less pure and the impurities in this have been given as[185]:

| | |
|---|---|
| Arsenic as As | 40–113 p.p.m. |
| Sulphur as S | 5–10 p.p.m. |
| Iron as Fe | 3–20 p.p.m. |
| Magnesium as Mg | 1–3 p.p.m. |
| Antimony as Sb | 130–135 p.p.m. |
| Silicon as Si | 5000–10,000 p.p.m. |
| Carbon as C | 50–1400 p.p.m. |
| Fluorine as $F_2$ | 7 p.p.m. |

Up to 5 p.p.m. of calcium and copper, and traces of lead and manganese may also be present.

Various methods of purification have been described. The procedures used depend on the quality of the phosphorus required, the purest material being that used in semiconductors. Stirring molten yellow phosphorus with a dilute solution of sodium or potassium dichromate acidified with sulphuric acid removes traces of phosphorus pentoxide, calcium oxide, fluorine, iron and some organic matter.[116] A white or colourless phosphorus is obtained by filtering the liquid through a bed of active carbon. Heating phosphorus for a short time at 70°C. in an inert atmosphere with a small percentage of polyphosphoric acid (75–85% $P_2O_5$) and then filtering through active carbon and Fullers earth reduces the organic impurities (hydrocarbons and phenols) to less than 0·01% and the inorganic impurities (As, Pb, Fe, Mn, Si, Ca and Mg) to 0·005%.[186]

Most of the arsenic can be removed by steam distillation, but to reduce the content to 5 p.p.m. of $As_2O_3$ or less requires a multistage process.[187] Purification of crude phosphorus by solvent extraction[188] or by distillation in an inert atmosphere alone[189] or in the presence of active charcoal[273] has been suggested.

Several procedures have been described for obtaining very pure phosphorus for use in preparing semiconductors. In one method phosphorus is heated in contact with silver, cobalt, copper, chromium, iron or molybdenum at 200° to 900°C. This gives the metal phosphide which is then decomposed at a higher temperature or a lower pressure to give phosphorus of semiconductor purity.[190] Arsenic, sulphur or selenium can be removed by heating phosphorus under reflux with lead or aluminium.[274] Electrodialysis[275] or agitation[276] of phosphorus with dilute nitric acid also effects purification. Technical yellow phosphorus can be purified by filtering at 90°C., stirring with 20% potassium hydroxide, cooling and then removing the alkali. The phosphorus is then heated to 50°C. in a nitrogen atmosphere and stirred with 5% sulphuric acid, then with water, and finally it is distilled at 100°C. and 2 mm. pressure. Most of the halogens, sulphur, arsenic, silicon, copper, magnesium, calcium, antimony and iron are removed by this treatment. The carbon content is reduced to below 20 p.p.m. by passing phosphorus vapour over quartz at 900° to 1200°C. and chilling. Much red phosphorus is formed during this operation, and is removed by distilling or filtering. The white phosphorus is then vacuum distilled, the first 10% being rejected and the next 30% is recovered.[185] A further reduction to below 5 p.p.m. of carbon is achieved by vaporizing the purified phosphorus at 90° to 300°C. and 0·1–100 mm. pressure followed by heating at 800° to 1200°C. for 0·1–10 sec. in the presence of quartz. This decomposes hydrocarbons, deposits carbon on the quartz, and phosphorus is condensed out of the system.[191] The technique of zone refining has also been used to purify phosphorus, heat being applied by a heated perforated iron slug, moved magnetically.[277] Typical values for the trace elements in highly-purified phosphorus are[185]:

| | |
|---|---|
| Calcium | 0–4 p.p.m. |
| Copper | 0·2 p.p.m. |
| Magnesium | 0·1–0·9 p.p.m. |
| Carbon | < 5 p.p.m. |
| Silicon | 2–4 p.p.m. |
| Antimony | 0·5 p.p.m. |
| Arsenic | 15–40 p.p.m. |
| Sulphur | nil |
| Iron | nil |
| Halogens | nil |

Pure red phosphorus has been obtained by heating pure white phosphorus to 200°C. and then raising the temperature in steps of 50° to 350°C. over a period of four days. After 48 hr. at 350°C. the product is slowly cooled to give red phosphorus containing the minimum amount of the white variety[185] (see also p. 138).

Heating red phosphorus at 70–95°C. with a 3–5% solution of a mineral acid and then distilling at $10^{-2}$ to $10^{-4}$ mm. pressure is claimed to reduce the total iron, aluminium, copper and silicon content from above 80 p.p.m. to 5 p.p.m.[192] Evaporating red phosphorus in a vacuum at 900° to 950°C. or in the presence of hydrogen, helium or argon and then condensing in a quartz tube is said to give pure phosphorus.[193]

Potassium, calcium, iron, manganese and copper are removed by heating red phosphorus with 10% potassium hydroxide solution, drying the phosphorus and then vacuum distilling at 400°C. The distillate is then heated for several days at 300°C. in a sealed quartz tube to convert it into red phosphorus. This is again converted into white phosphorus by distilling it in the presence of metallic indium and allowing it to stand in contact with indium for one day at 150°C. The product is finally distilled at 300°C. to convert it into red phosphorus of 99·9999% purity, containing 1–2 p.p.m. of silicon and magnesium.[194] Oxide impurities in trace amounts are often present in phosphorus which has been purified by sublimation in hydrogen, by zone melting or by vacuum distillation. These are reduced to a minimum by subliming red phosphorus at 300° to 380°C. and $4 \times 10^{-5}$ mm. pressure and then redistilling the white phosphorus in quartz at 150°C. Titanium metal is used to absorb traces of oxygen in the apparatus.[195]

### Chemical Reactions in the Phosphorus Furnace

The formation of phosphorus by the reaction of fluorapatite with carbon and silica in the temperature range 1400° to 1600°C. can be represented approximately by the equation[86]:

$$2Ca_{10}(PO_4)_6F_2 + 18SiO_2 + 30C = 3P_4 + 2CaF_2 + 18CaSiO_3 + 30CO$$

If variations in the lime:silica ratio in the furnace charge are taken into account, the following generalized equation may be written[129, 196]:

$$\begin{aligned}(4+4y)Ca_5(PO_4)_3F + (20x+1-9y)SiO_2 + (30+30y)C \\ = 20(CaO,xSiO_2,yCaF_2) + (1-9y)SiF_4 + (30+30y)CO + (3+3y)P_4\end{aligned}$$

The mechanism of the reduction has been the subject of much investigation. Various explanations have been given, but there seems to be insufficient experimental evidence to establish any one of them conclusively.

At high temperatures silica and, to a lesser extent, alumina act as strong acids in the decomposition of phosphate rock. Silica and tricalcium phosphate start to react at about 1150°C. and at 1630°C. the compound $Ca_3P_2O_8,3SiO_2$ is said to be formed. This compound is readily reduced by carbon.[133] Silica alone does not form elemental phosphorus when it reacts with phosphate rock at furnace temperatures, but at higher temperatures (above 1800°C.) some phosphorus pentoxide may be liberated (reference 116, page 3).

When carbon and silica are both present the latter accelerates the sublimation of phosphorus from fluorapatite and also lowers the temperature at which this occurs. At 1600°C. phosphorus is completely volatilized in 1 hr. on heating fluorapatite with wood charcoal in the presence of 1% of silica. If the amount of silica is increased to give a $SiO_2$:CaO ratio of 1·07 in the system, the same result is obtained at temperatures as low as 1350°C. Silica and carbon are also necessary for the removal of fluorine from fluorapatite. None of this element is volatilized at 1600°C. when only carbon is present. However, with the addition of silica as much as 50% of the fluorine can be removed in 1 hr. at 1450°C.[82]

Most of the investigations into the reactions occurring in the phosphorus furnace have been carried out with tricalcium phosphate. It is well established that the reaction of this material with carbon and silica at temperatures between 1000° and 1600°C. is represented by the equation:

$$Ca_3(PO_4)_2 + 5C + 3SiO_2 = \tfrac{1}{2}P_4 + 3CaSiO_3 + 5CO$$

The heat required for this reaction is very close to that calculated for the above equation, when a blast furnace process is used.[197]

In the absence of silica the net effect is:

$$2Ca_3(PO_4)_2 + 10C = P_4 + 6CaO + 10CO$$

Various figures between 1000° and 1400°C. have been given for the temperature at which tricalcium phosphate is reduced by carbon. This may be as low as 1100°C., but at this temperature the reaction is very slow.[198] It is also necessary to consider the temperature in relation to the amount of silica present, because this compound lowers the reaction temperature. For example, it is reported[199] that 90% of the phosphorus is volatilized in 1 hr. at 1300°C. from a mixture of equal weights of coke and phosphate rock. However, this mixture contained 7·5% of silica, derived from the coke and the rock. On the other hand if silica is absent phosphorus is volatilized from a mixture of carbon and tricalcium phosphate at a rate of 45% in 1 hr. at 1300°C., 96% at 1400°C. and 100% at 1550°C. In small scale experiments using pure carbon flour and tricalcium phosphate, volatilization of phosphorus was found to start at 1150°C.

The effect of the amount of carbon is shown in Table XI for mixtures heated for 1 hr. at 1400°C.[127]

Rates of reaction in the temperature range 1200° to 1500°C. have been measured[127] for mixtures of tricalcium phosphate and carbon and also for mixtures containing added silica and alumina.[200] The rate of reaction was found to be first order with respect to the tricalcium phosphate. The values of $k$ in the first order equation $kt = \log_e(a/a-x)$ were calculated with the results shown in Table XII.

*Table XI.—The Effect of Carbon to Phosphorus Ratio on the Volatilization of Phosphorus from Tricalcium Phosphate in 1 hr. at 1400°C.*

| Weight ratio $C:P_2O_5$ | Phosphorus volatilized % |
|---|---|
| 0·383 | 82·2 |
| 0·543 | 88·6 |
| 0·933 | 95·2 |
| 2·188 | 99·8 |

Because these reactions are first order it was suggested that the mechanism of the reduction involved the dissociation of tricalcium phosphate into lime and phosphorus pentoxide, followed by the reduction of the latter by carbon:

$$Ca_3(PO_4)_2 \rightleftharpoons 3CaO + P_2O_5$$
$$P_2O_5 + 5C \doteq 5CO + P_2$$

*Table XII.—First-order Velocity Constants for the Reduction of Tricalcium Phosphate*[127]

| Temp. °C. | Velocity constant, $k$ mm.$^{-1}$ C alone | $C+SiO_2$ | $C+Al_2O_3$ |
|---|---|---|---|
| 1200 | 0·00346 | 0·0167 | — |
| 1250 | 0·01126 | 0·0492 | — |
| 1300 | — | 0·1257 | 0·0682 |
| 1400 | 0·0747 | — | — |
| 1500 | 0·329 | — | — |

It was observed that the reduction of phosphorus pentoxide started at 800°C. On this basis it was concluded that this reaction would be rapid at 1200°C., so that the rate-determining step in the reduction of the tricalcium phosphate is the dissociation of the latter.[127] However, it has also been reported that substantially no reduction of phosphorus pentoxide by carbon occurs at temperatures below 1200°C.[201] Since this reduction takes place between solids at the lower temperatures, the explanation of the two observations may be that in one of them[127] a considerable excess of carbon was used. Analysis of samples taken from a phosphorus furnace during overhaul showed that no appreciable volatilization of phosphorus from the phosphorite occurs until it has melted, probably by slagging with silica.[266] Carbon monoxide does not reduce phosphorus pentoxide to any extent under normal furnace conditions, but it is possible that any carbon monoxide formed by reduction of the pentoxide may act as a catalyst in some other reaction. No dissociation of tricalcium phosphate was observed on heating it in a vacuum for 1 hr. at 1300° to 1400°C.[128] In the presence of carbon, therefore, the following reaction can occur:

$$2Ca_3(PO_4)_2 + 10CO = 6CaO + 10CO_2 + P_4$$

The action of silica in accelerating the reduction of phosphate rock by carbon has been known since 1826,[202–3] but no systematic examination of this was carried out for a century. The effect of variations in the flux:lime ratio on the volatilization of phosphorus from mixtures containing equal weights of tricalcium phosphate and carbon is shown in Fig. 8.[200]

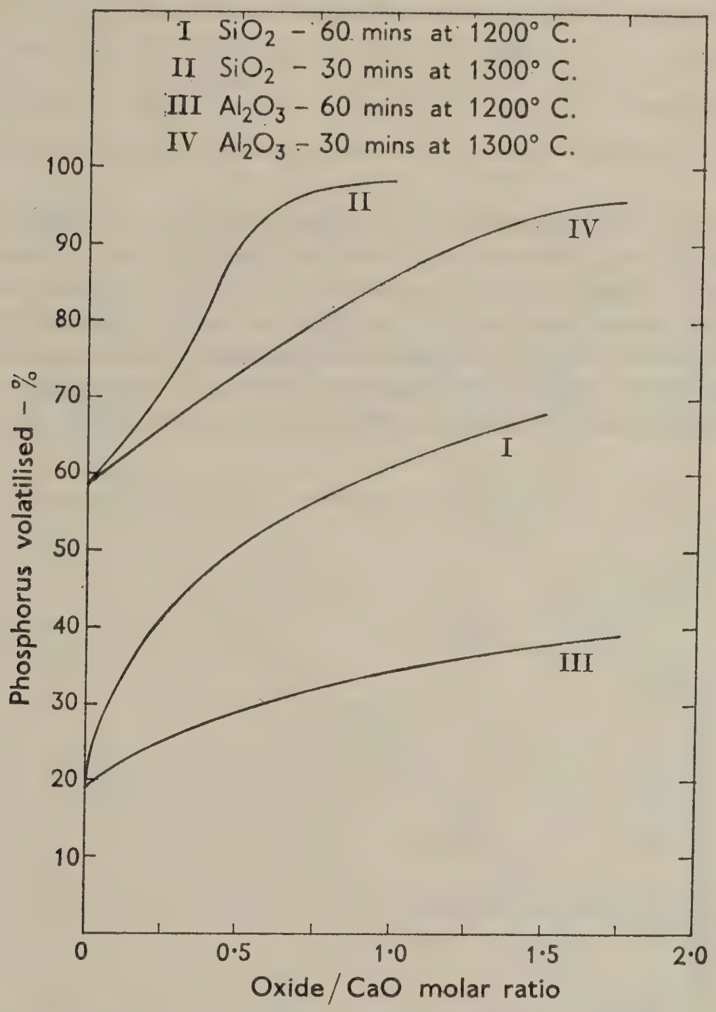

FIG. 8.—The effect of silica and alumina on the reduction of tricalcium phosphate with an equal weight of carbon[200]

For a constant molar $Ca_3(PO_4)_2:SiO_2$ ratio of 1:3 the amount of phosphorus volatilized increased with the amount of carbon in the mixture as shown in Fig. 9. These results indicate that silica promotes the reduction to a greater extent than alumina does. It is also evident that no phosphorus is formed with silica alone. The effect of temperature is given in Table XIII for a mixture containing equal weights of carbon and tricalcium phosphate and having a molar $CaO:SiO_2$ ratio of 1:1. The time of heating was 1 hr. at every temperature.

*Table XIII.—Effect of Temperature on the Reduction of Tricalcium Phosphate in the Presence of Molar Quantities of Silica and Carbon*[200]

| Temperature °C. | 1050 | 1100 | 1150 | 1200 | 1250 |
|---|---|---|---|---|---|
| % P volatilized | 1·0 | 11·7 | 28·4 | 61·6 | 95·3 |

**Refs. p. 143**

A naturally-occurring aluminium phosphate, wavellite, was found to be more readily reduced than tricalcium phosphate when heated with an equal weight of carbon for 1 hr. at various temperatures. The percentages of phosphorus volatilized are given in Table XIV.

*Table XIV.—Reduction of Aluminium Phosphate Ore with Carbon*

| Temperature °C. | 1050 | 1100 | 1150 | 1200 | 1300 | 1400 |
|---|---|---|---|---|---|---|
| % P volatilized | 5·4 | 71·9 | 83·2 | 83·9 | 88·6 | 90·2 |

The decrease in the rate of reduction at temperatures above 1150°C. was attributed to the formation of iron phosphide as a result of the high iron content of the ore.[200]

The reduction of phosphate rock by carbon in the presence of silica has also been shown to be a first-order reaction.[116] The reaction rate is indicated in Fig. 10.

These data give lower velocity constants than those for the reduction of tricalcium phosphate (Table XII). This is in agreement with other observations[83, 134, 204] that the phosphorus pentoxide in tricalcium phosphate is more easily reduced by carbon than that in fluorapatite. The breaks in the graphs shown in Fig. 10 were attributed to reaction between the melt and carbon which had segregated in it.[116]

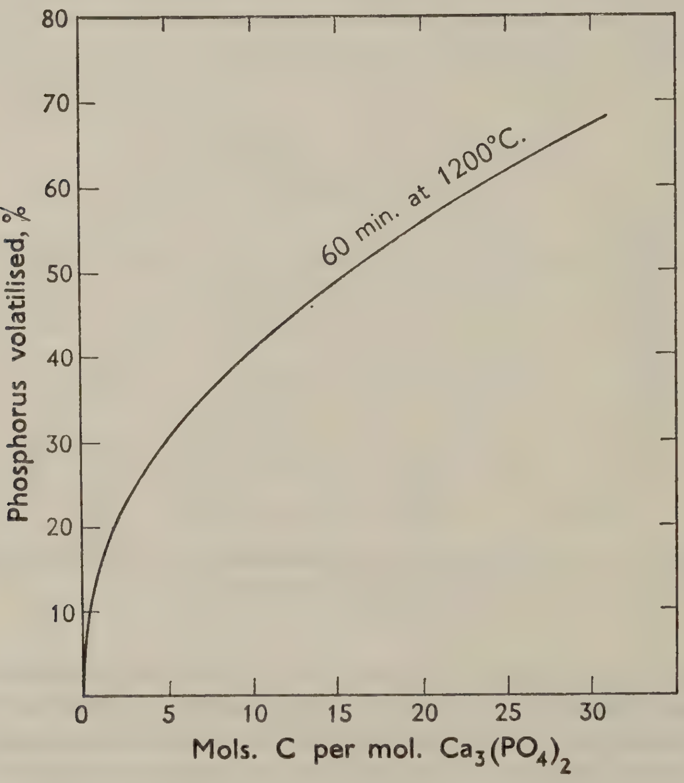

FIG. 9.—The effect of carbon on the reduction at 1200°C. of a mixture having a constant molar $Ca_3(PO_4)_2/SiO_2$ ratio of 1:3[200]

Equilibrium constants have been calculated[92, 199] for a number of reactions involving tricalcium phosphate. Table XV gives the temperatures at which the equilibrium pressure of the reaction gases is 1 atm.

The data in Table XV were calculated from the Nernst approximation formula:

$$\log K_{p(\mathrm{atm.})} = -\frac{\Delta H}{4{\cdot}57T} + \Sigma\,\nu\,.1{\cdot}75\log T + \Sigma\,\nu c$$

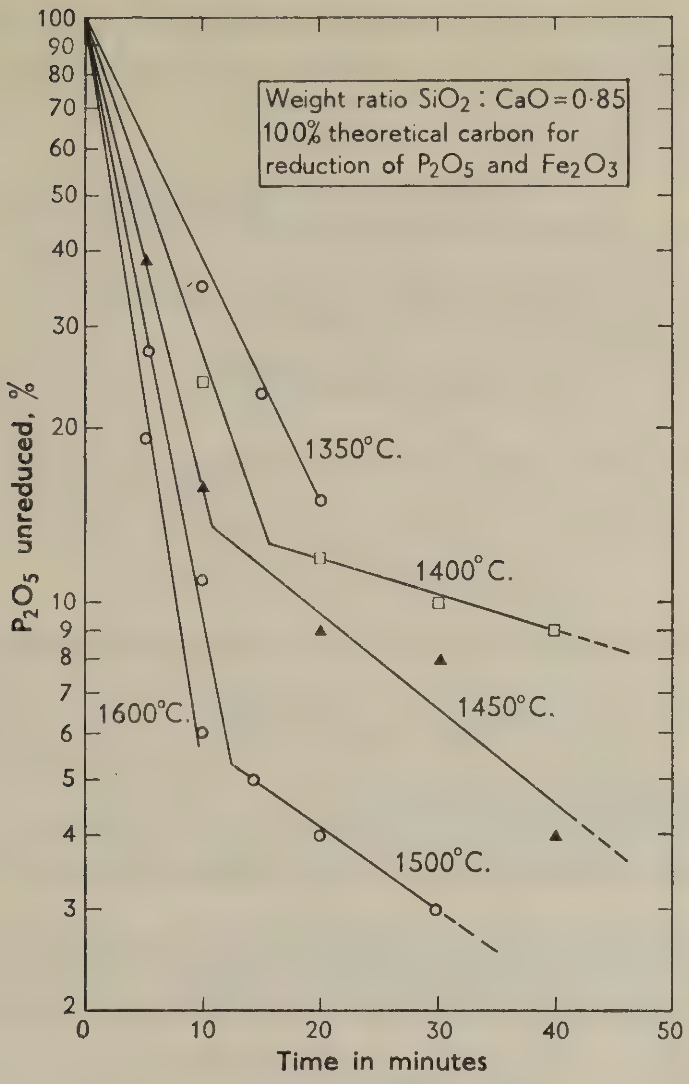

FIG. 10.—Rate of reduction of $P_2O_5$ in brown rock phosphate when heated with carbon

| $Ca_3(PO_4)_2 = 3CaO + P_2O_5$ | 4300 | — |

### POSSIBLE FORMATION OF CALCIUM PHOSPHIDE AND CARBIDE

There is some evidence that the formation of calcium phosphide could be involved in the mechanism of the reaction and that interaction of this with tricalcium phosphate gives phosphorus according to the equations[128]:

$$\begin{aligned} Ca_3(PO_4)_2+8C &= Ca_3P_2+8CO \\ 5Ca_3P_2+3Ca_3(PO_4)_2 &= 8P_2+24CaO \end{aligned}$$

From the data the equilibrium pressure of carbon monoxide in the first of these reactions is given in atmospheres by the equation[205]:

$$\log p = 9 - \frac{16{,}480}{T}$$

This gives a pressure of 1 atm. at 1540°C. For the second reaction the pressure is given by:

$$\log p = 4{\cdot}532 - \frac{8190}{T}$$

which leads to a value of 1 atm. at about 1550°C. The pressure equation for the total reaction is:

$$\log p = 4{\cdot}841 - \frac{8480}{T}$$

which gives a pressure of 1 atm. at 1480°C.

The second of the above reactions is reversible and at temperatures below 900°C phosphorus vapour combines with lime to form calcium phosphide.[205]

*Table XVI.—Volatilization of Phosphorus from Tricalcium Phosphate and Carbon at* 1200°*C.*–1840°*C.*

| Temp. °C. | Time min. | Reaction products % | | | | | |
|---|---|---|---|---|---|---|---|
| | | $Ca_3(PO_4)_2$ | $Ca_3P_2$ | $CaC_2$ | $CaCN_2$ | CaO | P |
| 1200 | 30 | 87·6 | — | — | — | — | 12·4 |
| 1430 | 30 | 1·6 | — | 1·7 | 0·3 | 96·4 | 98·3 |
| 1530 | 30 | 0·7 | 0·15 | — | — | — | 99·0 |
| 1620 | 45 | 1·5 | 1·1 | 2·9 | 27·7 | 66·8 | 96·6 |
| 1640 | 60 | 2·0 | 1·2 | 7·4 | 42·3 | 47·0 | 95·9 |
| 1735 | 45 | 2·0 | 3·7 | 32·9 | 22·2 | 39·2 | 91·8 |
| 1820 | 30 | 0·4 | 8·5 | 46·8 | 23·4 | 20·9 | 85·0 |

Experiments in which carbon was heated with 1·7 parts by weight of tricalcium phosphate in a stream of nitrogen indicated that the optimum temperature for volatilization of phosphorus was 1550°C. Calcium phosphide in the solid residue was less than 5% at temperatures below 1750°C. The results are summarized in Table XVI from which it will be seen that appreciable amounts of calcium carbide and calcium cyanamide are formed at temperatures above 1600°C. The formation of calcium carbide may be due to reaction of lime with the excess of carbon present, according to the equation[82, 128]:

$$CaO+3C = CaC_2+CO$$

The equilibrium pressure for this reaction is 1 atm. at 1780°C. The carbide is also formed from calcium phosphide and carbon, a reaction which is exothermic at 590°C.[205]:

$$Ca_3P_2+6C = 3CaC_2+P_2$$

The equilibrium constant in atmospheres is given by:

$$\log K_p = \frac{-77{,}500}{4{\cdot}57T} + 1{\cdot}75 \log T + 3{\cdot}0$$

for which the pressure is 1 atm. at 1660°C. Experiment showed that decomposition of calcium phosphide is incomplete at 1470°C.

Tricalcium phosphate reacts with calcium carbide according to the equation:

$$Ca_3(PO_4)_2 + 8CaC_2 = Ca_3P_2 + 8CaO + 16C$$

This appears to be followed by reaction of the phosphide with tricalcium phosphate, because on heating at 1200–1400°C. the product contains 74% CaO, 15% C and 3% tricalcium phosphate.

### REDUCTION BY CARBON MONOXIDE

The reduction of tricalcium phosphate by carbon monoxide:

$$Ca_3(PO_4)_2 + 5CO = 3CaO + 5CO_2 + P_2$$

has been considered[127] as a possible reaction in the formation of phosphorus. The evidence for this is conflicting. From a study of the phosphate–carbon–silica system[133] it was reported that there was no reaction with carbon monoxide at 1400° to 1600°C. The heat of reaction has been estimated to be −219 kcal.[92] Assuming that the Nernst approximation formula applies, this heat leads to an equilibrium pressure of 1 atm. at above 2000°C. In the presence of silica the heat change for the reaction:

$$Ca_3(PO_4)_2 + 5CO + 3SiO_2 = P_2 + 5CO_2 + 3CaSiO_3$$

is given as −134·7 kcal. which corresponds to 1 atm. pressure at 3000°C. More recently[206] it has been reported that on heating mixtures of tricalcium phosphate and carbon at 850–1150°C. *in vacuo* the rate of reduction ($V$) in mg./hr. per g. of material is given by:

$$\log V = \frac{-47{,}100}{4{\cdot}575T} + 8{\cdot}96$$

From a comparison with data obtained on the reduction of oxides by carbon, and because the energy required for all these reactions is very nearly the same as that for the reduction of carbon dioxide by carbon, it is suggested that the mechanism for the tricalcium phosphate–carbon monoxide reaction is represented by the following reactions, of which the second is the rate-determining step:

$$Ca_3(PO_4)_2 + 5CO = 3CaO + 5CO_2 + P_2$$
$$CO_2 + C = 2CO$$

At temperatures of 1200–1400°C. it has been observed (reference 116, page 11) that the rate of reduction of phosphate rock by carbon and silica in an atmosphere of carbon monoxide varies directly with the rate of flow of gas. In 1 hr. at 1300°C. the amount of phosphorus volatilized was 33% and this increased to 52% when the carbon monoxide was replaced by nitrogen. No volatilization of phosphorus occurred at 1300°C. when the rock was heated in carbon monoxide in the absence of carbon.

### VOLATILIZATION OF SILICON

Volatilization of silica can occur in the phosphorus furnace. It is possible that this may be volatilization of silicon monoxide formed during the reduction process. Silica is reduced by carbon at temperatures above 1500°C. according to the equation[207]:

$$SiO_2 + C \rightleftharpoons CO + SiO$$

Silicon monoxide is also formed by reaction of silica with silicon. It is unstable at temperatures below about 1200°C.[208] and with carbon monoxide it forms silicon carbide:

$$3SiO + CO = 2SiO_2 + SiC$$

Tricalcium phosphate is reduced by silicon monoxide at 1350°C.[207]:

$$2Ca_3(PO_4)_2 + 10SiO = P_4 + 3Ca_2SiO_4 + 7SiO_2$$

A mechanism for the reduction of phosphate which involves silicon monoxide seems to be less likely than the others which have been proposed. The vapour pressure of silicon monoxide in the presence of silica at 1570°C. is about $3 \times 10^{-2}$ mm.[209–10] The heat of formation of silicon monoxide from silicon and silica is about +164 kcal. and from carbon and silica it is about +160 kcal.[207, 211]

The experimental evidence suggests that carbon monoxide has only a minor role in the reduction. The same applies to the hypothesis of the dissociation of tricalcium phosphate into calcium oxide and phosphorus pentoxide followed by reduction of the latter.

## RED PHOSPHORUS

### PREPARATION

The red variety of phosphorus, generally referred to as amorphous, is manufactured substantially by the method previously described (Mellor, VIII, 746). This is usually a batch process in which white phosphorus is heated in a closed cast iron or steel vessel at temperatures above 250°C. The reaction is exothermic and the temperature must be carefully controlled in the initial stages.[86] At the end of the reaction the temperature is kept at 400°C. for several hours. The solid product is dug out, ground under water and boiled with sodium carbonate to remove unchanged white phosphorus. It is then filtered and vacuum dried. The material can be stabilized against oxidation by suspending it in a 1% solution of sodium aluminate. Magnesium and zinc oxides have a similar effect.[212] The resistance to oxidation is also improved by removing the iron and copper impurities by boiling with 8% sodium cyanide solution.[213] Other methods which have been suggested include boiling with hydrochloric, sulphuric or nitric acid,[214] heating in moist air at 40° to 90°C. followed by washing[215] and coating the particles with concentrated phosphoric acid.[216]

Copper, iron, bismuth, silver and nickel have been shown to increase the oxidation rate greatly. Cadmium and tin have a smaller effect, lead and chromium very little, and aluminium and zinc reduce the oxidation rate. The best procedure for stabilization appears to be boiling for 4–6 hr. with 5% sulphuric acid to remove iron, followed by boiling for ½ hr. with a solution containing 5% of sodium cyanide and 1·5% of sodium hydroxide. 0·5–7% of aluminium hydroxide is then precipitated on the phosphorus.[217]

In order to avoid the troublesome procedure of having to break up the product, a ball mill procedure has been suggested.[218] A continuous process has been developed[219] in which white phosphorus is heated at its boiling point until the conversion is about 50% complete. Under these conditions (approximately 6·5 hr. at 280°C.) the reaction mixture remains fluid with the red phosphorus suspended in it. To prevent volatilization of phosphorus the temperature must be kept below 285°C. The red phosphorus is separated by sedimentation and traces of white phosphorus are removed by heating at 200°C. in a stream of carbon monoxide, or by solvent extraction or flash, vacuum or steam distillation.[220] Other procedures, involving purification at 250°C.[221] and 300° to 350°C.[222] have been suggested. Oxidation with air[223] or dilute hydrogen peroxide[224] is said to remove both iron and white phosphorus. Apparatus for the continuous process has been described.[225]

Various other procedures have been suggested, including heating white phosphorus under reflux at 220° and 240°C. in a liquid such as diphenyl,[226] passing phosphorus through molten lead,[227] subjecting phosphorus vapour to the action of nitrogen oxides, iodine or bromine[228] or an electric discharge,[229] atomizing phosphorus in a closed chamber at 300° to 450°C.,[230] heating phosphorus in a closed container, under a strictly controlled temperature regime at up to 275° and subsequently to 325° to 340°,[283] and exposing a solution of phosphorus in carbon disulphide to ultra-violet light.[231] It has also been proposed to heat phosphorus vapour at 400° to 500°C. under 10–25 atm. pressure and then to cool it by rapid expansion.[232]

The reaction of phosphorus tribromide with magnesium, zinc or aluminium powder in anhydrous ether is said to give red phosphorus of 99% purity[233] (see also page 156). Small yields are also reported from the reaction in the presence of an electric discharge between hydrogen and phosphorus trichloride, phosphorus oxychloride or phosphorus tribromide.[234]

### MECHANISM OF THE CONVERSION

The mechanism of the conversion of white into red phosphorus has been studied by a number of investigators. The effect of time on the conversion when white phosphorus is heated in sealed glass ampoules is shown in Table XVII.[235] Red phosphorus, lime, silica gel, iron, selenium, $Fe_2O_3$ or $U_3O_8$ failed to catalyze the reaction.

*Table XVII.—Effect of Time and Temperature on the Conversion of White to Red Phosphorus*[235]

| Temp. °C. | Time hr. | % red P formed |
|---|---|---|
| 220–250 | 3 | 17 |
| 220–250 | 47 | 69 |
| 320–350 | 18 | 72 |
| 320–350 | 26 | 76 |
| 400 | 1¼ | 100 |
| 500 | 1 | 100 |

Observations in the temperature range 176–373°C. showed that the conversion is a first-order reaction below 263°C. At the higher temperatures the rate increases, suggesting that the reaction is autocatalytic.[236] A later investigation gave no indica-

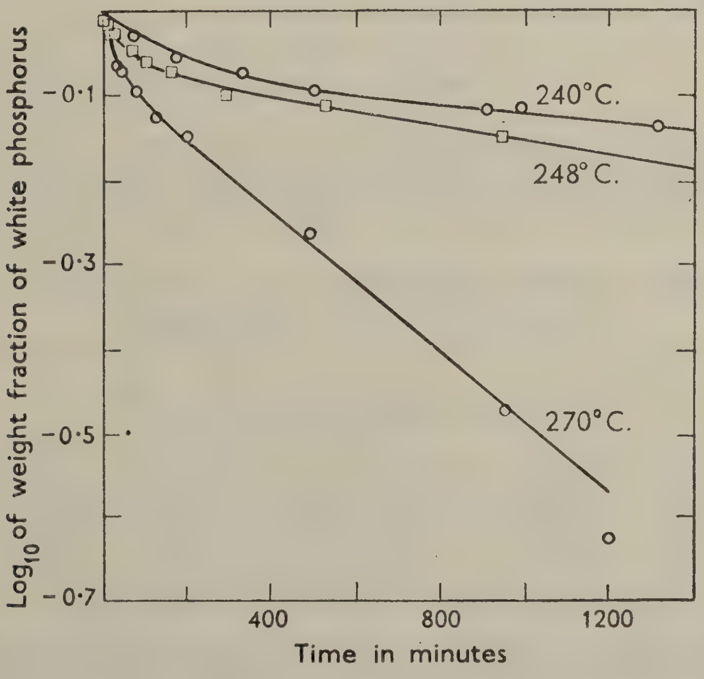

FIG. 11.—Rates of conversion of white to red phosphorus in the presence of 0·05% of iodine

tion of the reaction being autocatalytic and at temperatures in the range of 250–400°C. the first order velocity constant in min.$^{-1}$ was given by the equation:

$$\log_{10} k = -\frac{8470}{T} + 12{\cdot}62$$

which gives an activation energy of 38,700 g.-cal./mole. In the presence of iodine or sulphur as catalysts the rates of conversion are as shown in Figs. 11 and 12 respectively.

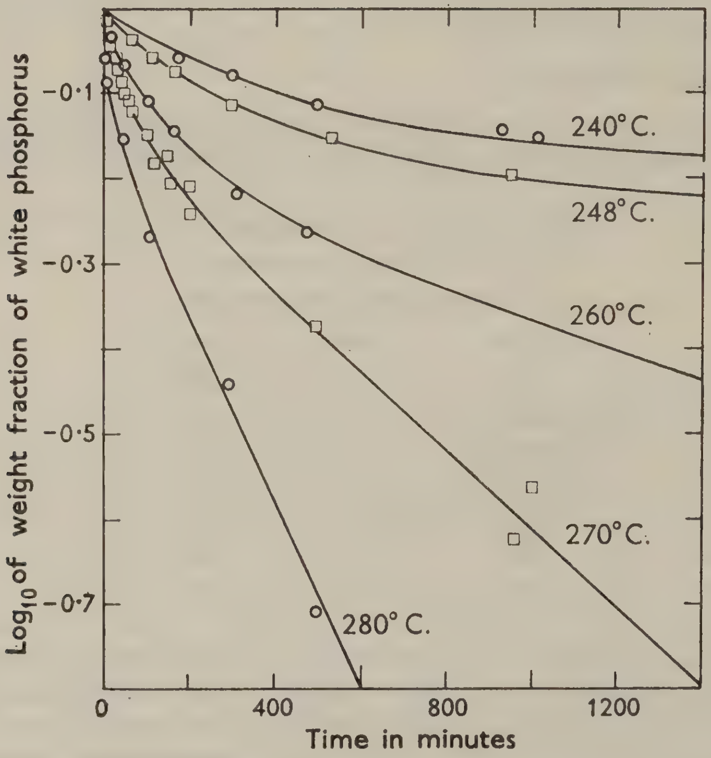

FIG. 12.—Rates of conversion of white to red phosphorus in the presence of 1·0% of sulphur

The rates of the catalyzed reactions are given by:

$$-2{\cdot}303 \log \frac{m}{m_0} = k_1 t + k_2 c(1 - e^{-k_3 t})$$

where $m/m_0$ is the fraction of white phosphorus remaining at time $t$, $c$ is the initial concentration of catalyst, $k_1$ is the first-order velocity constant for the uncatalyzed reaction, $k_2$ the constant for the formation of red phosphorus and $k_3$ is the constant for the disappearance of the catalyst. $k_2$ is independent of temperature and has an average value of 500 for iodine as catalyst, and 50 for sulphur. The values obtained for $k_3$ are given in Table XVIII and Table XIX.

*Table XVIII.—Velocity Constant, $k_3$ min.$^{-1}$, for the Iodine-catalyzed Conversion of White to Red Phosphorus*

| Mol. fraction $\frac{I_2}{P_4} \times 10^3$ | $k_3$ min.$^{-1} \times 10^3$ | | |
|---|---|---|---|
| | 240°C. | 248°C. | 270°C. |
| 0·0489 | 7·81 | 17·9 | — |
| 0·244 | 3·47 | 14·0 | 36·6 |
| 0·489 | — | 25·2 | 64·8 |

In the initial stages of the reaction and up to 50% conversion of the white phosphorus, the mixture remains fluid. It then becomes rapidly viscous and passes through a plastic state before solidifying. Between 6 and 10% conversion the reaction mixture contains particles of red phosphorus, about 20 to 30 microns in diameter, suspended in it. These grow in size and number until they touch and form an interlocking mass.[237] Between 6 and 60% conversion at 280°C. the particles increased from 1 to 150 microns in diameter, the average size being 26 to 60 microns. The specific surface as measured by adsorption of propane at −78·6°C. is found to be inversely proportional to the percentage conversion of white to red phosphorus. The mechanism proposed for the reaction is an initial formation of nuclei of red phosphorus according to a first-order law. The nuclei then agglomerate to form aggregates which give rise to a porous three-dimensional network. There is no evidence of chain formation.[238] It has been pointed out that this mechanism agrees with the kinetic data, if during the production of nuclei the phosphorus atoms are rearranged, without dissociation of $P_4$ molecules, to form red phosphorus molecules which are more compact than those of the white phosphorus from which they are formed.[139] In the initial stages of the iodine and sulphur catalyzed reactions a chain mechanism, which is independent of temperature, appears to be involved.

*Table XIX.—Velocity Constant, $k_3$ min.$^{-1}$, for the Sulphur-catalyzed Conversion of White to Red Phosphorus*

| Mol. fraction $\frac{S_8}{P_4} \times 10^3$ | $k_3$ min.$^{-1} \times 10^3$ | | | | |
|---|---|---|---|---|---|
| | 240°C. | 248°C. | 260°C. | 270°C. | 280°C. |
| 2·42 | 0·85 | — | — | 20·9 | — |
| 4·86 | 1·77 | 4·38 | 9·35 | 31·8 | 32·7 |
| 7·31 | — | — | 18·7 | 45·7 | 85·1 |

## BROWN PHOSPHORUS

If white phosphorus is heated above 600°C. and the vapour condensed at liquid nitrogen temperatures a coloured product is obtained. Condensation from 1000°C. or higher produces a dark-brown deposit which is insoluble in carbon disulphide, ethylene and propane. The material is also formed by irradiating white phosphorus at −190°C. with a quartz mercury vapour lamp.

Brown phosphorus is stable at −190°C. but begins to decompose irreversibly at −100°C. At room temperature the change is almost instantaneous. The decomposition always gives a mixture containing about 20% of red and 80% of white phosphorus.[239] At −43°C. to −88°C. the decomposition is first-order, the velocity constant being given by

$$\log_{10} k\,(\text{min.}^{-1}) = -\frac{738}{T} + 4{\cdot}49$$

## BLACK PHOSPHORUS

The methods of preparing dark-coloured products, described in the earlier literature as black phosphorus, have been summarized. Attention has been drawn to the fact these were impure forms of white phosphorus and that they should not be confused with the black allotrope first made by Bridgman under high pressure (Mellor, VIII, 747–8). A later observation[240] showed that white phosphorus could be converted into the black variety at room temperature and 35,000–40,000 atm. pressure, but there was some doubt as to whether this was the same as the product obtained at 12,000 atm. and 200°C. Similar results have been found when a pressure of 100,000 atm. is used,[241] the conversion being instantaneous under these conditions. The product, however, underwent a spontaneous reverse transformation to white phosphorus.

A more detailed study of the conversion of white to black phosphorus showed that there is an amorphous and a crystalline variety of the black allotrope. In the usual course of the formation of the crystalline form there is a slow transformation for 10 to 15 min. with slight decrease in volume. This is followed by a sudden transition during which the volume decreases extremely rapidly. The reaction goes instantaneously at any given pressure if the temperature is high enough. When there is no sudden decrease in volume within 15 min. an amorphous form is produced. The pressure–temperature relation is shown in Fig. 13. In region I only amorphous black phosphorus is formed. In region II there is an induction period for the reaction and in the third region crystalline black phosphorus is formed instantaneously. The amorphous form is not changed into the crystalline variety at 300°C. under 15,000 atm. pressure nor at 500°C. and 12,000 atm. pressure. The transformation of white into crystalline black phosphorus does not therefore proceed by formation of amorphous black phosphorus and subsequent change of this into the crystalline form. The transition from white to black phosphorus appears to occur because the heat of formation of the amorphous variety is sufficient to raise the temperature to a value high enough for the crystalline variety to be formed. For adiabatic conditions a 1% conversion of white to amorphous black phosphorus is sufficient to raise the temperature by 26°C.[242] More recent studies have shown that white phosphorus is very readily changed to the black form as the pressure is increased up to 100,000 atm.[243] No new modification of black phosphorus has been found at pressures up to 34,000 atm. and temperatures up to 600°C.[244] The m.p. rises with increased pressure and at 18,000 atm. black phosphorus melts at about 1000°C.[245] Further increase of pressure to 425,000 atm. does not alter the properties of black phosphorus.[246]

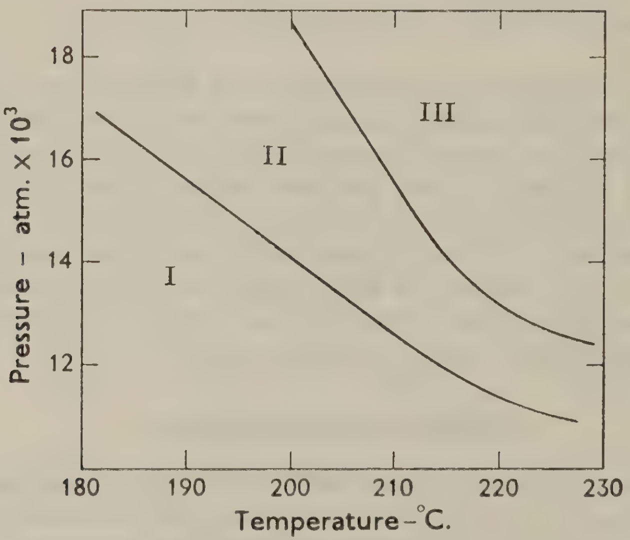

FIG. 13.—Pressure–temperature diagram for black phosphorus

Other observations have been reported[247] on the conversion of white phosphorus into the black modification at 100–200°C. and at pressures up to 48,500 kg./cm.$^2$ These indicate a longer conversion time and higher pressures for a given temperature than the results quoted above. From the data the temperatures and pressures above which white phosphorus cannot exist are given by the equation:

$$P\ (\text{kg./cm.}^2) = -379T + 193{,}273$$

where $T$ is the absolute temperature.[248] This gives a pressure of 82,000 atm. for a transition at 20°C. as compared with Bridgman's figure of 35,000 to 40,000 atm.[240]

**Refs. p. 143**

A low-pressure method of preparing black phosphorus has been described.[249, 252] According to this, white phosphorus is heated for 24–48 hr. at 250° to 600°C. in th presence of mercury which is then removed by extraction with molten lead at 300° to 400°C., to give a product containing about 1 at.-% of mercury. This is reduced to 0·4–0·5 at.-% by treatment with gold at 370° to 440°C. Pressures of 300 to 3,000 atm. assist the reaction.[250] Alkali metals, alkali metal phosphides, phosphine, ammonia, water and aliphatic tertiary amines are said to be catalysts.[251] *X*-Ray diagrams and physical properties show that the phosphorus made by this procedure is distinct from the very early forms of so-called black phosphorus. On the other hand it appears to oxidize in air more rapidly than red phosphorus and in the presence of moisture becomes coated with a viscous film of phosphoric acid.[250] Instead of mercury, molten bismuth has been used successfully as a recrystallizing solvent for black phosphorus.[253]

## SECTION IV

# THE PHYSICAL PROPERTIES OF PHOSPHORUS

BY D. R. PECK

## NUCLEAR, ATOMIC AND MOLECULAR STRUCTURE

The atomic number of phosphorus is 15 and there is one stable isotope $^{31}_{15}$P. In addition, six radioactive isotopes have been reported up to 1958.[1] Table I gives a brief description of these isotopes. More detailed information is contained in the section on the radiochemistry of phosphorus.

*Table I.—The Isotopes of Phosphorus*

| Isotope | Half life | Type of decay | Physical at. wt. ($^{16}$O = 16·0000) | References |
|---|---|---|---|---|
| $^{28}$P | 0·28 sec.<br>0·29 sec.<br>0·27 sec. | $\beta^+$<br>$\gamma$ | 28·0012 | 1–5 |
| $^{29}$P | 4·45 sec.<br>4·60 sec. | $\beta^+$<br>$\gamma$ | 28·9910 | 1, 6–9 |
| $^{30}$P | 2·55 min.<br>2·52 min.<br>2·18 min. | $\beta^+$<br>$\gamma$ | 29·9881 | 1, 9–19 |
| $^{31}$P | Stable isotope | | 30·9836 | 1, 20–4 |
| $^{32}$P | 14·22 days<br>14·30 days<br>14·35 days<br>14·50 days<br>14·07 days<br>14·60 days | $\beta^-$<br>(no $\gamma$) | 31·9842 | 1, 9, 18, 23, 25–41 |
| $^{33}$P | 24·4 days<br>24·8 days<br>25·0 days | $\beta^-$<br>(no $\gamma$) | 32·9822 | 1, 9, 23, 34, 37, 42, 43 |
| $^{34}$P | 12·4 sec.<br>12·7 sec. | $\beta^-$<br>$\gamma$ | 33·9826 | 1, 9, 44–7 |

The atomic weights in the above table are given in atomic mass units (1 A.M.U. $= 1{\cdot}661 \times 10^{-24}$ g.) based on the $^{16}$O oxygen isotope with an atomic weight of exactly 16. They can be converted to the chemical scale by dividing by 1·000275. It should be noted that the chemical and physical atomic weight scales were replaced in 1960 by a single scale based on the $^{12}$C carbon isotope with an atomic weight of 12·0000. This is discussed in more detail on page 217.

A complete list of nuclidic masses on the $^{12}$C scale is given in reference 48 from which the data in Table II are taken.

The nucleus of the stable isotope $^{31}_{15}P$ has been described[49, 50] as consisting of 15 protons and 16 neutrons: the forces between these are due to exchange processes which involve the transformation of neutrons into protons and *vice versa*. The neutrino and several types of mesons are also thought to be involved in this transformation.[51]

Evidence has been reported[52] which leads to the hypothesis that the nucleus of an atom consists of closed shells of protons and neutrons.[53–4] On this basis the configuration of the nucleus of the phosphorus atom is given as $1s^2 2p^6 3d^6 2s^1$.[55–6]

*Table II.—Relative Nuclidic Masses of Phosphorus Isotopes*

| Isotope | Nuclidic mass | |
|---|---|---|
| | $^{12}C = 12{\cdot}0000$ | $^{16}O = 16{\cdot}0000$ |
| $^{28}P$ | $27{\cdot}99174 \pm 3{\cdot}2 \times 10^{-4}$ | 28·00064 |
| $^{29}P$ | $28{\cdot}981816 \pm 0{\cdot}1 \times 10^{-4}$ | 28·99103 |
| $^{30}P$ | $29{\cdot}97832 \pm 0{\cdot}1 \times 10^{-4}$ | 29·98785 |
| $^{31}P$ | $30{\cdot}973763 \pm 0{\cdot}02 \times 10^{-4}$ | 30·98361 |
| $^{32}P$ | $31{\cdot}973908 \pm 0{\cdot}02 \times 10^{-4}$ | 31·98407 |
| $^{33}P$ | $32{\cdot}971728 \pm 0{\cdot}02 \times 10^{-4}$ | 32·98221 |
| $^{34}P$ | $33{\cdot}973340 \pm 2{\cdot}1 \times 10^{-4}$ | 33·98414 |

An analysis of the emission spectrum of diatomic phosphorus vapour shows that the nuclear spin is $\frac{1}{2}\hbar$.[57] The nuclear magnetic dipole moment has been variously reported to be +1·1317[58–60] and 1·13165[61] nuclear magnetons, the most recent value being 1·1305.[1] The nuclear quadrupole moment is zero, indicating a spherically symmetrical charge distribution in the nucleus. The diameter of the nucleus is about $10^{-12}$ cm. and the atomic diameter about $2 \times 10^{-7}$ cm.

The neutral state of the stable isotope of phosphorus has the electron configuration $1s^2 2s^2 2p^6 3s^2 3p^3$, the ground term being $4s_{3/2}$. The ionization potentials, in electron volts (1 e.v. = 23·053 kcal. mole$^{-1}$) for successive ionization stages, are given in Table III.[62] As will be seen from this Table, the energy required to form $P^{3+}$ and $P^{5+}$ ions is 695 and 1498 kcal. mole$^{-1}$ respectively. These energies are much higher than the heats of most chemical reactions carried out at temperatures below 1000°C. and indicate that in most of the stable compounds of phosphorus there is little or no charge on the phosphorus atom.

*Table III.—Ionization Potentials of Phosphorus*[62]

| Initial state | Ionization potential e.v. | Initial state | Ionization potential e.v. |
|---|---|---|---|
| P(I) $3p^3\ {}^4S_{3/2}$ | 11·0 | P(VIII) $2p^4\ {}^3P_2$ | 309·26 |
| P(II) $3p^2\ {}^3P_0$ | 19·65 | P(IX) $2p^3\ {}^4S_{3/2}$ | 372·62 |
| P(III) $3p\ {}^2P_{1/2}$ | 30·16 | P(X) $2p^2\ {}^3P_0$ | 425·46 |
| P(IV) $3s^2\ {}^1S_0$ | 51·36 | P(XI) $2p\ {}^2P_{1/2}$ | 479·4 |
| P(V) $3s\ {}^2S_{1/2}$ | 65·01 | P(XII) $2s^2\ {}^1S_0$ | 560·3 |
| P(VI) $2p^6\ {}^1S_0$ | 220·41 | P(XIII) $2s\ {}^2S_{1/2}$ | 611·45 |
| P(VII) $2p^5\ {}^2P_{3/2}$ | 263·31 | | |

At temperatures below 800°C. electron diffraction data[63] show that phosphorus vapour is composed of tetratomic molecules, in which the phosphorus atoms are situated at the corners of regular tetrahedra. The P–P distance is 2·21 ± 0·02 Å. and the moments of inertia are $I_A = I_B = I_C = 251 \times 10^{-40}$ g.cm.$^2$ Since the bond angle in the $P_4$ molecule is 60° as compared with 90° for an unstrained P–P–P linkage, it has been calculated that there is a strain energy of 22·8 kcal. mole$^{-1}$ in the molecule.[64] This is discussed in more detail in the section on valency (page 153).

The tetrahedral structure has been shown to persist in liquid and solid white phosphorus. *X*-Ray diffraction shows that liquid phosphorus is composed of $P_4$ molecules which are tetrahedral with a P–P distance of 2·25 A.[65] Infra-red[66–7] and Raman[68–9] spectra show only small frequency changes in passing from the solid through liquid to the vapour phase of white phosphorus. Interpretation of the vibrational spectrum is consistent with a tetrahedral structure of $T_d$ symmetry.[67, 70] In the ordinary or α-form of solid white phosphorus the $P_4$ tetrahedra are free to rotate.

At temperatures above 800°C. phosphorus is dissociated into $P_2$ molecules. The emission[57, 71–2] and ultra-violet[73–5] absorption spectra have been studied and from the emission spectrum the vibrational energy levels are represented by the equation[76]

$$E_v/hc = 780{\cdot}43(v+\tfrac{1}{2}) - 2{\cdot}804(v+\tfrac{1}{2})^2 \text{ cm.}^{-1}$$

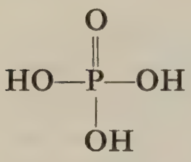
The original values of $90{\cdot}47 \times 10^{-40}$ g. cm.$^2$ for the moment of inertia and 1·88 A. for the internuclear distance were calculated[77] from the emission spectrum data.[78] More recent values, considered to be more accurate, are $92{\cdot}36 \times 10^{-40}$ g. cm.$^2$ and 1·895 A. respectively.[74] The spectrum of the $P_2^+$ molecule has been analysed. This shows two band systems which are attributed to the $P_2^+$ molecule. One of these, which in its lower region probably corresponds to the ground state of the $P_2{}^+$ molecule, is a $^2\Pi$–$^2\Pi$ band system at a wave-length of 3400–3850 A. The other one is a $^2\Sigma$–$^2\Sigma$ system lying in the region 3900–4400 A.[79]

Dissociation of diatomic phosphorus into phosphorus atoms of ground state $^4S_{3/2}$ and nuclear spin $\frac{1}{2}\hbar$ requires a dissociation energy of 5·033 electron volts (116 kcal. mole$^{-1}$) at absolute zero.[80] Spectroscopic calculations[77] show that at 1500°C. the amount of monatomic phosphorus in the vapour is less than 0·01% (see page 201, Table XLVII). Calculations[484] based on the spin polarization concept predict a negative sign for the magnetic hyperfine constant of the $^4S$ ground state of $^{31}P$, which is at variance with the positive value obtained experimentally.[485–6]

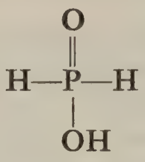
## VALENCY AND CHEMICAL BONDING OF PHOSPHORUS

In common with the other elements of the second short period of the Periodic System, phosphorus can have a normal valence V as well as one of V − 8. The oxidation state is +5 when five electrons are removed from the outer or M-shell and −3 when three electrons are added to it. It was even suggested that white phosphorus should be formulated with a phosphide structure $(P^{3+})(P^-)$. This was claimed to explain a number of reactions, such as the formation of phosphine and hypophosphite from phosphorus and caustic alkalis and the reaction of phosphorus with copper sulphate to give copper, copper phosphide and phosphoric acid.[81] However, this view implies that phosphorus ions exist in phosphorus compounds; i.e. that the phosphorus carries an electrical charge which is not neutralized by opposite charges on atoms to which it is bonded. Although both positive and negative ions have been produced under exceptional conditions, for example when phosphorus vapour is subjected to the action of an electric discharge,[82] it would appear that ionized phosphorus is not common under normal conditions. The investigations of Van Wazer and co-workers[50, 83] have provided substantial evidence in favour of the view that phosphorus is covalently bonded in the majority of its compounds. Nuclear magnetic resonance studies show that the picture of sodium phosphates made up of close-packed $P^{5+}$, $Na^+$ and $O^{2-}$ ions, with alternation of positive and negative charges, is erroneous. The spin-spin splitting observed in the N.M.R. spectra of phosphorus compounds is more closely in agreement with a structure of covalently-bonded phosphorus and oxygen atoms making up phosphate molecule-anions. The negative charges of these are then balanced by counter ions, such as $Na^+$, some of which may be closely associated with the oxygen atoms of the molecule-anion. For example, N.M.R. measurements show that in the tripoly- and tetrapolyphosphate anions the P–O–P linkages are essentially covalent. The data also indicate that the postulated $P^{5+}$ ion does not exist in phosphates.[83] In many molecules of which the structure has been determined by *X*-ray methods, phosphorus is found to be joined to the other atoms by covalent bonds. More detailed information is given in Section XXXIV. It has been shown, for example, that $P_4O_{12}^{4-}$ ions are present in crystalline aluminium metaphosphate[84] and in ammonium tetrametaphosphate.[85] In the latter the ammonium ions form hydrogen bonds with the oxygen atoms of the tetrametaphosphate anion.[86] Similar structures have been found for phosphoric acid[87] and phosphorus oxides.[88] Hartree–Fock–Slater atomic scattering factors for phosphorus in a number of valence hybrid states have been presented.[482–3]

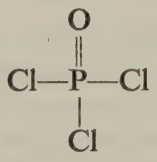
According to classical ideas of valency, phosphorus is regarded as being either tervalent or pentavalent. This has given rise to a notation in which compounds containing phosphorus joined to four other atoms are represented with a double bond as shown below:



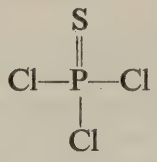
$\mathrm{HO{-}\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}{-}OH}$



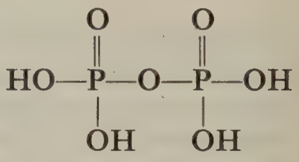
$\mathrm{H{-}\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}{-}H}$



$\mathrm{Cl{-}\overset{\overset{O}{\|}}{\underset{\underset{Cl}{|}}{P}}{-}Cl}$



$\mathrm{Cl{-}\overset{\overset{S}{\|}}{\underset{\underset{Cl}{|}}{P}}{-}Cl}$



$\mathrm{HO{-}\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}{-}O{-}\overset{\overset{O}{\|}}{\underset{\underset{OH}{|}}{P}}{-}OH}$

As an alternative, the double bond is often replaced by an arrow to indicate a co-ordinate linkage or a dative or semi-polar bond in which the bonding is formed from two electrons both of which are contributed by the phosphorus atom to the oxygen or to the sulphur atom. These ideas, however, suggest that in the orthophosphate ion, for example, one of the four oxygen atoms would differ from the other three. There is no physical evidence for this; physical data indicate that all four oxygen atoms are equivalent.

Phosphorus in its compounds can be linked with 1, 3, 4, 5 or 6 other atoms, the most common co-ordination numbers being 3 and 4. Compounds of co-ordination number 1 are very unstable under normal conditions, but have been identified in band spectra. Those with co-ordination number 3 are reasonably stable, but act as electron donors. In so doing the phosphorus increases its co-ordination number to 4, in which state it is the most stable. Compounds in which phosphorus is joined to five or six atoms are very reactive and only a few are known, e.g. $P(C_6H_5)_5$, $PCl_2F_3$, $PBr_2F_3$, $PBr_5$ and the anions $PF_6^-$ and $PCl_6^-$.[89]

The observed interatomic distances of 3-co-ordinate phosphorus compounds agree with values calculated from covalent radii[90] or from atomic radii and bond energies.[91] For single and 4-co-ordinate compounds the observed distances are usually shorter than the calculated values[91–2] and this has been attributed to $\pi$-bonding.[93] The molecular orbital theory postulates that single bonds are formed by collinear overlapping of atomic orbitals. These bonds, which are symmetrical and known as $\sigma$ bonds, occur when an *s*-orbital combines with any other kind of orbital, and when *p*- and *d*-orbitals combine end to end. When *p*- and *d*-orbitals overlap sideways or *d*-orbitals combine in a similar manner, $\pi$-bonds are said to be formed. In applying this to phosphorus compounds, Van Wazer[89] finds that for diatomic molecules, in which the bonding occurs mainly through *p*-orbital electrons, there are between one and two $\pi$-bonds per $\sigma$-bond. In 3-co-ordinated compounds the bonding has primarily a $p^3$-orbital character and here $\pi$-bonding is slight or absent. The 4-co-ordinated phosphorus has $sp^3$-bonding characteristics and it is found that in these compounds there are three or four $\sigma$-bonds to every $\pi$-bond. When the phosphorus is linked to five or six other atoms the *d*-orbitals, five in number, which have energy levels not greatly above the 3*s*- and 3*p*-orbitals, are involved. This gives rise to $sp^3d$ and $sp^3d^2$ hybridization respectively, and in such compounds virtually no $\pi$-bonding is observed. Because the energy of promotion of an electron into a *d*-orbital is large, these higher valencies are developed only when the energy of formation is great, i.e. when phosphorus is combined with fluorine or oxygen.[94]

These generalizations do not give a complete explanation of all the observed bonding phenomena in phosphorus compounds. For example, the amount of $\pi$-bonding as determined from observed bond lengths in rubidium metaphosphate,[95] phosphorus pentoxide,[88] phosphorus sulphoxide[96] and in phosphorus oxyhalides, thiohalides[97] and mixed halides[98] is between 0·8 and 1·5 $\pi$-bonds per $\sigma$-bond for the P–O and P–S linkages. 4-Co-ordinated phosphorus compounds containing phenyl groups show very little $\pi$-bonding for such phosphorus atoms.[99–101] On the other hand, quantum mechanics indicates that $\pi$-bonding should be found in 4-co-ordinated phosphorus compounds and should be absent in 3-, 5- and 6-co-ordinated ones.[102] Nuclear magnetic resonance data from phosphorus compounds can also be explained on the basis of changes in the hybridization and $\pi$-bond character of the phosphorus atom.[103] Resonance shifts between similar or homologous phosphorus compounds have been explained by considering changes in the relative importance of their ionic and double-bonded electronic structures.[104]

Solid,[105] liquid[65, 68–9] and gaseous[63, 66] phosphorus all contain the tetra-atomic $P_4$ molecules in which the phosphorus atoms are arranged in tetrahedra. The angles between the bonds are 60° and the bonding has predominantly $p^3$-orbital characteristics.[106] Because the three $p$-orbitals are at right angles to one another, the bond angle in the P–P–P linkage should be 90°. It has been suggested[107] that this could be explained by supposing that the phosphorus atoms are bonded by $pd^2$ hybrid orbitals. Although this gives a bond angle of nearly 60°, spectroscopic data show that the promotion of a $3p$-electron to a $3d$-orbital requires about 194 kcal. mole$^{-1}$. To form three $pd^2$ bonds, two electrons have to be promoted, corresponding to an energy of 388 kcal. for the $P_4$ molecule. The energy requirement is considerably less if the molecule is assumed to contain bent or strained bonds. However, a more recent treatment predicts that strong $\pi$-bonds are present in the molecule, and their presence leads to a resonance which in turn makes it unnecessary to postulate 'bent bonds', and vitiates the concept of 'strain energy' in $P_4$. A calculation of the electronic spectrum of $P_4$ assuming a pure $3p$ basis was in adequate agreement with the observed spectrum.[488] The P–P bond energy for an angle of 60° in the $P_4$ molecule has been estimated to be 44 kcal. mole$^{-1}$,[108] increasing to 47·5 kcal. mole$^{-1}$ for a normal bond, thus giving a strain energy of 3·5 kcal. per P–P bond. By assuming that the bonds are formed by pure $p^3$-orbitals, the strain energy has been calculated to be 7·1 kcal. for every P–P bond.[109] The bonding has also been described in terms of *pd* hybridization[110] and this has been extended to *spd* hybrid bond orbitals involving a bond angle of 73°.[111] The latter hybridization has been adapted for a bond angle of 60°.[112] In black phosphorus and in the phosphorus trihalides the P–P bond angle varies between 99° and 102°. By assuming that the normal bond angle is 101° and considering the bonds to be *spd* hybrids, the strain energy has been calculated[64] to be 3·8 kcal. per P–P bond or 22·8 kcal. mole$^{-1}$ per $P_4$ molecule. The character of this type of bonding is largely that of a $p$-orbital, the contribution of the $3s$-orbital being about 0·4% and that of the $3d$-orbital about 2·2%. The bond angles,[113] valency[114] and bond characteristics[115] in phosphorus compounds have been discussed by a number of authors. Molecular orbital calculations have been reported for pentavalent phosphorus compounds. From these it appears that a free-atom $3d$ atomic orbital is too diffuse to give a strong bond by itself. There is, however, evidence that some $d$-hybridization occurs.[116] The effect of the availability of $3d$-orbitals on the mechanism and the products of the general reactions of phosphorus has been discussed in some detail.[117] Various empirical relations have been proposed connecting bond length with potential energy,[118] bond multiplicity,[119] internuclear distances in crystals[120] and the ionic radii of positive and negative ions.[121] These apply to phosphorus with various degrees of accuracy. A more accurate expression is

$$R = R_1\left[\frac{2}{3}+\frac{1}{3}\left(\frac{n-1}{n+1}\right)^{p/2}\right]$$

where $R$ is the covalent bond distance, $R_1$ the length of a single bond, $n$ is the principal quantum number of the valence electrons and $p$, the bond order, is 0 for a single bond, 1 for a double bond and 2 for a triple bond.[122]

## ATOMIC RADII OF PHOSPHORUS

Various atomic or structural radii have been reported for phosphorus. The normal covalent radius and the tetrahedral covalent radius have the same value, 1·10 A. for a single bond,[123] obtained by dividing the P–P bond distance by two.[63] This value has been used to calculate bond distances in phosphorus compounds, but in most instances a correction is necessary to allow for the partial ionic character of bonds formed between phosphorus and atoms other than itself. An approximation for this correction is based on the difference ($X_A \sim X_B$) of the Pauling electronegativities of the atoms concerned (see page 183). The bond length is then given by the expression

$$r_{AB} = r_A + r_B - 0{\cdot}09(X_A \sim X_B)$$

where $r_A$ and $r_B$ are the covalent radii of the atoms.[87]

This method of calculation gives bond lengths which are longer for P–O and P–F linkages by 0·1–0·2 A. than observed values.[124] Better agreement is found by using the relationship

$$r_{AB} = R_A + R_B - \tfrac{1}{2}\log_{10} D_{AB}$$

where $D_{AB}$ is the bond energy in kcal. mole$^{-1}$ and $R$ is the constant energy covalent radius. Values of $R$ have been computed[91] by considering the radius of an atom in an environment where the repulsion energy is constant. For phosphorus this radius is 1·53 A. Using this radius and the above expression, P–O and P–F bond distances can be estimated to within 0·05 A. of the values obtained by electron diffraction.[125–6]

An atomic radius of 1·28 A. has been calculated for a 12-co-ordinate phosphorus atom in which the atoms are joined by electron-pair bonds and the lattice is body-centred cubic.[127] A value of 1·65 A. has been given for a non-bonded electronegative phosphorus atom surrounded by twelve equidistant atoms.[128] The atomic radius has been estimated to be 1·70 A. from compressibility and thermal expansion data (see page 172).

The above data, together with values for other radii, are summarized in Table IV.

*Table IV.—Covalent, Atomic and Crystal Radii of Phosphorus*

| Type of radius | Radius, A. | Ref. |
|---|---|---|
| Normal covalent | 1·10 | 123 |
| Tetrahedral covalent | 1·10 | 123 |
| Constant energy covalent | 1·53 | 91 |
| 12-Co-ordinated metallic | 1·28 | 127 |
| Double bond covalent | 1·00 | 123 |
| Triple bond covalent | 0·93 | 123 |
| Non-bonded or Van der Waals | 1·90 | 123 |
| Univalent ionic for $P^{5+}$ | 0·59 | 129 |
| Univalent ionic for $P^{3-}$ | 2·79 | 129 |
| Crystal for $P^{5+}$ | 0·34 | 129 |
| Crystal for $P^{3-}$ | 2·12 | 129 |
| 12-Co-ordinated covalent | 1·65 | 128 |
| Atomic (calculated) | 1·70 | 130 |

The univalent ionic radius is hypothetical and refers to the value which the radius would have if phosphorus behaved as a univalent ion. It should be noted that although a value has been reported for the crystal radius of the pentavalent phosphorus ion, it is unlikely that this ion exists in phosphorus compounds.

Other data useful for estimating bond lengths are listed on page 213, Table LXII.

## THE ALLOTROPES OF PHOSPHORUS

Solid phosphorus exists in more polymorphic forms than almost any other element. Most of the allotropes have more than one variety. For example, there are two crystalline forms of white phosphorus, an amorphous and crystalline black phosphorus and several varieties of red phosphorus. The phase relations of the main forms have previously been discussed (Mellor, VIII, 752). The known allotropes are shown in Table V.

*Table V.—Allotropic Modifications of Phosphorus*

| Allotrope | Crystal structure | Density (g. c.c.$^{-1}$) | m.p. (°C.) | Heat of sublimation (kcal. mole$^{-1}$) |
|---|---|---|---|---|
| α-white | Cubic | 1·828 | 44·1 | 13·4 |
| β-white | Orthorhombic | 1·88 | — | — |
| Red I | Amorphous | 2·16 | — | 19·7 |
| Red II | Probably hexagonal | 2·31 | — | 24 |
| Red III | Probably hexagonal | 2·31 | — | — |
| Red IV | Tetragonal | 2·31 | — | 28 |
| Red V | Triclinic | 2·31 | 590 | 28·8 |
| Red VI | ? | ? | ? | ? |
| Black I | Amorphous | 2·25 | — | — |
| Black II | Orthorhombic | 2·69 | — | 38·7 |
| Vitreous | ? | 2·26 | — | — |
| Brown | ? | ? | Decomp. | Decomp. |

### α-White Phosphorus

This is the common form of the element and is always obtained when phosphorus vapour is condensed to a liquid and this is allowed to solidify. It normally has a yellowish coloration, but can be formed as white crystals by cooling a saturated solution of phosphorus in benzene. Transparent crystals have been obtained from a benzene solution at 200°C. and 60–70 atmospheres pressure. White phosphorus is also produced when the red form is sublimed in a vacuum (10 mm. pressure or less) at temperatures of 500°C. and over.[131]

The α-form crystallizes in the cubic system and the lattice constant is $a = 18{\cdot}51$ A.[105] The value $a = 7{\cdot}17$ A. reported earlier appears to be in error.[132] The molecular unit in the solid is $P_4$ and the unit cell contains 56 units.

### β-White Phosphorus

This variety is formed by cooling α-white phosphorus to below the transition temperature of −76·9°C. at ordinary atmospheric pressure. The effect of pressure on the transition temperature is shown in Fig. 1.[133] β-White phosphorus is doubly refractive[134] whereas the high temperature form is isotropic.[135–6]

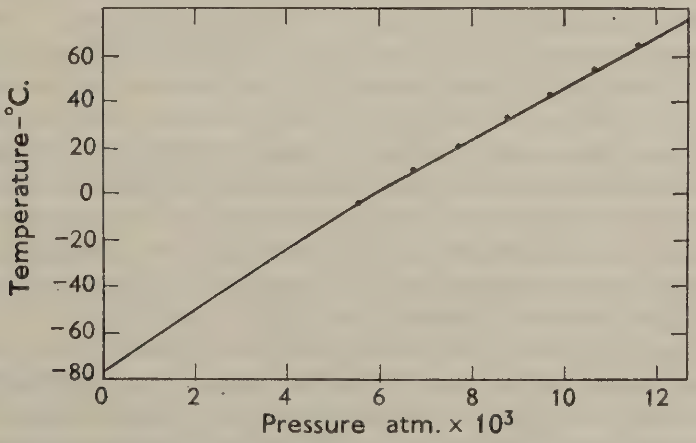


FIG. 1.—Effect of pressure on the transition temperature of α- to β-phosphorus

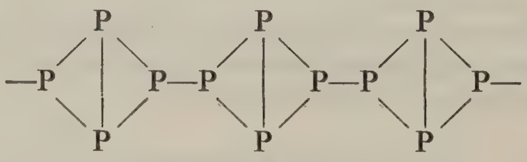
The instability of white phosphorus has been attributed to strain in the molecule caused by the 40° distortion of the valence angles.[137]

## Red Phosphorus

The structure, properties and forms of red phosphorus have been the subject of many conflicting reports in the literature. It has been classed as amorphous (Mellor, VIII, 745), cubic,[138] monoclinic,[139] hexagonal and triclinic.[140] The colour has been described as red,[141–2] scarlet,[136] purple,[144] violet,[145] ruby[144] and metallic.[146] It has been considered to be a mixture of the black and purple forms,[147] a solid solution of the ruby and purple varieties,[148] an equilibrium state between white and violet,[149] and a solid solution of several varieties of red phosphorus (Mellor, VIII, 752). It has also been described as a polymer of white phosphorus in which terminal groups such as hydroxyl, or bromine or iodine atoms[150] are present, and a combination of minute particles of the violet allotrope on which white phosphorus is adsorbed.[142]

It is evident that the method of preparation and subsequent treatment of red phosphorus have a marked influence on its structure and properties. Significant differences have been found in the thermochemical properties and vapour pressure of red phosphorus made at different temperatures.[146] Varieties prepared by heating white phosphorus in the presence of catalysts usually have an ill-defined crystal structure, a density of between 2·10 and 2·32, and vary in colour from red to violet.[142] Large crystals of red phosphorus are generally purple in colour, but the finely divided material can be scarlet.[151]

The hypothesis that some forms of red phosphorus may contain foreign atoms is supported by a number of observations. It is known that in the conversion of white to amorphous red phosphorus the latter takes up catalysts such as iodine or sulphur.[152] This reaction may be regarded as a type of polymerization, in that the tetrahedral $P_4$ unit of white phosphorus is converted into a more complex structure. For example, it has been suggested[64] that the $P_4$ molecule is opened by the rupture of a single P–P bond, leading to the formation of long chains of bonded atoms arranged in a manner similar to the following:



In such an arrangement, catalyst atoms could act as terminal groups or might give rise to a cross-linked network of chains. If white phosphorus is heated in the presence of water, yellow or yellowish brown products are obtained which contain 15–44 atomic-% of hydrogen. In the presence of light and moisture, purple materials are formed. These contain 10% of phosphorus oxides and water combined as hydrogen atoms and hydroxyl groups. The scarlet phosphorus of Schenck,[143] which is prepared by heating white phosphorus with phosphorus tribromide, is a polymer containing 10–30 at.-% of bromine, i.e. one out of 7–27 of the phosphorus valency bonds is joined to a bromine atom. Washing this product with water removes the bromine atoms and replaces them with hydroxyl groups.[153] Orange-coloured products are also formed when pentaerythritol tetrabromide is prepared by refluxing 1 mole of pentaerythritol with 2 moles of phosphorus tribromide at up to 175°C.[153a] The coloured material contains bromine, but because it was treated with water at an intermediate stage in the preparation, it is possible that it may also contain some of the lower oxidation product $(P_4(OH))_n$ (see page 245).[153b]

If organic halides are used as solvent the organic radical is strongly attached to the phosphorus and cannot be removed by boiling water. Oxidation of the product with nitric acid gives alkyl or aryl phosphinic acids (Van Wazer, reference 50, page 115). Irradiation of white phosphorus in a solvent, e.g. carbon disulphide, yields an amorphous red phosphorus containing impurities derived from the solvent.[150, 153]

Similar results have been observed when the conversion of white to red phosphorus in diphenylmethane is catalyzed by tributylamine.[154]

Commercial red phosphorus is usually amorphous or micro-crystalline. The amorphous form is obtained in laboratory preparations carried out below 350°C. or by depositing red phosphorus from the vapour which has been in contact with a hot tungsten filament at 200° to 425°C.[140] *X*-Ray studies show that the radial distribution curve has peaks at 2·29 and 3·50 A., from which it is inferred that the P–P–P bond angle is about 99°.[65, 475] The effect of heat on amorphous red phosphorus has been investigated by *X*-ray and differential thermal analysis procedures.[140] Exothermic peaks corresponding to about 200, 70 and 50 g.-cal./g. atom respectively are found at 460°, 520° and 540°C. The initial material was that designated as red phosphorus-I in Table V and was prepared by heating white phosphorus for 6–8 hr. at 280°C. in an inert atmosphere. The density as determined by a nitrogen gas densitometer was 2·16 g./c.c. It should be noted that this is lower than the density of 2·32–2·34 obtained for commercial amorphous phosphorus. The difference is most probably due to the higher temperatures (400° to 450°C.) used in the final stages of the manufacture of the commercial product. The differential thermal analysis peak at 460°C. corresponds to the transformation of red phosphorus-I into form II. This is followed by transformation into form III and form IV at 520° and 540°C., respectively. Form II and form III are poorly-crystallized materials and may be identical. They may also be identical with form IV which is tetragonal.[478] On the other hand, microscopical examination does indicate that there are both hexagonal and tetragonal varieties of red phosphorus. Form IV is birefringent and well-formed crystals have been obtained by slow condensation of phosphorus vapour at 425°C. and 1 atm. pressure, or at 20 atm. by heating to 535°C. and condensing on a surface at 500° to 510°C.[155] A micro-crystalline variety has been obtained by crystallization at 550°C.[139]

The best defined variety of red phosphorus is form V, which is triclinic. Differential thermal analysis shows no peak corresponding to the transition from form IV to form V. The material has been prepared by condensing phosphorus vapour at 550°C. on to a surface at 545°C. over a period of 30 days, or by heating amorphous red phosphorus at 550°C. for 6–30 days. *X*-Ray patterns of phosphorus-V are similar to those given by Hittorf's metallic or violet phosphorus. The latter was obtained[156] by heating phosphorus with lead at 500° to 600°C. in a sealed tube, then cooling and removing the lead by dissolving in dilute nitric acid. Similar patterns are given by material crystallized from lead at 525° to 590°C. or from bismuth at 570° to 580°C.[138] in sealed tubes. However, a detailed crystallographic study of Hittorf's violet phosphorus has shown that it crystallizes in the monoclinic system with space group $P2/c$, $a = 9{\cdot}21$, $b = 9{\cdot}15$, $c = 22{\cdot}59$ A., $\beta = 106{\cdot}1°$, and 84 atoms in the unit cell. The structure is based on two units, a $P_8$ group and a $P_9$ group, which are linked, each through two further phosphorus atoms, to form infinite tube-like structures of pentagonal cross section (Fig. 2). The tubes are packed parallel to one another in layers, pairs of layers being arranged roughly at right angles to one another.[487]

Red phosphorus-VI was obtained by heating white phosphorus at 300°C. and a pressure of 8000 atm.[157] It is deep red in colour and differs in appearance and in its *X*-ray pattern from other forms of red phosphorus. The material does not appear to have been examined in any detail.

Vitreous phosphorus has recently been reported to be formed by heating white phosphorus to above 250°C. under a pressure of 7000 atm. No sudden volume change, such as that which occurs in the formation of black phosphorus, was observed during this operation. The same material was obtained by heating white phosphorus with mercury in a sealed tube for 4 days at 380°C. (not above); the mercury was then extracted with molten lead or gold. Red phosphorus was not changed to the vitreous form by either of these procedures. The material is amorphous and has *d* 2·26. Its resistivity is above 1000 ohm-cm. at room temperature, increasing to a kilo-megohm-cm. in liquid nitrogen. Vitreous phosphorus is stable for an indefinite period in warm, moist air, but is oxidized slowly by nitric acid and rapidly by aqueous bromine. It sparks like flint when sawn or struck and may ignite. When heated in a sealed tube it is converted to red phosphorus in 4 days at 400°C. Under the same conditions in the presence of mercury it gives amorphous black phosphorus. On subliming in a vacuum, white phosphorus is formed. The various transformations which are possible between the different forms of phosphorus are shown diagrammatically in Fig. 3. It should be noted that there are no records of any changes from the black or red modifications of phosphorus to the vitreous form.[158]

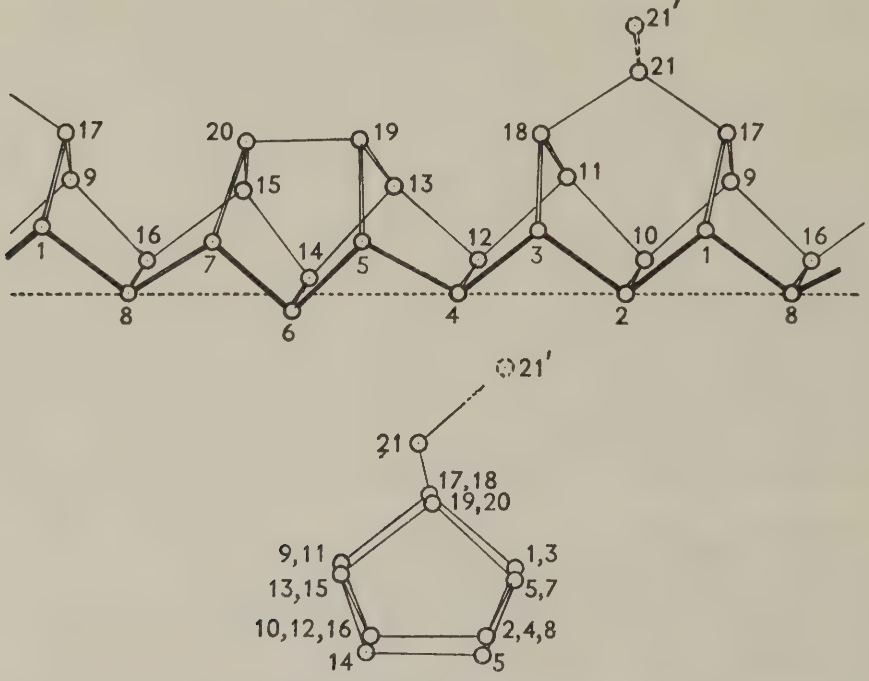


FIG. 2.—Section of a 'tube' of violet phosphorus. Above: parallel perspective. Below: projection parallel to the tube axis (end view)

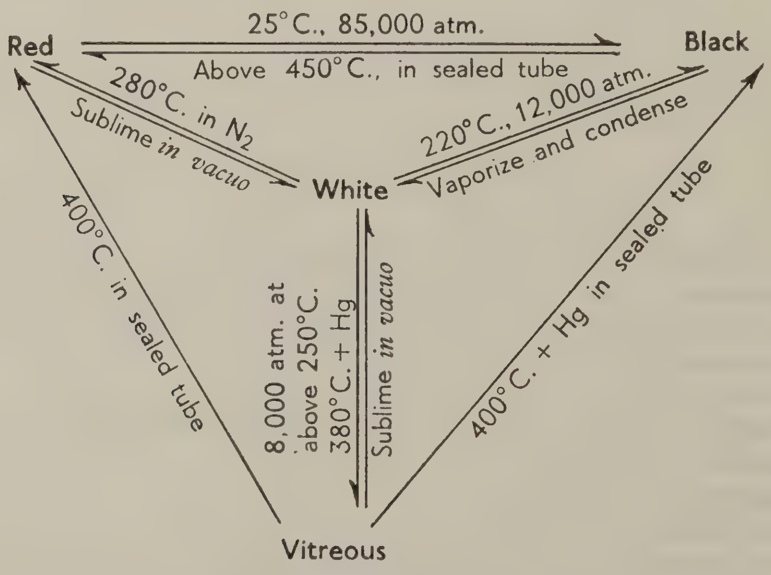

FIG. 3.—Transformations between allotropes of phosphorus

Approximate equations for the sublimation pressure of four modifications of phosphorus described above have been obtained.[155] These are given in Table VI.

Of the above equations, that for red phosphorus-V is considered to be the most accurate and reliable. The data for forms I and II may be subject to some error due to changes which the materials undergo when heated above 400°C.

Three other forms of red phosphorus have been reported. One of these is a cubic form made by heating ordinary red phosphorus at 600°C.[159] A reversible transition of red phosphorus to a new modification is said to occur at 600°C. under a pressure of about 40,000 atm.[160, 161] A new form of red phosphorus has been observed when yellow phosphorus is irradiated for 30 hr. with copper *X*-radiation (35 kv., 5 ma.). The yield was 4·5%.[136] There does not appear to be sufficient evidence to decide whether any of these forms are distinct from those described above. In later experiments, in which samples of red phosphorus were prepared at temperatures from 300° to 610°C., only two allotropic forms of red phosphorus were observed, corresponding to forms IV and V described above. They were well crystallized, and exhibited completely different *X*-ray diffraction and fluorescence spectra, one set associated with samples heated at temperatures greater than 426°C., and the other with samples heated to less than 420°C. Other *X*-ray diffraction patterns observed, which resembled those of forms I, II and III, were claimed to be associated with the growth of crystallites with poorly diffracting planes of less than 50 A. to well-developed crystallites, and were a regular function of the temperature at which the samples were prepared.[478]

*Table VI.—Sublimation Pressure Equations and Heats of Sublimation of Red Phosphorus*[155]

| Form | Equation ($p$ atm., $T$°K.) | Temp. (°C.) | Heat of sublimation (kcal. mole$^{-1}$) |
|---|---|---|---|
| I | $\log p = -4296/T + 6{\cdot}404$ | 320–500 | 19·7 |
| II | $\log p = -5250/T + 7{\cdot}61$ | 310–500 | 24 |
| IV | $\log p = -6070/T + 8{\cdot}67$ | 380–560 | 28 |
| V | $\log p = -6298/T + 8{\cdot}944$ | 320–510 | 28·8 |

Brown phosphorus, which may have some relation to the red variety, has been described in the section on the preparation of phosphorus (p. 141).

## Black Phosphorus

Reference has been made (page 142) to the two forms of black phosphorus, and to some of their properties, in a previous section. Crystalline black phosphorus is orthorhombic, with lattice constants of $a = 3{\cdot}3136$, $b = 10{\cdot}478$, $c = 4{\cdot}3763$ A.[481] There are eight phosphorus atoms in the unit cell, and the density is 2·70.[157, 162] The crystal is made up of double layers in which each phosphorus atom is bonded with three neighbours at distances of 2·244, 2·224, 2·224 A. Two of the bonds are in the plane of a layer, with a bond angle of 96·34°. The third is between the layers, with a bond angle of 102·09°. The nearest approach of atoms in adjacent layers is 3·59 A.[481] These data are a refinement of earlier measurements.[157, 152] The arrangement of the atoms is shown in Fig. 4.

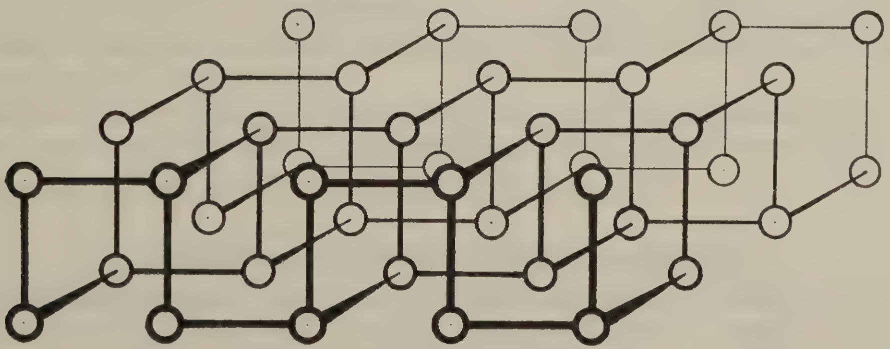

FIG. 4.—Structure of black phosphorus

Black phosphorus is completely stable in air and can be cut and machined without igniting, but burns with difficulty on being lighted. It is flaky and similar in appearance to graphite, though it has no free electrons which can move in the direction of the cleavage planes of the crystal (Van Wazer, reference 50, page 123). On heating at 550°C. it is converted to violet phosphorus. It can be crystallized from solutions of phosphorus in liquid bismuth.[481]

Amorphous black phosphorus, which is prepared by heating white phosphorus under high pressures but at temperatures lower than those required for the formation of the crystalline variety, has $d$ 2·25 g./c.c. $X$-Ray data[163] show that each phosphorus atom is bonded to three neighbours at a distance of 2·27 A. The next nearest atoms are at a distance of 3·34 A. The structure contains no simple $P_4$ molecules and is similar to that of red phosphorus.[65] The most probable atomic arrangement is a puckered network for which the average bond angle is 95·6°. The amorphous form appears to be less stable than the crystalline variety because on prolonged heating at 125°C. it is transformed into violet phosphorus.[164]

Black phosphorus forms mixed crystals with arsenic. For a composition of 53–74 atom-% of arsenic it is sufficient to cool a melt of the required composition. For crystals containing 43–53 atom-% of arsenic the melt has to be heated for several days at 600°C. and for 0–43 atom-% it is necessary to use mercury as a catalyst.[165]

Resonance bonding of $p$-orbital electrons is said to occur in black phosphorus.[166] The characteristic crystal lattice has been explained in terms of the distortion of a symmetrical crystal lattice by unsymmetrical resonance bonds arising from hybridized atomic orbitals.[167] It has also been suggested that the polymorphic forms of phosphorus are chemical isomers, according to which white phosphorus is constituted as $P_4$, red as $(P_2)_n$ and black as $P_8$ or $(P_2)_4$.[168]

*Table VII.—The Best-known Modifications of Phosphorus*

| Modification | Specific gravity | Characteristics |
|---|---|---|
| α-white | 1·83 | Cubic crystals. $P_4$ tetrahedral structure |
| β-white | 1·88 | Hexagonal crystals. $P_4$ tetrahedral structure. Formed below −77°C. |
| Amorphous red | 2·16 | Structure unknown |
| Crystalline red | 2·31 | Violet. Triclinic |
| Amorphous black | 2·25 | Structure probably a puckered network |
| Crystalline black | 2·69 | Orthorhombic with a layer-type structure |

From the information at present available it may be concluded that the modifications of phosphorus which have been definitely established are those shown in Table VII.

## The Relative Stability of Phosphorus Allotropes

White phosphorus is the most reactive and crystalline black phosphorus is the least reactive of the forms of elemental phosphorus. There is, however, considerable difference of opinion as to which is the most stable modification. Bridgman[133] found that between 350° and 450°C. black phosphorus had a vapour pressure lower than that of the red form and concluded that black phosphorus was the more stable variety. Smits and co-workers,[169, 170] however, observed that at temperatures below 560°C. black phosphorus had the lower vapour pressure, whereas at above this temperature the red modification gave the lower values. They concluded that black phosphorus was apparently metastable below 560°C. This was supported by the observation that the triple point of black phosphorus was slightly below that of the red variety and that the vapour pressure of black phosphorus in the lower temperature range was not constant, but increased slowly with time. However, the vapour pressure data of these two investigators do not overlap and on plotting the values of $\log p$ against $1/T$ two lines of different slope are obtained, from which differing heats of vaporization can be calculated. The Bridgman data agree better with the supposition that black phosphorus is the more stable form than do those of Smits.

In a more recent investigation[164] the heat evolved per gram-atom when the various forms of phosphorus react with bromine in carbon disulphide has been measured. The results are given in Table VIII (see also page 192).

*Table VIII.—Heats of Reaction of Phosphorus Allotropes with Bromine at 20°C.*[164]

| Form of phosphorus | Heat of reaction (kcal./g.-atom) |
|---|---|
| Crystalline black | 36·6 |
| Amorphous black | 44·1 |
| Bridgman's black | 38·3 |
| Commercial red | 42·2 |
| Laboratory red | 42·5 |
| White | 59·5 |

The laboratory red phosphorus was made by heating white phosphorus at 300°C. and 6000 atm. pressure.

The above results suggest that white phosphorus is the least stable, red next and crystalline black phosphorus is the most stable. The difference between the heats of reaction of crystalline black phosphorus and Bridgman's material was attributed to the presence of some amorphous material in the latter sample.

The densities and chemical stability (except possibly for amorphous black phosphorus) also seem to imply that crystalline black phosphorus is the most stable. This is followed by red phosphorus (triclinic, form V), amorphous black phosphorus and the white form.

Most thermodynamic properties are referred to white phosphorus as their basis. In some reports, however, triclinic red phosphorus has been preferred.[171–2]

## GENERAL PHYSICAL PROPERTIES

In the following data, 'amorphous phosphorus' refers to the ordinary commercial or laboratory made material and not to the amorphous phosphorus form I, referred to above, unless specifically stated.

### Density

The densities of solid phosphorus are given in Table IX.

*Table IX.—The Density of Solid Forms of Phosphorus*

| Variety | Density (g./c.c.) | Ref. |
|---|---|---|
| α-white | $d_4^{20} = 1{\cdot}8233$ $d_4^{44\cdot2} = 1{\cdot}8079$ | 173 |
| β-white | 1·88 | 174 |
| Amorphous—Form I | 2·16 | 131 |
| Amorphous red | 2·20–2·34 | |
| Triclinic—Form V | 2·31 | 131 |
| Amorphous black | 2·25 | 164 |
| Crystalline black | 2·69 | 133, 162 |

The density and atomic volume of white phosphorus at low temperatures have been determined with the results shown in Table X.

*Table X.—Density and Atomic Volume of White Phosphorus*[175]

| Temp. (°C.) | Density (g./c.c.) | Atomic vol. (c.c.) |
|---|---|---|
| −273 | 2·01 | 15·4 |
| −195 | 1·994 | 15·6 |
| −79 | 1·891 | 16·4 |
| +19 | 1·824 | 17·0 |

The values for the density of white phosphorus given above, with the exception of the density at −195°C. which appears to be anomalous, are represented with a maximum error of 0·2% by the equation

$$d_t = 1{\cdot}838 - 6{\cdot}5 \times 10^{-4} t \qquad (t = -273° \text{ to } +44°\text{C.})$$

where $d_t$ is the density at $t$°C. This gives a mean coefficient of cubical expansion of $3{\cdot}53 \times 10^{-4}$.

The atomic volumes of red ($d_{16°} = 2{\cdot}33$) and black phosphorus ($d_{16°} = 2{\cdot}70$) are 13·2 and 11·4, respectively, at −273°C.[175] (see also page 216).

White phosphorus has an expansion of 3·26% on melting.[173] The density of the liquid for the temperature range 20° to 280°C. has been given as[176]

$$d_4^t = 1{\cdot}76705 - 9{\cdot}222 \times 10^{-4}(t-20)$$

Another equation covering the range 7° to 68°C. is[177]

$$d = 1{\cdot}78685 - 9{\cdot}386 \times 10^{-4} t$$

Measurements of the liquid density between 100°C. and 280°C.[178] have been combined with those below 70°C.[177] to give the equation[155]

$$d = 1{\cdot}7862 - 9{\cdot}195 \times 10^{-4} t$$

This equation is valid between 10° and 280°C. and represents the data with an average error of 0·02% and a maximum error of 0·04%.

These equations give a mean coefficient of cubical expansion of liquid phosphorus between 10° and 280°C. of $5{\cdot}18 \times 10^{-4}$. This is substantially in agreement with data previously recorded (Mellor, VIII, 759).

Somewhat lower values for the liquid density have been reported[179] for white phosphorus saturated with water. These data are represented by the equation

$$d = 1{\cdot}782 - 9{\cdot}0 \times 10^{-4} t \qquad (t = 45° \text{ to } 95°\text{C.})$$

Other data for the density of solid and liquid white phosphorus are given in Table XI (see also page 215).

*Table XI.—Density of Solid and Liquid White Phosphorus*

| Temp. (°C.) | Density (g./c.c.) | |
|---|---|---|
| | Solid | Liquid |
| 0 | 1·83676 | — |
| 20 | 1·82321 | — |
| 35 | — | 1·763 |
| 44·4 | — | 1·74529 |
| 100 | — | 1·69490 |

The following equation, which has been derived for the effect of pressure on the specific volumes of liquid and solid states of metals, has been found to apply also to phosphorus.[180]

$$\frac{\mathrm{d}(\Delta v)}{\mathrm{d}p} = \frac{\mathrm{d}T}{\mathrm{d}p}\left[\left(\frac{\partial V_e}{\partial T}\right)_p - \left(\frac{\partial V_s}{\partial T}\right)_p\right] + \left[\left(\frac{\partial V_e}{\partial p}\right)_T - \left(\frac{\partial V_s}{\partial p}\right)_T\right]$$

where $p$ is the pressure, $\Delta v$ the change in volume, $T$ is the transformation temperature and $V_s$ and $V_e$ are the specific volumes of solid and liquid respectively.

The ratio of the density of liquid phosphorus at its triple point to the density at the critical temperature has been given as 2·7.[181]

Red and black phosphorus, on melting, give a liquid which yields white phosphorus on cooling. The vapour pressure curves of red and white phosphorus in the liquid state seem to be different portions of the same curve. It seems likely therefore that there is no distinction to be made between liquid red, liquid black and liquid white phosphorus.[149, 155]

## Melting Point

The melting point of $\alpha$-white phosphorus is generally given as 44·1°C.[155, 174, 182] However, the determination of the melting point is subject to certain errors. Traces of arsenic and sulphur lower the melting temperature. Owing to the high molecular depression of freezing point—41°C. for 1000 g. of solvent—phosphorus of at least 99·996% purity is required if the melting point is to be accurate to within 0·1°C. Supercooling, to which phosphorus is very prone, must also be avoided. Taking these factors into account, the most accurate value for the melting temperature is 44·25° ± 0·05°C. at atmospheric pressure.[173] The pressure dependence of the melting point is 0·0313°C. per atmosphere, and the effect of pressure is given with a maximum error of 0·5% by the equation

$$t = 44{\cdot}22 + 0{\cdot}030p - 0{\cdot}77 \times 10^{-6}\, p^2$$

where $t$ is the melting point in °C. and $p$ is the pressure in kg. cm.$^{-2}$. This equation[183] agrees with data obtained at pressures up to 6000 kg. cm.$^{-2}$

The melting point of red phosphorus has been given various values between 590° and 600°C.[141, 149, 155, 174] However, it appears that the true melting point coincides with the triple point, i.e. 589·5°C. at 43·1 atmospheres.[184–5] Black phosphorus is reported to melt at about 610°C.[133]

## Boiling Point, Critical Temperature and Pressure

The accepted value for the boiling point of white phosphorus is 280·5°C. at atmospheric pressure. The critical temperature and pressure are 695°C. and 82·2 atmospheres respectively.[185]

Rapid transformation of white into red phosphorus occurs between 350° and 500°C. and here liquid phosphorus does not exist.

## Supercooling and Velocity of Crystallization

Liquid white phosphorus has a marked tendency to supercool and can be kept indefinitely in the liquid state at room temperature. Droplets of 1 mm. diameter have been cooled to as low as −71·3°C. before solidification occurred. There is no evidence of glass formation at this temperature.[186]

This supercooling phenomenon has been explained in terms of spontaneous nucleation, the free energy of nucleus formation and the interfacial tension between the solid and the liquid.[187]

The velocity of crystallization at 21·3°C. of the supercooled liquid is 210 cm. sec.$^{-1}$ The temperature dependence of the crystallization velocity $V$ in cm./sec. is given by the equation

$$(\eta V)^{\frac{1}{2}} = 1{\cdot}01\,(44{\cdot}1 - t)$$

where $t$°C. is the temperature and $\eta$ is the viscosity in centipoises.[188]

The theory of crystal growth has been discussed,[189] but the equation derived for the velocity of crystallization does not apply to supercooled liquid phosphorus. The calculated value is about a thousand times smaller than the observed velocity.

### Vapour Pressure

Most of the data on the vapour pressure of phosphorus have already been summarized (Mellor, VIII, 761). This information is discussed below in the light of more recent observations.

Values for the vapour pressure of solid white phosphorus are based largely on the measurements of Centnerszwer.[190] These were obtained by a transpiration method in which hydrogen, carbon dioxide, coal gas and iodobenzene were used as gas streams. Except for hydrogen the measurements were carried out at 20°C. only. Some eight or ten determinations were made with each gas and the average of these is 0·0262 mm. at 20°C. The range, however, was from 0·0192 mm. to 0·0347 mm. The data for hydrogen are given in Table XII.

*Table XII.—Vapour Pressure of Solid White Phosphorus*[190]

| Temp. (°C.) | Vapour pressure (mm.) | |
|---|---|---|
| | Average | Range |
| 20 | 0·0253 | 0·0215–0·0309 |
| 25 | 0·0426 | 0·0397–0·0461 |
| 30 | 0·0729 | 0·0594–0·0860 |
| 35 | 0·0889 | 0·0819–0·1090 |
| 40 | 0·1221 | 0·1174–0·1268 |

These values do not give a linear plot of log $p$ against $1/T$. On the other hand the value at 20°C. seems to be reliable and the free energy of sublimation calculated from the sublimation pressure at 25°C. is in close agreement with that calculated from spectroscopic and calorimetric data combined with independent vapour pressure data (see below).

MacRae and Van Voorhis,[182] who made accurate measurements of the vapour pressure of liquid phosphorus (not of solid phosphorus as is sometimes reported) considered that the most accurate value for the vapour pressure of the liquid at 41·1°C. was 0·181 mm. They combined this with the value (0·0253 mm.) which Centnerszwer obtained at 20°C. and calculated the vapour pressure of solid white phosphorus to be given by the equation

$$\log_{10} p_{\text{mm.}} = 9{\cdot}6511 - 3297{\cdot}1T^{-1}$$

MacRae and Van Voorhis obtained a vapour pressure of 0·173 mm. at 44·1°C. Using this value and an expression for the heat of sublimation the following equation has been derived[155]

$$\log_{10} p_{\text{mm.}} = 1{\cdot}9198 - 3{\cdot}084\times10^{-3}T + 2{\cdot}7763\log T - 2{\cdot}641\times10^{3}T^{-1} - 3{\cdot}258\times10^{4}T^{-2}$$

Another and similar equation based on $p_{\text{mm.}} = 0{\cdot}181$ at the melting point is

$$\log_{10} p_{\text{mm.}} = 1{\cdot}9499 - 3{\cdot}0838\times10^{-3}T + 2{\cdot}8242\log T - 2{\cdot}6829\times10^{3}T^{-1} - 3{\cdot}2521\times10^{4}T^{-2}$$

The additional data used in this calculation are:

(1) heat of vaporization of $P_4 = 12{,}612$ g.-cal. mole$^{-1}$
(2) heat capacity of $P_4$ vapour[191]
(3) heat capacity of solid and liquid phosphorus[192]
(4) heat of fusion of $P_4 = 601$ g.-cal. mole$^{-1}$.[192]

The equation can be simplified, without loss of accuracy, to[173]

$$\log_{10} p_{\text{mm.}} = 8{\cdot}7011 - 2996{\cdot}2T^{-1}$$

Three determinations of the vapour pressure[193] have given the values of 0·0027, 0·0085 and 0·0269 mm. at 0°, 10° and 20°C., respectively. The only one in agreement with other data is 0·0269 mm. at 20°C.

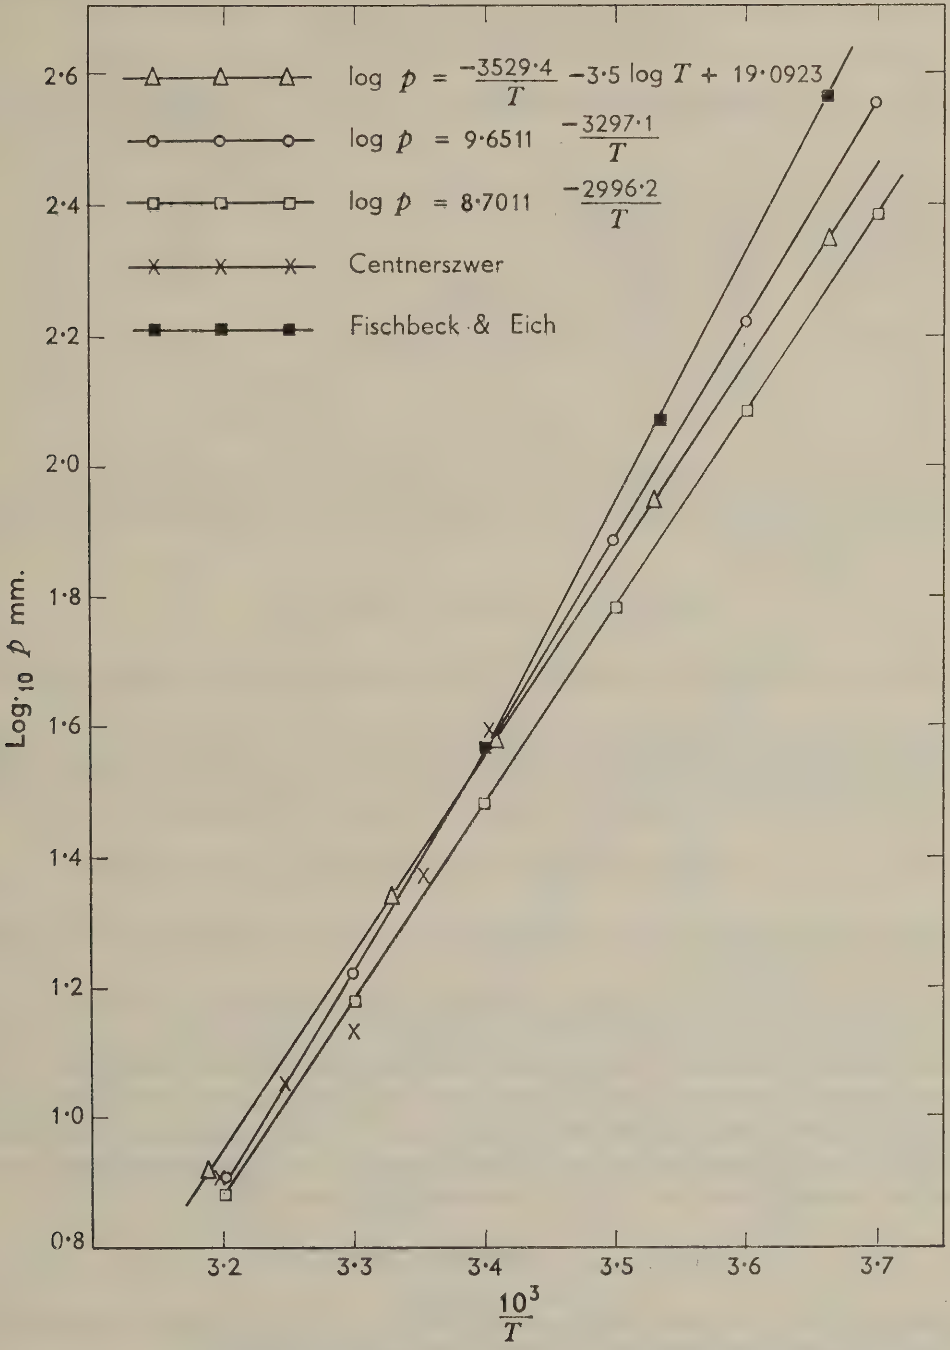

FIG. 5.—Vapour pressure of solid white phosphorus

More recently the vapour pressure has been measured between −23° and 40°C. by a radioactive tracer method.[194] The results were combined with Centnerszwer's value $p_{\text{mm.}} = 0{\cdot}0262$ at 20°C. to give the equation

$$\log_{10} p_{\text{mm.}} = -3529{\cdot}4T^{-1} - 3{\cdot}5 \log T + 19{\cdot}0923$$

The above equations all represent accurately the data to which they refer. However, as shown in Fig. 5 there are significant differences in the slopes of the log $p$

against $1/T$ plots. These differences are shown in Table XIII which gives the heats of sublimation calculated from the equations ($R = 1{\cdot}987$). It would appear that the most reliable value of the heat of sublimation lies between 13·8 and 14·1 kcal. mole$^{-1}$ of $P_4$. It has been calculated from free energy and vapour pressure data that the figure is 14·0 ± 0·3 kcal. mole$^{-1}$ at 25°C.[195]

*Table XIII.—Heats of Sublimation Calculated from the Vapour Pressure Equations of Solid White Phosphorus*

| Vapour pressure equation | Heat of sublimation (kcal. mole$^{-1}$) |
|---|---|
| $\log p_{\text{mm.}} = 19{\cdot}0923 - 3{\cdot}5 \log T - 3529{\cdot}4T^{-1}$ | 14·04 |
| $\log p_{\text{mm.}} = 8{\cdot}7011 - 2996{\cdot}2T^{-1}$ | 13·71 |
| $\log p_{\text{mm.}} = 9{\cdot}6511 - 3297{\cdot}1T^{-1}$ | 15·08 |
| $\log p_{\text{mm.}} = 1{\cdot}9198 - 2641T^{-1} - 32{,}580T^{-2} + 2{\cdot}7763 \log T - 3{\cdot}084 \times 10^{-3}T$ | 13·68 |
| $\log p_{\text{mm.}} = 11{\cdot}920 - 3960T^{-1}$ (data of Fischbeck and Eich) | 18·12 |

The most accurate values for the vapour pressure of liquid phosphorus seem to be those of MacRae and Van Voorhis, which are given for the temperature range 44° to 150°C. by the equation[182]

$$\log_{10} p_{\text{mm.}} = 7{\cdot}9515 - 2757{\cdot}5T^{-1}$$

It should be noted that the constant 7·9515 is sometimes erroneously reported as 7·9542.

The vapour pressure of the liquid has also been measured up to 356°C., at which temperature it is 3·90 atm.[169] Combination of these values with those of MacRae and Van Voorhis and data from other sources[185, 196] gives the equation[155]

$$\log_{10} p_{\text{mm.}} = 18{\cdot}8192 + 1{\cdot}074 \times 10^{-3}T - 3{\cdot}906 \log_{10} T - 3216{\cdot}7T^{-1}$$

which represents the data with an average error of 1·8% and a maximum error of 5·1% between 44° and 360°C.

Liquid yellow phosphorus is rapidly changed to red phosphorus between 350° and 500°C. At temperatures above 500° C. the rate of the reverse change is slow enough to enable the vapour pressure of supercooled red phosphorus to be determined. From the vapour pressure diagram (see Fig. 6 below), it is fairly certain that this phase is identical with liquid white phosphorus. The data[145] from these high temperature measurements are represented by the following equation with a maximum error of 1·1% and an average error of 0·5%,[155] between 504° and 634°C.

$$\log_{10} p_{\text{mm.}} = 7{\cdot}0663 - 2196{\cdot}0T^{-1}$$

This equation gives a vapour pressure of 82·6 atm. for the critical temperature of 695°C. and a pressure of 43·6 atm. at the triple point, 589·5°C.

MacRae and Van Voorhis[182] (Mellor, VIII, 762) found that the vapour pressure measurements for liquid phosphorus between 44° and 634°C. reported by all investigators, with the exception of the data of Schroetter (1844), were given to within ±5% by the equation

$$\log_{10} p_{\text{mm.}} = 11{\cdot}5694 - 2898{\cdot}1T^{-1} - 1{\cdot}2566 \log_{10} T$$

Vapour pressure equations for solid red phosphorus in its various forms have been given above (page 159) for temperatures between 310° and 560°C. The data[184] previously reported (Mellor, VIII, 761) for solid red phosphorus made by heating the white modification for 5 hr. at 550°C., are summarized by the equation[155, 169]

$$\log_{10} p_{\text{mm.}} = 11{\cdot}0844 - 5667{\cdot}7T^{-1}$$

This equation agrees with the data to within ±5% between 280° and 590°C.

The available data[133, 170, 183] on the vapour pressure of solid black phosphorus are summarized by the equation

$$\log_{10} p_{\text{mm.}} = 13{\cdot}14 - 7400T^{-1}$$

which applies in the temperature range of 350° to 590°C. with an average error of 8·5% and a maximum error of 17%.

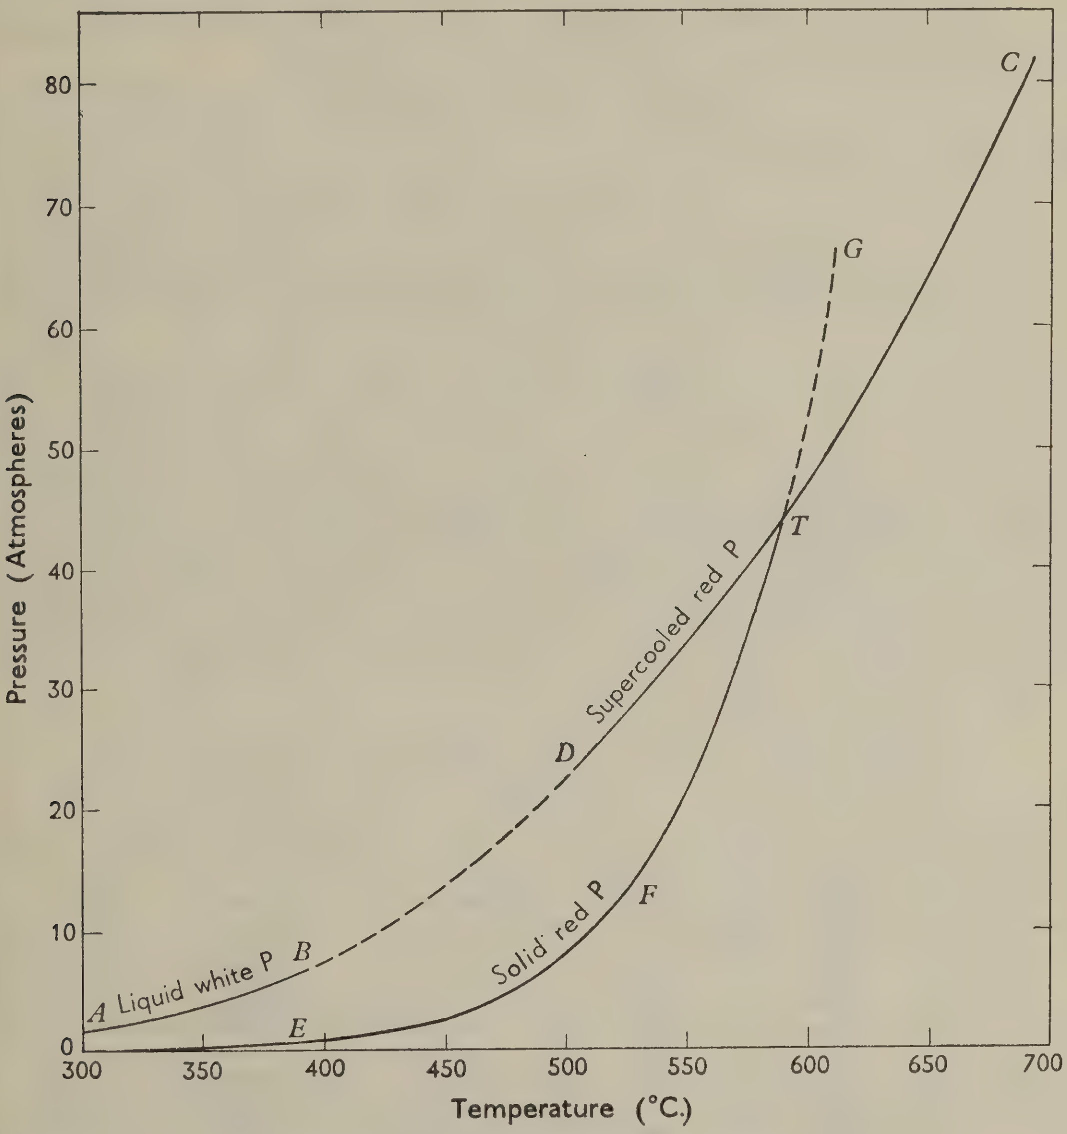

FIG. 6.—Vapour pressure of phosphorus

The vapour pressure data are shown in Fig. 6 for temperatures between 300°C. and the critical point (see also Mellor, VIII, 751–2, and ref. 173, p. 497). Curve *AB* represents the vapour pressure of molten white phosphorus up to nearly 400°C. This is followed by the portion *BD* for which no measurements are available. *TC* is the vapour pressure of molten red phosphorus, measured up to 634°C. and 58·6 atm. and produced to the critical temperature *C* at 695°C. *TD* gives the data for supercooled red phosphorus from the triple point *T* down to the lowest temperature (504°C.) at which measurements could be made. This portion, which is continuous with *AB*, indicates that molten white phosphorus is identical with supercooled red. *EFT* is the vapour pressure curve for solid red phosphorus and *TG* represents the effect of pressure on the melting point of the latter. At *T* red phosphorus melts to give a yellow liquid.

### Vapour Equilibria

In the equilibrium $P_4 \rightleftharpoons 2P_2$ between tetratomic and diatomic phosphorus vapour, anomalies in the early vapour pressure measurements were found to be explained if it were assumed that $P_2$ molecules were in equilibrium with red phosphorus.[197] According to this hypothesis, red phosphorus evaporated in $P_2$ units, but the evidence for this was not conclusive (see ref. 173, p. 487). The vapour pressure of red phosphorus has been measured by evaporating it into a vacuum. Application of the Hertz–Knudsen effusion equation $v = pN/\sqrt{2\pi MRT}$, where $v$ is the effusion velocity, $N$ is Avogadro's number, $p$ is pressure in dynes cm.$^{-2}$ and $M$ is the molecular weight,[198] gave values which are represented by the equation

$$\log_{10} p_{\mathrm{mm.}} = 1{\cdot}10 - 4110T^{-1}$$

between 300° and 480°C.

These data are about $10^{-7}$ times those given by static methods. This was explained as being due to the evaporation of $P_2$ molecules which, under the conditions of the experimental measurements, had no opportunity to recombine as $P_4$ molecules.[199]

The earlier data on the dissociation of phosphorus vapour obtained by Preuner and Brockmöller[200] and by Stock, Gibson and Stamm[201] have already been summarized (Mellor, VIII, 757). At that time there were no means of deciding which were the more reliable data, although it is to be noted that Preuner and Brockmöller considered that their measurements were only approximate. They concluded that there were measurable amounts of $P_4$, $P_2$ and P molecules present at temperatures between 800° and 1200°C., whereas Stock and co-workers found that the only dissociation at these temperatures was that of tetratomic into diatomic molecules.

Calculations[77] based on spectroscopic[71–2, 74, 76] and molecular structure[63] data show that the conclusions and measurements of Stock, Gibson and Stamm are correct and substantially free from error. The data of Stock *et al.* are given in Table XIV, together with the calculated equilibrium constant based on the dissociation energy $\Delta H_0^\circ = 53{,}600$ g.-cal. per mole.[77]

*Table XIV.—The Dissociation of Phosphorus Vapour*[201]

$P_4 \rightleftharpoons 2P_2$

| Temp. (°C.) | Pressure (mm.) | Vapour density | Degree of dissociation | Constant ($K_{\mathrm{atm.}}$) | $K_{\mathrm{atm.}}$ calc.[77] |
|---|---|---|---|---|---|
| 900 | 606 | 58·7 | 0·05 | 0·00717 | 0·00645 |
| | 433 | 58·9 | 0·05 | 0·00440 | |
| | 243 | 57·8 | 0·07 | 0·00520 | |
| | 99 | 55·0 | 0·12 | 0·00600 | |
| 1000 | 691 | 55·5 | 0·11 | 0·0430 | 0·0375 |
| | 498 | 55·2 | 0·11 | 0·0330 | |
| | 283 | 53·4 | 0·15 | 0·0351 | |
| | 119 | 50·0 | 0·23 | 0·0349 | |
| 1100 | 804 | 51·1 | 0·20 | 0·1890 | 0·167 |
| | 586 | 50·3 | 0·22 | 0·1582 | |
| | 339 | 47·7 | 0·29 | 0·1603 | |
| | 145 | 43·6 | 0·41 | 0·1515 | |
| 1200 | 950 | 46·0 | 0·34 | 0·600 | 0·612 |
| | 699 | 44·8 | 0·38 | 0·638 | |
| | 412 | 41·7 | 0·48 | 0·629 | |
| | 175 | 38·3 | 0·61 | 0·527 | |

The vapour density in the above table is referred to hydrogen. The degree of dissociation $\alpha$ is calculated from $\alpha=(\delta-\Delta)/\Delta$, where $\delta$ is the normal vapour density (61·47) of phosphorus and $\Delta$ is the measured value, both referred to hydrogen. From these data the dissociation constant was obtained by using the expression

$$K=\frac{4(\delta-\Delta)^2P}{\delta(2\Delta-\delta)}$$

where $P$ is the pressure in atmospheres (ref. 154, p. 15).

The values of $K_{\text{atm.}}$ from Preuner and Brockmöller's measurements at 900°, 1000°, 1100° and 1200°C. are 0·033, 0·105, 0·276 and 0·658, respectively. The calculated values of $K$ in Table XIV are represented by the equation

$$\log_{10} K_{\text{atm.}} = -11{,}505T^{-1}+7{\cdot}582$$

The dissociation into phosphorus atoms, which Preuner and Brockmöller's data indicated, has also been investigated. Values of the equilibrium constant $K$ derived from these data were used to calculate the heat of dissociation $\Delta H_0^\circ$ from the equation

$$\Delta H_0^\circ = -RT\log_e K - RT.\Delta(\log_e N_0-\log_e Q)$$

where $N_0$ is Avogadro's number and $Q$ is the partition function given by

$$Q=\sum_{n=1}^{\infty}\exp.\{-\epsilon_n/RT\}$$

The results are given in column 3 of Table XV.

The equilibrium constant was also calculated from spectroscopic data alone. These show [72–4] that the dissociated state is $^4S$ with a dissociation energy of $D_0^\circ=5{\cdot}008$ e.v. which corresponds to $\Delta H_0^\circ=115{,}450$ g.-cal. mole$^{-1}$ (1 e.v. = 23·053 kcal. mole$^{-1}$). With this value for $\Delta H_0^\circ$, log $K$ and $K$ were found to be as shown in columns 4 and 5 of Table XV.

*Table XV.—The Dissociation,* $P_2 \rightleftharpoons 2P$, *of Phosphorus Vapour*[77]

| Temp. (°C.) | Experimental data | | Spectroscopic data | |
|---|---|---|---|---|
| | $-\log_{10} K_{\text{atm.}}$ | $\Delta H_0^\circ$ g.-cal. | $-\log_{10} K_{\text{atm.}}$ | $K_{\text{atm.}}$ |
| 800 | 4·355 | 49,400 | 20·13 | $7{\cdot}4\times10^{-21}$ |
| 900 | 3·501 | 49,600 | 18·04 | $9{\cdot}1\times10^{-19}$ |
| 1000 | 2·802 | 49,900 | 16·27 | $5{\cdot}4\times10^{-17}$ |
| 1100 | 2·200 | 50,200 | 14·77 | $1{\cdot}7\times10^{-15}$ |
| 1200 | 1·676 | 50,500 | 13·44 | $3{\cdot}6\times10^{-14}$ |

It will be seen that the values of $\Delta H_0^\circ$ derived from the experimental data are not constant and are very much smaller than the spectroscopic dissociation energy. It should be noted that the latter has been reported to be 5·2 e.v.[202] and 5·031 e.v.[75, 203, 204] of which the second value is probably the more reliable.

The above considerations show that dissociation of phosphorus vapour into atoms is negligible at 1200°C., and the spectroscopic values of $K$ in Table XV conform to the equation

$$\log_{10} K_{\text{atm.}} = 4{\cdot}560-26{,}500T^{-1} \qquad (T \text{ in °K.})$$

This gives an average value of $\Delta H^\circ=121{,}200$ g.-cal. mole$^{-1}$ and an equilibrium constant of $K_{\text{atm.}}=5\times10^{-85}$ at 25°C.

Calculations based on the equilibrium have been extended[205] to temperatures up to 3000°C. with the results shown in Table XVI (see also ref. 154, p. 17).

*Table XVI.—The Equilibrium* $P_2 \rightleftharpoons 2P$ *at High Temperatures*[205]

| Temp. °C. | $K_p$ (atm.) | % dissociation $= 100 \times \left(\frac{K}{K+4}\right)^{1/2}$ |
|---|---|---|
| 25 | $2{\cdot}8 \times 10^{-80}$ | $8 \times 10^{-39}$ |
| 727 | $3 \times 10^{-20}$ | $8{\cdot}7 \times 10^{-9}$ |
| 1000 | $9{\cdot}1 \times 10^{-15}$ | $4{\cdot}8 \times 10^{-6}$ |
| 1227 | $1{\cdot}0 \times 10^{-11}$ | $1{\cdot}6 \times 10^{-4}$ |
| 1500 | $4{\cdot}6 \times 10^{-9}$ | $3{\cdot}4 \times 10^{-3}$ |
| 1727 | $3{\cdot}0 \times 10^{-7}$ | $2{\cdot}7 \times 10^{-2}$ |
| 2000 | $7{\cdot}6 \times 10^{-6}$ | $1{\cdot}4 \times 10^{-1}$ |
| 2500 | $8{\cdot}8 \times 10^{-4}$ | 1·48 |
| 3000 | $2{\cdot}5 \times 10^{-2}$ | 7·86 |

The above data are based on $\Delta H_0^\circ = 115{,}450$ g.-cal. mole$^{-1}$ and give the equation

$$\log_{10} K_{\text{atm.}} = 6{\cdot}100 - 25{,}550T^{-1} \qquad (T \text{ in } ^\circ\text{K.})$$

which gives an average of $\Delta H^\circ = 116{,}850$ g.-cal. mole$^{-1}$.

## Rate of Evaporation

The rate of evaporation of white phosphorus into a vacuum between −20°C. and +20°C. has been measured by a radioactive method using $^{32}$P. The results are given in Table XVII, where $i$ is the number of molecules evaporating per second per sq. cm.

*Table XVII.—Rate of Evaporation of White Phosphorus*[206]

| Temp. (°C.) | Evaporation rate ($i \times 10^{-17}$ cm.$^2$ sec.$^{-1}$) | Evaporation coefficient |
|---|---|---|
| −20·3 | 0·78 | 0·74 |
| −13·1 | 1·56 | 0·70 |
| −6·8 | 3·10 | 0·70 |
| −0·3 | 5·90 | 0·71 |
| 0 | 5·14 | 0·59 |
| 1·0 | 3·90 | 0·43 |
| 2·3 | 6·00 | 0·56 |
| 2·7 | 5·90 | 0·53 |
| 3·0 | 6·20 | 0·56 |
| 4·4 | 5·40 | 0·42 |
| 8·0 | 7·00 | 0·40 |
| 12·0 | 12·10 | 0·48 |
| 17·1 | 20·0 | 0·53 |
| 20·2 | 33·0 | 0·67 |
| 20·3 | 27·0 | 0·54 |

of surface and $\alpha$ is the evaporation coefficient,[206] i.e. the fraction of impinging molecules which condense on the surface.[198]

For red phosphorus the following results have been reported, in g. cm.$^{-2}$ sec.$^{-1}$, for an evaporation coefficient of unity.[199]

*Table XVIII.—Rate of Evaporation of Red Phosphorus*[199]

| Temp. (°C.) | Evaporation rate ($m \times 10^6$ g. cm.$^{-2}$ sec.$^{-1}$) |
|---|---|
| 305 | 1·15 |
| 350 | 3·57 |
| 400 | 7·92 |
| 410 | 6·84 |
| 480 | 5·50 |

No evaporation of red phosphorus was observed at 100°C. under 0·5 mm. pressure.[207]

### Compressibility

The compressibilities of white and red phosphorus between pressures of 100 and 500 atm. at 20°C. have been reported previously (Mellor, VIII, 759). The data for red phosphorus refer to material of density 2·15.[208]

At 30°C. the compressibility, i.e. change in volume divided by the applied pressure, for red phosphorus of density 2·348 (at 20°C.) is 5·05 × $10^{-6}$ cm.$^2$ kg.$^{-1}$ under a pressure of 2000 kg. cm.$^{-2}$ and 3·91 × $10^{-6}$ cm.$^2$ kg.$^{-1}$ for a pressure of 12,000 kg. cm.$^{-2}$. At 75°C. the corresponding values are 5·00 × $10^{-6}$ cm.$^2$ kg.$^{-1}$ and 3·97 × $10^{-6}$ cm.$^2$ kg.$^{-1}$. In the same units the respective data for black phosphorus at the same temperatures and pressures are, 2·6 × $10^{-6}$, 1·7 × $10^{-6}$ and 2·6 × $10^{-6}$ and 1·74 × $10^{-6}$.

Measurements at much higher pressures at room temperature gave the results shown in Table XIX.[209, 210]

*Table XIX.—Compressibility of Red and Black Phosphorus*[209–10]

| Pressure (kg. cm.$^{-2}$) | Relative volume | | Compressibility (cm.$^2$ kg.$^{-1}$) × $10^6$ | |
|---|---|---|---|---|
| | Red | Black | Red | Black |
| 1 | 1 | 1 | 1 | 1 |
| 25,000 | 0·903 | 0·935 | 3·88 | 2·60 |
| 30,000 | 0·885 | 0·927 | 3·45 | 2·43 |
| 40,000 | 0·853 | 0·912 | 3·68 | 2·20 |
| 50,000 | 0·829 | 0·899 | 3·42 | 2·02 |
| | | 0·849(b) | | 3·02 |
| 60,000 | 0·809 | 0·837(b) | 3·18 | 2·72 |
| 70,000 | 0·793 | 0·825 | 2·96 | 2·50 |
| 80,000 | 0·780 | 0·816 | 2·75 | 2·30 |
| 90,000 | 0·667(a) | 0·807 | 3·70 | 2·14 |
| 100,000 | 0·660 | 0·799 | 3·30 | 2·01 |

(a) Irreversible change of red to black phosphorus occurs at 85,000 kg. cm.$^{-2}$, with a volume change from 0·773 to 0·670.

(b) Reversible change occurs at 50,000 kg. cm.$^{-2}$

The above data give straight lines if the logarithm of pressure is plotted against the reciprocal of the relative volume. These lines show breaks where transitions occur. The data conform to the empirical equation

$$p_{\text{atm.}} = C \exp.\{B/V\}$$

where $V$ is the relative volume and $B$ and $C$ are constants. From this it can be shown that

$$\log_{10} p_{\text{atm.}} = 2{\cdot}303\, Ad_0(d-1)$$

where $d_0$ is the density at atmospheric pressure and $A$ is the slope of the $\log_{10} p$ against $1/V$ plot.[211]

The compressibility has been used to calculate the atomic radius of white phosphorus from the expression[130]

$$r^3 = \frac{3V_0}{4\pi N} = \frac{3}{4\pi N}\left(V - \frac{\beta R}{\alpha}\right)$$

where $r$ = radius in A.
$V_0$ and $V$ = molecular volume at 0°K. and $T$°K.
$\alpha$ = coefficient of cubical expansion = $36 \times 10^{-5}$
$\beta$ = compressibility in cm.$^2$ dyne$^{-1}$ = $20{\cdot}3 \times 10^{-12}$
$\boldsymbol{R}$ = gas constant in dyne-cm.$^2$ and cm.$^3$ = $8{\cdot}3144 \times 10^7$
$N$ = Avogadro's number.

Putting $V = 17{\cdot}0$ at 290°K., then $V_0 = 12{\cdot}3$ cm.$^3$ and the radius becomes $1{\cdot}70 \times 10^{-8}$ cm. This is considerably larger than the covalent radius (1·10 A.) or the metallic

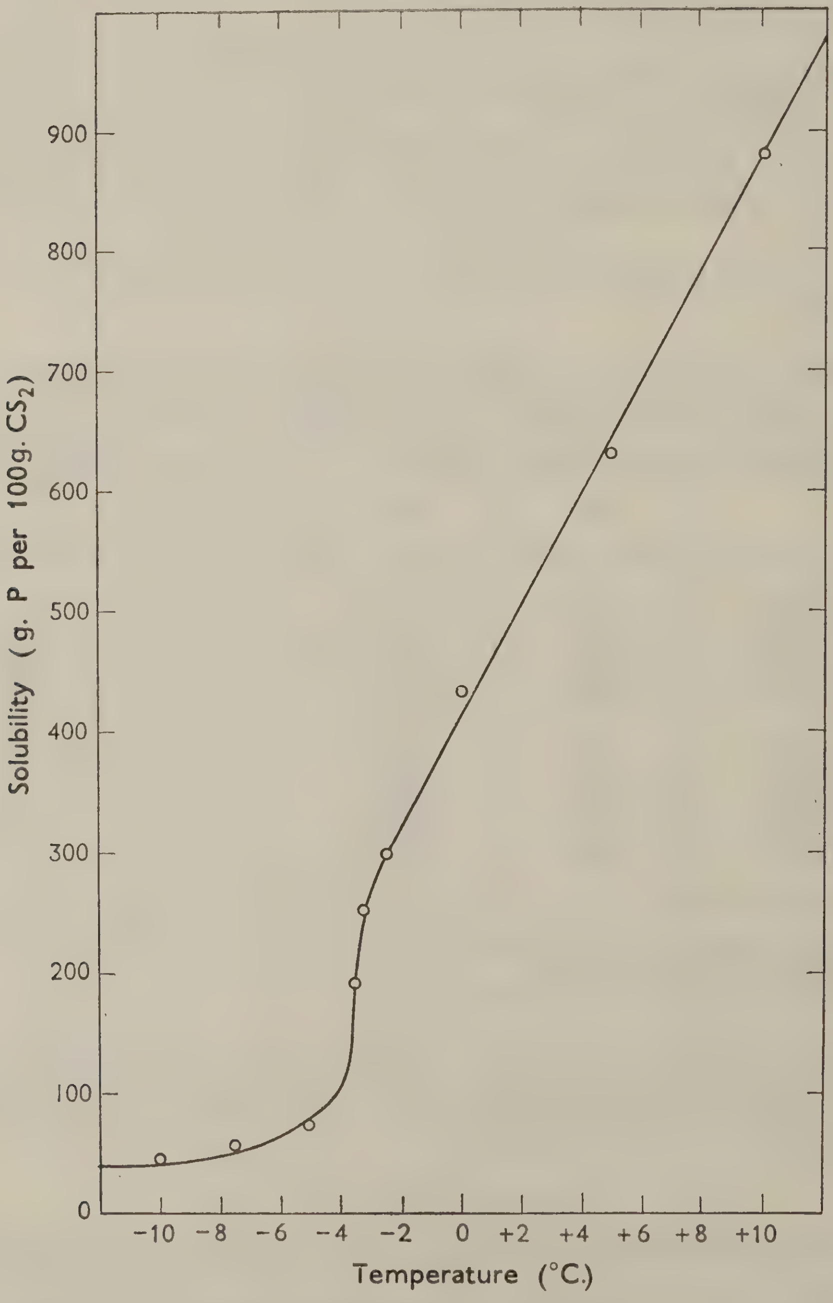

FIG. 7.—Solubility of white phosphorus in carbon disulphide

radius (1·28 A.) of phosphorus.[127] It is more nearly in agreement with the value 1·65 A. given for the radius of a non-bonded phosphorus atom surrounded by twelve neighbours.[128]

### Solubility and Solvent Properties

The solubility of phosphorus in most solvents has already been reported (Mellor, VIII, 789–91). Carbon disulphide is the best solvent and the data previously given for white phosphorus are shown graphically in Fig. 7 where the solubility is expressed as grams of phosphorus per 100 g. of $CS_2$. The break in the curve is attributed to separation of the solution into two immiscible layers between −3°C. and −8°C. It is not due to formation of a compound between phosphorus and the solvent.[212] Below −2°C. the data are not linearly represented by a plot of the logarithm of the solubility against the reciprocal of the absolute temperature.[49] Certain hazards are involved in the dissolution of phosphorus in carbon disulphide, and a suitable technique for doing this has been described.[213]

*Table XX.—Solubility of White Phosphorus in Organic Solvents*

| Temp. (°C.) | Solubility—grams per 100 g. solvent | | | | |
|---|---|---|---|---|---|
| | $CCl_4$ | $n$-$C_7H_{16}$ | $CH_3COCH_3$ | $(C_2H_5)_2O$ | $C_6H_6$ |

| 100 | 4·55 | 5·66 | — | — | — |
| 131 | — | 7·58 | — | — | — |

The solubility of white phosphorus in carbon tetrachloride,[214] $n$-heptane and acetone[215] are given in Table XX. The data for benzene and diethyl ether previously recorded (Mellor, VIII, 790) are included for comparison.

Since liquid white phosphorus has a very high internal pressure, which is much larger than that of most non-polar solvents, solutions of phosphorus show very large deviations from Raoult's law. It has been shown[214] that the solubility in organic solvents can be calculated from the equation

$$RT \log_e \left(\frac{a}{N_2}\right) = V_2\left(\frac{N_1V_1}{N_1V_1+N_2V_2}\right)^2(\delta_2-\delta_1)^2$$

where $a$ = activity of phosphorus referred to the pure liquid
$N_1$ = molecular fraction of solvent
$N_2$ = molecular fraction of phosphorus
$V_1$ = molar volume of solvent at $T$°K.
$V_2$ = molar volume of phosphorus at $T$°K.

$\delta_1$ and $\delta_2$ are the solubility parameters at $T$°K. of the solvent and phosphorus respectively and are a measure of the internal pressures. The parameters are given by the relation

$$\delta = \sqrt{\frac{\Delta E}{V}}$$

where $\Delta E\,(=\Delta H - RT)$ is the molar energy of vaporization. The activity is obtained from the expression

$$\log_e a = \frac{-\Delta H^F}{R}\left(\frac{1}{T} - \frac{1}{T_m}\right)$$

in which $T_m$ is the m.p. (317·4°K.) of phosphorus and $\Delta H^F$ the molar heat of fusion. This molar heat was computed from the equations for heat capacity of solid and liquid phosphorus and the heat of fusion (601 g.-cal. mole$^{-1}$) at the melting point, which lead to the equation

$$\Delta H^F = 10{\cdot}523T - 8{\cdot}40\times10^{-3}T^2 - 1{\cdot}31\times10^{-5}T^3 - 1473 \text{ g.-cal. mole}^{-1}$$

The values of the activity at 0° and 25°C. are 0·863 and 0·947, respectively.

The solubility equation cannot be solved directly, but a graphical solution may be obtained by inserting arbitrary values of $N_2$ in both sides of the equation and determining the point of intersection of the resulting curves.[214] A practical measure for interpolating or extrapolating solubilities is to calculate $\delta_2 - \delta_1$, for two or more temperatures. These values are then plotted against the temperature and a straight line drawn through the points.[216] Molecular volume and solubility parameter data are given in Table XXI.[215]

*Table XXI.—Molecular Volumes and Solubility Parameters of Phosphorus*[215]

| Solvent | Molecular volume (c.c.) | | | | Solubility parameter $\delta_1$ | | | |
|---|---|---|---|---|---|---|---|---|
| | 0°C. | 25°C. | 40°C. | 75°C. | 0°C. | 25°C. | 40°C. | 75°C. |
| $CS_2$ | 58·8 | 60·6 | 61·8 | — | 10·27 | 9·92 | 9·70 | — |
| $C_6H_6$ | — | 89·3 | 91·1 | 95·1 | — | 9·16 | 8·94 | 8·4 |
| $CCl_4$ | 94·2 | 97·2 | 99·0 | 103·5 | 8·90 | 8·58 | 8·38 | 7·92 |
| $n$-$C_7H_{16}$ | 143 | 147·5 | 150·2 | 157·6 | 7·76 | 7·43 | 7·24 | 6·78 |
| $(C_2H_5)_2O$ | 100·6 | 104·5 | 107·2 | — | 7·92 | 7·56 | — | — |

More recent data on the solvent powers of paraffin hydrocarbons suggest that a more accurate value of the solubility parameter of $n$-heptane is 8·1 at 25°C.[217] The molar energies of vaporization used to obtain values of $\delta_1$ were calculated from the following equations

$CS_2$ $\quad \Delta E = 8810 - 9{\cdot}6T$
$CCl_4$ $\quad \Delta E = 10990 - 12{\cdot}9T$
$C_6H_6$ $\quad \Delta E = 12100 - 15{\cdot}4T$
$n$-$C_7H_{16}$ $\quad \Delta E = 13490 - 17{\cdot}9T$
$(C_2H_5)_2O$ $\quad \Delta E = 10960 - 17{\cdot}0T$

The molecular volumes of $P_4$ at 0°, 25°, 40° and 75°C. are 69·4, 70·4, 70·9 and 72·3, respectively. The solubility parameters $\delta_2$ for phosphorus, as determined from the solubility in various solvents, are given in Table XXII. No value is given for carbon disulphide at 25°C. because the solubility at this temperature is ideal.[215]

For practical purposes an average value of $\delta_2 = 14{\cdot}4$ may be used for all solvents.[218, 219] It should be noted that values of $\delta_2$ calculated from the molar energies of vaporization (for $P_4, \Delta E = 15{,}135 - 8{\cdot}87T$) are smaller than those derived from the actual solubility data.[215]

*Table XXII.—Solubility Parameters of Phosphorus in Various Solvents*[215]

| Solvent | Solubility parameter $\delta_2$ | |
|---|---|---|
| | at 0°C. | at 25°C. |
| $CS_2$ | 15·0 | — |
| $C_6H_6$ | — | 14·9 |
| $CCl_4$ | 15·0 | 14·5 |
| $n$-$C_7H_{16}$ | 13·9 | 13·5 |
| $(C_2H_5)_2O$ | 14·6 | 13·9 |

If the solubility is plotted in terms of log $X$ against log $T$, where $X$ is the mole fraction of $P_4$ dissolved and $T$ is the absolute temperature, straight lines are obtained, as shown in Fig. 8. The slope of the line gives the entropy of solution.[220]

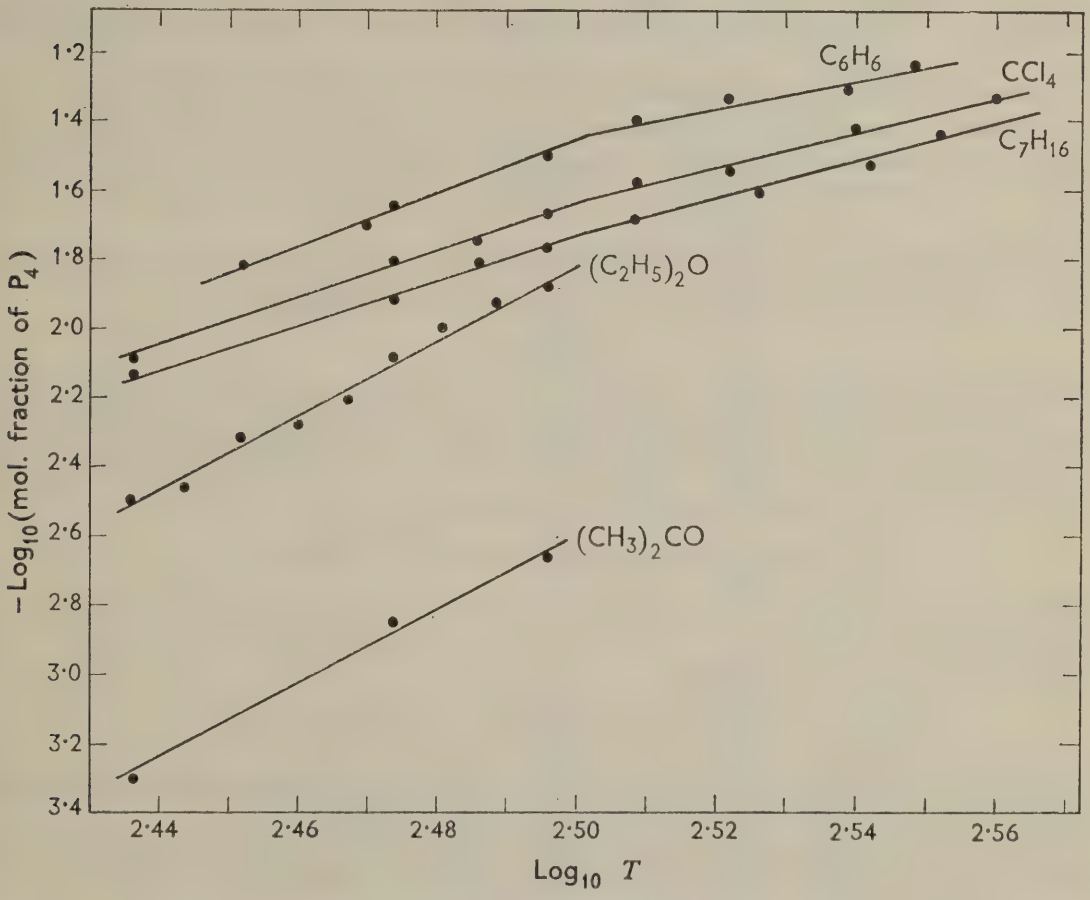

FIG. 8.—Solubility of phosphorus in organic solvents

For those solvents in which the solubility can be measured above the melting point of phosphorus, a break in the curve is found, giving two straight lines which intersect at the melting temperature.[221]

Solubility data for solvents in which phosphorus is only slightly soluble are given in Table XXIII. For information on other solvents and the critical solution temperatures of phosphorus in various liquids, reference should be made to Mellor, VIII, 780–91.

*Table XXIII.—The Solubility of Phosphorus in Miscellaneous Solvents*

| Solvent | Temp. (°C.) | Solubility (g./100 g. solvent) | Ref. |
|---|---|---|---|
| Water | 15 | 0·00033 | 222 |
| Ethyl iodide | 20 | 6·2 | 150 |
| Butyl iodide | 20 | 4·1 | 150 |
| Amyl iodide | 20 | 3·4 | 150 |
| Phenyl iodide | 20 | 5·0 | 150 |
| Phenyl bromide | 20 | 1·9 | 150 |
| Phenyl chloride | 20 | 1·9 | 150 |
| α-Iron | 400 | 0·7 | 223 |
| α-Iron | 700 | 1·2 | 223 |
| α-Iron | 1000 | 4 | 223 |

White phosphorus is readily soluble in molten antimony tribromide, but is quickly converted to red phosphorus which is much less soluble.[224]

Phosphorus is a solvent for thallium, the latter dissolving to the extent of 25 atomic-% to form a solid solution.[225] At 25°C., 0·0285 g. of mercury dissolves in 100 g. of phosphorus under water. The solubility is 0·0338 g. in 100 g. of dry phosphorus.[226] Water is said to dissolve in phosphorus to the extent of about 0·36 g. per 100 g. of phosphorus.[227] Since phosphorus has a cryoscopic constant of 41·3 the presence of 0·36% of water should lower the melting point by 8·25°C., but this has not been observed. The difference between the densities of liquid phosphorus and liquid phosphorus saturated with water (see page 162) corresponds to a solubility of about 0·24 g. of water per 100 g. of phosphorus at temperatures between 40° and 60°C.

Liquid phosphorus at 45°C. has been used as a component in systems having seven,[228] eight,[229] nine,[230] and ten[221] liquid phases in equilibrium.

## Viscosity

The viscosity of liquid white phosphorus has been measured[231] in the temperature range 18° to 80°C., and also between 20° and 140°C.[232] The results of the two sets of measurements are in agreement and give a continuous curve if log $\eta$ is plotted against $1/T$. This curve can be represented by the equation[155]

$$\log_{10} \eta \text{ (centipoise)} = 514{\cdot}4T^{-1} - 1{\cdot}3879$$

which has an average error of 1·08% and a maximum error of 3·1% from the observed values.

The equation (ref. 173, p. 486)

$$\log_{10} \eta \text{ (centipoise)} = 9 \times 10^4 T^{-2} - 10{\cdot}67T^{-1} - 0{\cdot}6318$$

agrees more closely with the data up to 90°C. but over the whole temperature range has an average error of 1·4% and a maximum error of 4·0%.

The data show some scatter, particularly between 40° and 80°C., and the best straight line through the points appears to be given by the equation

$$\log_{10} \eta \text{ (centipoise)} = 526{\cdot}3T^{-1} - 1{\cdot}4273$$

which has a maximum error of 3·5% and an average error of 1·3%.

The viscosity of molten white phosphorus saturated with water is reported[233] to be represented by the equation

$$\eta \text{ (centipoise)} = 3{\cdot}314 - 9{\cdot}65 \times 10^{-2}t + 1{\cdot}279 \times 10^{-3}t^2 - 5{\cdot}76 \times 10^{-6}t^3$$

where $t$ is in the range 45° to 95°C. Data calculated from this equation are 60% (at 45°C.) to 74% (at 95°C.) of the values given above. In view of the low solubility of water in liquid phosphorus the effect on the viscosity seems anomalous.

Calculated values for the viscosity of phosphorus vapour are given on page 212.

### Surface Tension and Parachor

The surface tension of liquid white phosphorus is given in Table XXIV. These values give a parachor of 204·8 c.c. for the $P_4$ molecule[234, 235] (see also page 213).

*Table XXIV.—Surface Tension of Liquid White Phosphorus*

| Temp. (°C.) | Surface tension (dynes cm.$^{-1}$) |
|---|---|
| 50 | 69·70 |
| 54 | 68·53 |
| 60·2 | 66·95 |
| 68·7 | 64·95 |

These measurements were made by a bubble pressure method in an atmosphere of carbon dioxide. The data previously reported (Mellor, VIII, 759) were obtained by a capillary rise method and in calculating the surface tension it was assumed that the angle of contact between phosphorus and glass was zero. This angle is in fact not zero so that the previous values for the surface tension are too small.

*Table XXV.—Interfacial Tension between Phosphorus and Various Liquids*

| Liquid | Temp. (°C.) | Interfacial tension (dynes cm.$^{-1}$) |
|---|---|---|
| Water | 46·0 | 52·9 |
| | 52·8 | 51·2 |
| | 61·0 | 49·7 |
| | 64·0 | 48·1 |
| | 71·0 | 46·7 |
| Benzene | 52 | 13·0 |
| | 60 | 12·5 |
| | 67 | 11·5 |
| *cyclo*Hexane | 50 | 18·1 |
| | 58 | 17·9 |
| | 69 | 17·2 |
| *n*-Hexane | 50 | 23·3 |
| | 60 | 23·7 |
| Ethanol | 50 | 29·7 |
| | 60 | 27·9 |
| | 68 | 27·4 |
| Acetone | 46·5 | 29·4 |
| | 50 | 29·1 |
| | 54 | 29·1 |

The interfacial tension between phosphorus and a number of liquids has been measured, with the results[234] shown in Table XXV.

It is reported that phosphorus, unlike sulphur, does not alter the surface tension of liquid iron–carbon–sulphur alloys to any marked degree.[236] The effect of phosphorus is, however, greater than that of silicon.[237]

## Tensile Strength

The ultimate tensile strength of white phosphorus has been measured[238] at temperatures between −5° and 44°C. For this purpose cylindrical rods of phosphorus 13 cm. long and 1·0 cm. in diameter were subjected to a load, starting at zero and increasing at the rate of 2·2 kg./min. until breaking occurred. The value of the breaking load was reproducible to within 4% at any given temperature. At some temperatures there was considerable elongation of the rods before fracture occurred. The elongation was measured with an accuracy of ±2 mm. The data obtained are given in Table XXVI and the effect of temperature on the tensile strength is shown graphically in Fig. 9.

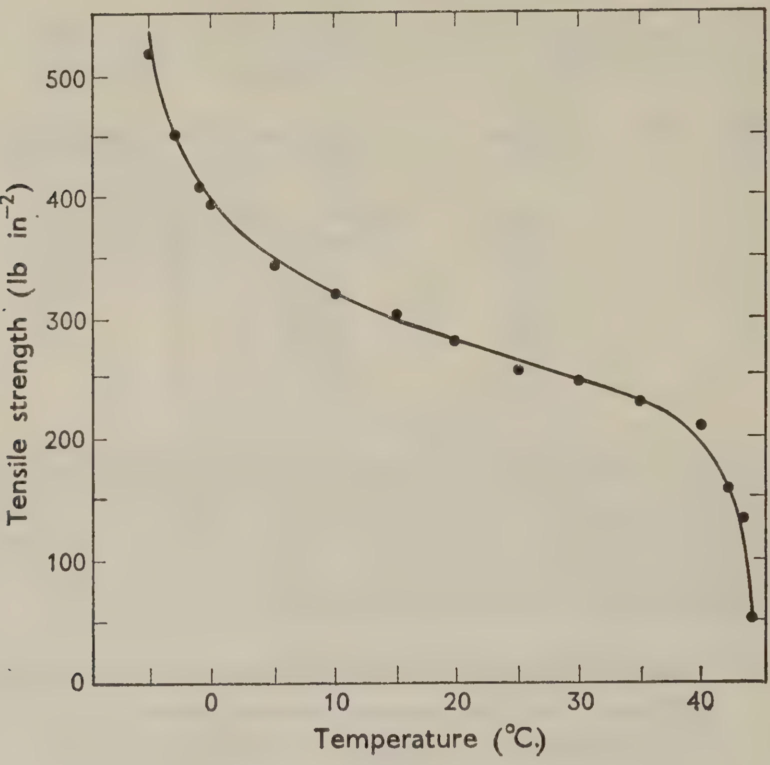

FIG. 9.—Tensile strength of white phosphorus

*Table XXVI.—The Tensile Strength of White Phosphorus*

| Temp. (°C.) | Tensile strength | | Elongation | |
|---|---|---|---|---|
| | (kg. cm.$^{-2}$) | (lb. in.$^{-2}$) | (mm.) | (%) |
| −5 | 36·4 | 517 | 0 | 0 |
| —3 | 31·8 | 451 | 2·3 | 1·8 |

| 44 | 3·6 | 50 | 35·6 | 27·4 |

Below 0°C. the phosphorus was very brittle and broke suddenly to give a square-ended fracture. Above this temperature there was a gradual decrease in brittleness, this becoming negligible at about 15°C. Between 15° and 35°C. there was a rapid increase in elongation before breakage occurred, and conical fractures were produced. Increased brittleness and decreased elongation were found above 35°C. At all temperatures the phosphorus showed little or no elasticity, and did not recover its original length on removing the load, even when the amount of stretching was only 2 mm.

### Creep

Bending creep in white phosphorus has been reported for temperatures of 27° and 41° at pressures up to 6 kbar.[476] The activation volume for creep is $50{\cdot}3 \times 10^{-24}$ cm.$^3$/atom, which agrees with the value for self-diffusion reported earlier.[240]

### Diffusion

The coefficient of self-diffusion in white phosphorus varies with temperature as shown in Table XXVII.

*Table XXVII.—Self-diffusion in α-White Phosphorus*[239]

| Temp. (°C.) | Diffusion coefficient $D$ (cm.$^2$ sec.$^{-1}$) |
|---|---|
| 0 | $3{\cdot}19 \times 10^{-11}$ |
| 10 | $6{\cdot}07 \times 10^{-11}$ |
| 18·7 | $1{\cdot}07 \times 10^{-10}$ |
| 25 | $1{\cdot}40 \times 10^{-10}$ |
| 30 | $1{\cdot}75 \times 10^{-10}$ |
| 39·4 | $3{\cdot}94 \times 10^{-10}$ |
| 41·3 | $4{\cdot}58 \times 10^{-10}$ |
| 41·88 | $5{\cdot}91 \times 10^{-10}$ |
| 42·82 | $8{\cdot}01 \times 10^{-10}$ |
| 43·86 | $> 8 \times 10^{-10}$ |

A plot of log $D$ against $1/T$ deviates from a straight line above 30°C. as shown in Fig. 10. Below this temperature the diffusion coefficient is given by

$$\log_{10} D = -2{\cdot}971 - 2058T^{-1}$$

which gives an activation energy for self-diffusion of 9400 g.-cal. mole$^{-1}$. This agrees with the value found from

$$\Delta E = 16{\cdot}5L$$

where $L$ is the latent heat of fusion and the constant 16·5 applies for a face-centred or body-centred cubic crystal lattice. Below 30°C. the diffusion mechanism is believed to involve vacant sites in the lattice.

Above this temperature the diffusion coefficient is given by

$$\log_{10} D = 46{\cdot}3 - 17{,}635T^{-1}$$

This corresponds to an activation energy of 80,600 g.-cal. mole$^{-1}$ and a very high entropy. These high values are consistent with the supposition that near the melting point there are present liquid microphase regions. These contain, on average, about 130 phosphorus molecules and 10 vacant lattice sites which are the principal centres of diffusion.[239]

Increasing pressure decreases the rate of self-diffusion as shown in Fig. 11 for temperatures of 30°C. and 41·3°C. The slope of the 30°C. graph gives an activation volume of $49{\cdot}7 \times 10^{-24}$ cm.$^3$/atom. At 41·3°C. the activation volume is about

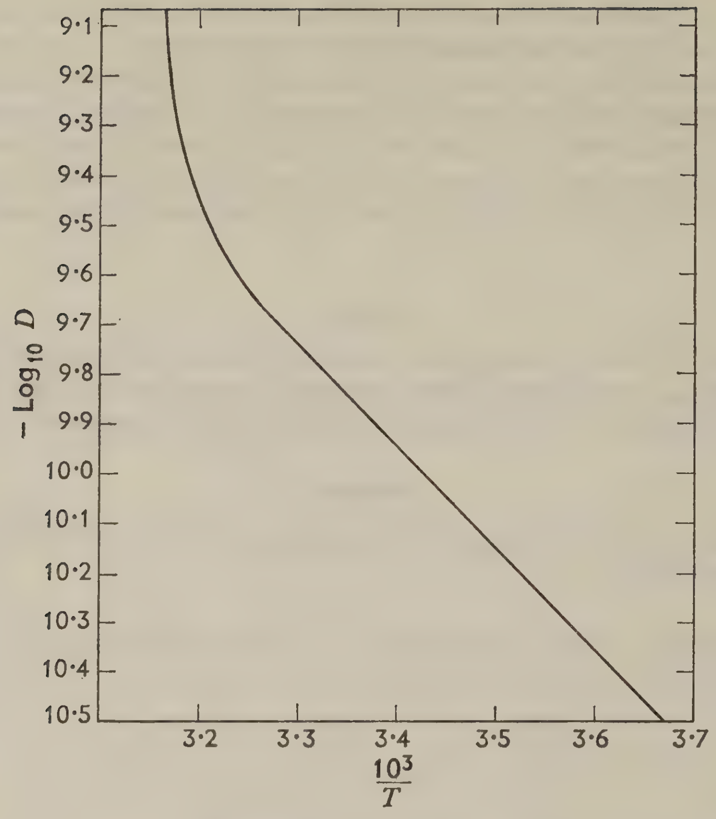

FIG. 10.—Variation of self-diffusion of phosphorus with temperature

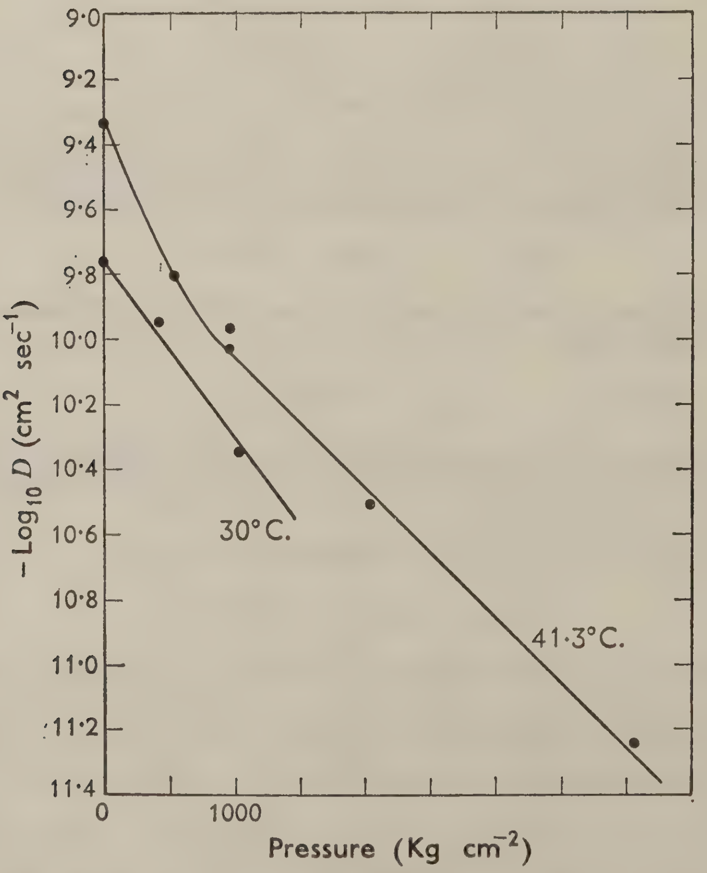

FIG. 11.—Effect of pressure on the self-diffusion of white phosphorus

$348 \times 10^{-24}$ cm.$^3$/atom. These data are interpreted as indicating a large disordering of the crystal lattice which begins well below the melting point of phosphorus.[240] The activation volumes have been used to calculate the entropy of diffusion from the coefficients of thermal expansion and compressibility. Agreement with observed entropy values, however, is not good.[241] The pressure dependence of the diffusion coefficients and the melting point has been reported to be identical for white phosphorus and metallic sodium.[242]

The coefficient of diffusion of phosphorus into copper covered with a layer of cuprous oxide is reported to be $2{\cdot}1 \times 10^{-8}$ cm.$^2$ sec.$^{-1}$ at about 1000°C.[243] At 1020°C. for a cuprous oxide layer about 0·20 mm. in thickness the concentration of phosphorus in atoms/c.c. was found to be $18 \times 10^{16}$, $37 \times 10^{16}$ and $200 \times 10^{16}$ at depths of 0·01, 0·10 and 0·172 mm., respectively.[244]

The diffusion of phosphorus into silicon has been studied in connection with the semiconductor properties of the latter. Conflicting values of the diffusion coefficient have been reported. Diffusion of phosphorus vapour into silicon oxide films 0·1–0·4 $\mu$ in thickness at temperatures of 1125° to 1250°C. is said to occur at a rate agreeing with the equation[245]

$$D = D_0 \exp\{-E/kT\}$$

where $D_0 = 3{\cdot}9 \times 10^{-12}$ cm.$^2$ sec.$^{-1}$, $k$ is Boltzmann's constant and the activation energy is 1·4 electron volts (32 kcal. mole$^{-1}$). This, however, does not agree with the observed value of $D = 2{\cdot}1 \times 10^{-15}$ cm.$^2$ sec.$^{-1}$ at 1150°C. The temperature dependence of $D$, as calculated from the experimental values, is

$$\log_{10} D = -10{\cdot}11 - 6500T^{-1} \quad \text{or} \quad D = 7{\cdot}76 \times 10^{-11} \exp\{-29{,}700/RT\}$$

The above data were interpreted in terms of a two-layer system of silicon and silicon oxide. In another investigation[246] it was shown that at 1100° to 1150°C. a glass of unknown composition $P_xSi_yO_z$ is formed between the silicon and silicon oxide, with a sharp boundary separating the glass from the oxide. An *n–p* junction was formed beneath the glass. The diffusion coefficients $D_1$ and $D_2$ for the diffusion of phosphorus into the glass and into silicon, respectively, are given in Table XXVIII.

*Table XXVIII.—Diffusion of Phosphorus in Silicon*

| Temp. (°C.) | Coefficient $D_1$ (cm.$^2$ sec.$^{-1}$) for PSiO glass | Coefficient $D_2$ (cm.$^2$ sec.$^{-1}$) for silicon |
|---|---|---|
| 1100 | $2 \times 10^{-13}$ | $1{\cdot}8 \times 10^{-12}$ |
| 1150 | $4 \times 10^{-13}$ | $3{\cdot}5 \times 10^{-12}$ |

The coefficient for the diffusion of phosphorus through an oxide layer into silicon is reported to be about $10^{-14}$ cm.$^2$ sec.$^{-1}$ at 1250°C.[247] This is much smaller than the values of $D_2$ for silicon in Table XXVIII, but agrees with the coefficient calculated from

$$\log_{10} D = -10{\cdot}11 - 6520T^{-1}$$

Presumably $10^{-14}$ cm.$^2$ sec.$^{-1}$ represents a coefficient for the diffusion of phosphorus in silicon oxide.

The diffusion of phosphorus from phosphorus pentoxide vapour into silicon at 970° to 1275°C. gives the following equation for the diffusion coefficient[248]

$$\log_{10} D = 1{\cdot}021 - 18{,}600T^{-1}$$

which corresponds to an activation energy of 85,000 g.-cal. mole$^{-1}$. The values of $D$ calculated from this equation are substantially in agreement with those of $D_2$ given above. The diffusion coefficients of phosphorus and boron are almost identical between 950° and 1300°C.,[248, 249] the activation energy of the latter being 81,000 g.-cal. $\text{mole}^{-1}$.[250]

Preliminary values for the diffusion of phosphorus into single crystal silicon, using phosphorus vapour at 1050° to 1250°C. gave diffusion coefficients represented by the equation[249]:

$$\log_{10} D = -3{\cdot}00 - 25{,}200T^{-1}$$

From these measurements, which are not in agreement with the values given above, it was estimated that either $D$ is in error by 50%, or there is a 15% error in the activation energy quoted above. The oxygen content of silicon is reported to have no appreciable effect on the diffusion or solubility of phosphorus in silicon,[251] the measured diffusion rates agreeing with those of ref. 248. Observations on the diffusion of phosphorus vapour in silicon indicate that the solubility of phosphorus in silicon is constant between 900°C. and 1300°C.[252] The diffusion rate at 1200°C.[253] gives a coefficient of $2{\cdot}7 \times 10^{-12}$ $\text{cm.}^2$ $\text{sec.}^{-1}$, in good agreement with the values of Fuller and Ditzenberger.[248] The technique[254, 255] and the thermodynamics[256] of the diffusion of phosphorus in silicon have been discussed.

The diffusion of phosphorus in germanium between 900° and 1200°C. is given by the equation

$$\log_{10} D = 0{\cdot}40 - 12{,}400T^{-1}$$

which gives an activation energy of 56,700 g.-cal. $\text{mole}^{-1}$. Similar activation energies are found for arsenic, antimony, zinc, gallium and indium, but boron has a much higher energy.[257]

The diffusion coefficient for phosphorus in a calcium aluminium silicate melt is reported to be $4{\cdot}4 \times 10^{-6}$ $\text{cm.}^2$ $\text{sec.}^{-1}$ at 1500°C.[258] At 1320°C. for a slag containing CaO 39·4, $Al_2O_3$ 21·2 and $SiO_2$ 38·8% the coefficient is $5{\cdot}7 \times 10^{-5}$ $\text{cm.}^2$ $\text{sec.}^{-1}$ [259]

Phosphorus is reported to migrate in calcium phosphate melts as the $P^{5+}$ ion with a mobility of $3{\cdot}4 \times 10^{-5}$ $\text{cm.}^2$ $\text{volt}^{-1}$ $\text{sec.}^{-1}$ [260]

## OPTICAL PROPERTIES

The refractive index of liquid phosphorus between 44° and 65°C. for sodium light is given by the equation[261]

$$n = 2{\cdot}11038 - 7{\cdot}9 \times 10^{-4}t$$

These values are somewhat smaller than those previously recorded (Mellor, VIII, 763).

The refractive index has also been measured for light of wave-lengths 4358, 5461, 5780 and 6907 A.

The value of $$\frac{(n^2-1)}{(n^2+2)d}$$

where $n$ is the refractive index and $d$ is the density, is constant at 0·3006 for the same range of temperatures. This gives a molar refraction of 37·3 for the $P_4$ molecule (see also page 208 for bond refraction).

White phosphorus becomes doubly refractive on cooling to −75°C., but the reverse change occurs on heating to −68°C. Hexagonal crystals of phosphorus, similar to those of $K_2PtCl_4$, were obtained on crystallizing the element from carbon disulphide at −80°C. or from ether at −100°C.[134]

The activation energy for photoconductivity is 1·40–1·56 electron-volts as compared with a thermal activation energy of 1·51–1·64 e.v. The threshold wave-length for the photoconductivity effect is $\lambda_{1/2}(\mu) = 0{\cdot}85$.[262]

The photoelectroluminescence of zinc sulphide activated by phosphorus has been described.[263] Luminescent flashes are observed when the material is irradiated with infra-red radiation.[264] The luminescence is said to involve a two-step excitation mechanism of long and short wave-lengths.[265]

The photochemical conversion of white phosphorus dissolved in carbon disulphide to red phosphorus is a unimolecular reaction. It is concluded that the dissociation $P_4 \rightleftharpoons 2P_2$ is involved.[266]

## ELECTRICAL AND MAGNETIC PROPERTIES

Most of the electrical and magnetic properties of phosphorus have been reported previously (Mellor, VIII, 766). Ionization potentials are summarized in Table III, page 150 above. The ionization energy of phosphorus as a donor impurity in germanium has been measured[267] by analyzing curves of carrier concentration against $1/T$. The value obtained was 0·0120 e.v.

In silicon the ionization energy of the ground state of phosphorus is 0·0455 e.v. The observed spacing $(2p, m = \pm 1) - (2p, m = 0)$ of the excited electronic levels is 0·0053 e.v., in agreement with the theoretical value of 0·0050 e.v.[268] The theory of the donor levels[269] and the hyperfine splitting of the donor states of phosphorus in silicon has been discussed. The lines observed in the hyperfine structure in *n*-type silicon correspond exactly to the nuclear spin of the added Group V elements. This shows that the electron-spin resonance is due to the resonance of electrons localized near the Group V atoms.[270]

The ionization potential has been used to calculate the atomic radius: a value of 0·44 A. has been obtained for the $P^{3+}$ ion.[271] The paramagnetic resonance of phosphorus in silicon has been studied and two lines separated by about 45 gauss were found.[272] The measured electric field gradient for phosphorus is 9·03, compared with a calculated value of 11·06.[273]

### Electronegativity and Electron Affinity

Electronegativity was first defined by Pauling[123] as the power of an atom or molecule to attract electrons to itself. He found an empirical relation between the energy of a bond and the electronegativities of the bonded atoms. From this he estimated electronegativities, on what is now referred to as the Pauling scale. Other scales of measurement have been proposed[274] but the values of Pauling are generally regarded as being the most useful and reliable for purposes of calculations involving electronegativity. On the Pauling scale the electronegativity of phosphorus is 2·1.

Mulliken[275] defined the atomic electronegativity $M$, for which he used the term electro-affinity, as the average of the ionization potential $I$ and the electron affinity $E$, both in electron volts, i.e.,

$$M = \tfrac{1}{2}[I + E]$$

On this scale the electronegativity of phosphorus is 5·80. Mulliken plotted his values against those of Pauling and found that for most elements his values were 2·78 times those of Pauling, a relationship which fits the data for phosphorus. A more recent evaluation[276] based on revised values of ionization potentials[62] suggests that a better factor is 3·15[274] but this does not correlate the two electronegativity values of phosphorus. Mulliken's values, which take into account the dependence of ionization energies on the orbital characteristics of an atom in a molecule, appear to be better and more precise than the Pauling electronegativity. They are, however, more difficult to apply quantitatively to most elements because of the lack of reliable data on electron affinities. In an extension of Mulliken's ideas, in which ionization potentials and electron affinities are referred to valency states rather than to physically measured values, electronegativity values for three valencies of phosphorus have been calculated[274, 276] with the results shown in Table XXIX.

Electronegativity has also been defined[277] as the potential at a distance $r$ (the covalent radius) from the nucleus which is caused by the nuclear charge effective at that distance. This charge was estimated by assuming that the electrons in the closed shells of an element exerted their full screening power on the nucleus. The screening

*Table XXIX.—Mulliken Electronegativities for Phosphorus*

| Valency state | Ionization potential (e.v.) | Electron affinity (e.v.) | Electronegativity |
|---|---|---|---|
| $s^3p^3, V_3$ | 10·15 | 1·29 | 5·72*p* |
| $sp^4, V_3$ | 11·94 | 2·42 | 7·18*p* |
| $sp^4, V_3$ | 24 | 8·60 | 16·3*s* |

constant of one valence electron for another was taken to be 0·5. The electronegativity, $x$, is then given by the expression

$$x = 0{\cdot}31\left(\frac{n+1}{r}\right)+0{\cdot}50$$

where $n$ is the number of electrons in the valency shell and $r$ is the covalent radius in Ångström units. For phosphorus ($r=1{\cdot}1$) this gives a value of 2·19.

A similar expression

$$x = 0{\cdot}44(z/r)+0{\cdot}28$$

where $z$ is the effective nuclear charge as defined by Slater[278] has also been used.[274] With $r=1{\cdot}1$ and $z/r=4{\cdot}36$ the electronegativity of phosphorus becomes 2·20.

More recently[279] electronegativity has been related to the force of attraction between a nucleus and an electron from a bonded atom. If $r$ is the distance between the nucleus and the electron, and $e$ is the electronic charge, then the charge which is effective at the electron due to the nucleus and its surrounding electrons is $ez$. The force of attraction, which is a measure of the electronegativity, is $F=e^2z/r^2$. A plot of $z/r^2$ against Pauling electronegativities gives the new electronegativity according to the equation

$$x = 0{\cdot}359(z/r^2)+0{\cdot}744$$

Using Slater's values for the effective nuclear charge $z$, then $z/r^2$ is 3·678 for phosphorus and the electronegativity is 2·06.

An alternative method of evaluating electronegativity, based on the stability ratio, has been proposed.[280] The electron density of an element, or the number of electrons per cubic Ångström unit is $3A/4\pi r^3$, where $A$ is the atomic number and $r$ is the covalent radius. The stability ratio, which has a maximum value of 1, is the ratio of the electron density of an atom to that of an iso-electronic inert atom.[281] The stability ratio $S$ is related to the Pauling electronegativity $P$ by the equation[282]

$$P^{1/2} = 0{\cdot}21S+0{\cdot}77$$

For a covalent radius of 1·06 the electron density of phosphorus is 3·04, giving a stability ratio of 3·34. This corresponds to an electronegativity of 2·16 on Pauling's scale.[280]

The electronegativity of cations as measured by the stability ratio has been empirically related to the ionization potential by the equation[283]

$$S = 1{\cdot}54I^{1/2}+c$$

where $S$ is the stability ratio and $c$ is a constant. The value used for $I$ is the sum of the ionization potentials required to form the ion from the neutral atom. For the $P^{5+}$ ion, $c$ is $-1{\cdot}33$ and $I$ is 177·2 (see Table III, page 150), giving 19·1 for $S$. In a similar manner, stability ratios of 3·87, 3·32 and 2·5 have been obtained for the $H_2PO_4^-$, $HPO_4^{2-}$ and $PO_4^{3-}$ ions, respectively.

The stability ratios of $PCl_3$, $P_4O_6$ and $P_4O_{10}$ have been reported to be 4·48, 4·36 and 4·59, respectively. The use of these ratios in interpreting chemical variations in the phosphorus halides[284] and in estimating partial charges in an atom of a molecule[285] have been discussed.

The electron affinity, defined as the energy liberated when a negative ion is formed by an atom acquiring an electron, has not been measured directly for phosphorus owing to experimental difficulties. Estimates of 1·33,[286] 1·10,[287] 0·8,[276, 288] 0·77,[289] 0·72,[290] 0·70[291] and 0·57[292] electron volts have been reported for the $P^-$ ion. The best value seems to be 0·72 e.v.

## Dielectric Constant of White Phosphorus

Measurements of the dielectric constant of liquid phosphorus between 34° and 85°C. show that the value of the constant at 45°C. is about 5% greater than that previously reported (Mellor, VIII, 767).

Some representative data for the dielectric constant $\epsilon$ are given in Table XXX.[293] From the Mosotti–Clausius relation

$$P = \frac{\epsilon - 1}{\epsilon + 2} \cdot \frac{M}{d}$$

the dielectric molar polarization $P$ is 35·9. This agrees with the value of the electron polarization as calculated from the refractive index for sodium light (page 182) for the $P_4$ molecule.

*Table XXX.—The Dielectric Constant of White Phosphorus*

| Temp. (°C.) | Dielectric constant |
|---|---|
| 34·0 | 4·096 |
| 38·1 | 4·082 |
| 41·1 | 4·073 |
| 42·2 | 4·069 |
| 44·0 | 4·064 |
| 46·1 | 4·057 |
| 47·0 | 4·055 |
| 48·0 | 4·052 |
| 48·6 | 4·052 |
| 49·0 | 4·047 |
| 51·3 | 4·039 |
| 55·0 | 4·027 |
| 59·4 | 4·008 |
| 70·4 | 3·961 |
| 76·2 | 3·929 |
| 85·0 | 3·860 |

The above data give a molecular polarizability of $14{\cdot}2 \times 10^{-24}$ Å$^3$. The atomic polarizability, calculated[294] from the expression $\alpha = 2{\cdot}3r^3$ ($r$ = single-bond covalent radius), is $3{\cdot}06 \times 10^{-24}$ Å.$^3$

## The Electrical Properties of Black Phosphorus

Data on the electrical resistance of black phosphorus at temperatures up to 100°C. and pressures up to 12,000 kg. cm.$^{-2}$ have been reported previously (Mellor, VIII, p. 766). It should be noted that the specific resistance at 0°C. is 1·0 ohm per cm. cube and not 1000 as given.[295]

Measurements at 30° and 75°C. at higher pressures show that for both temperatures the resistances at 20,000 kg. cm.$^{-2}$ pressure are less than one-hundredth of the corresponding values at atmospheric pressure. The resistance passes through a minimum at 23,000 kg. cm.$^{-2}$ pressure.[296] The temperature coefficient of resistance changes sign at 12,000 kg. cm.$^{-2}$, becoming positive like that of pure metals at higher pressures.[297]

The resistivity of black phosphorus has been measured between −200°C. and +350°C., with the results shown in Fig. 12.[298]
At temperatures above 0°C. the resistivity $\rho$ in ohm-cm. is given by

$$\rho = 0{\cdot}0030 \exp\{W/2kT\}$$

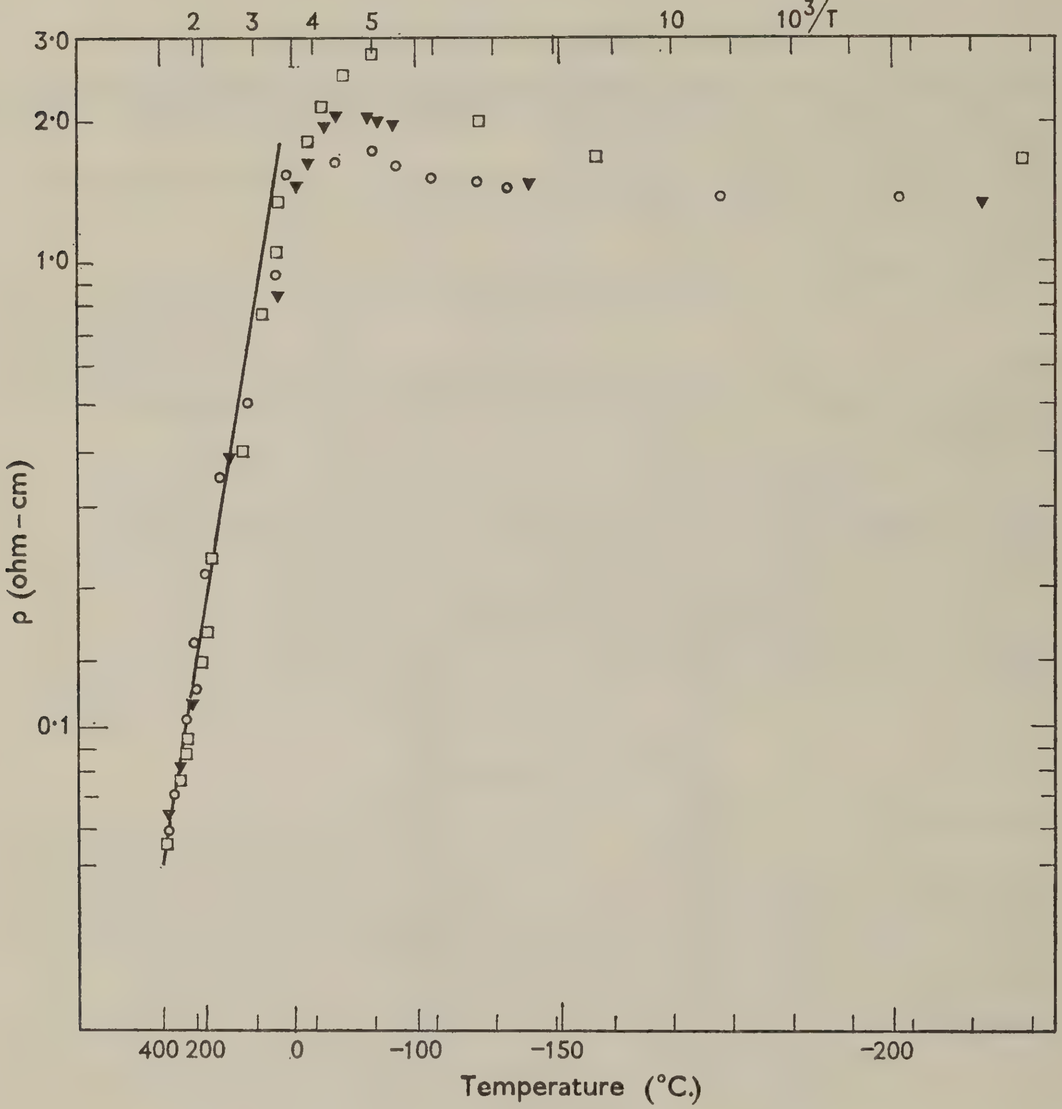

FIG. 12.—The resistivity of three different specimens of black phosphorus as a function of the reciprocal of the temperature in °K.

where $k$ is Boltzmann's constant and $W$ is 0·33 e.v. This is equivalent to

$$\log_{10} \rho = 834T^{-1} - 2{\cdot}523$$

The effect of pressure is shown in Fig. 13.

The Hall constant is shown plotted as a function of temperature in Fig. 14. This constant is independent of the magnetic field up to 5000 gauss. The sign of the Hall voltage indicates that the carriers are positive, a conclusion which is supported by the direction of the thermo-electric effect.

The material used in these measurements was prepared by heating white phosphorus at 200°C. under a pressure of 13,000 kg. cm.$^{-2}$ The volume change in the reaction was 0·18 c.c. g.$^{-1}$

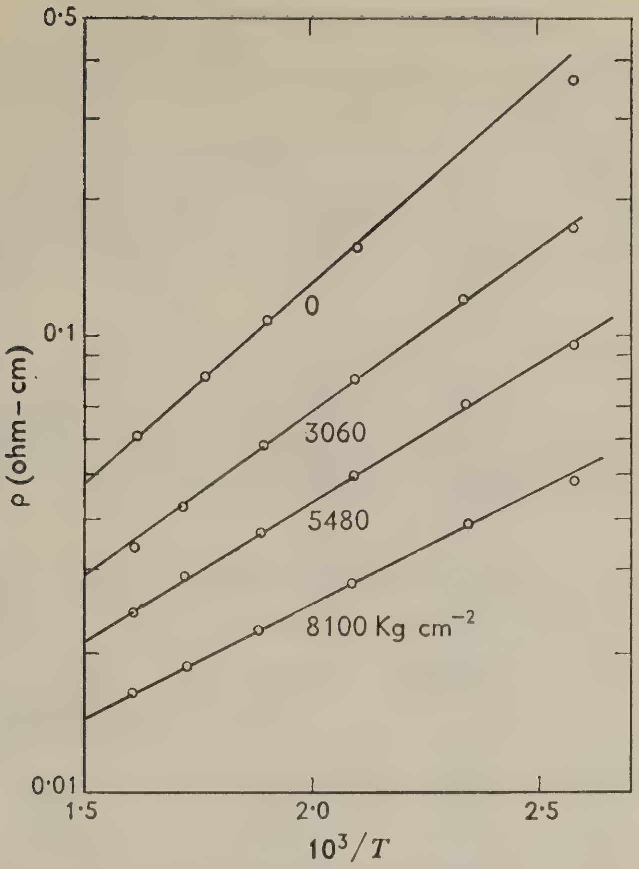

FIG. 13.—Temperature dependence of the resistivity of black phosphorus in the intrinsic range at various pressures

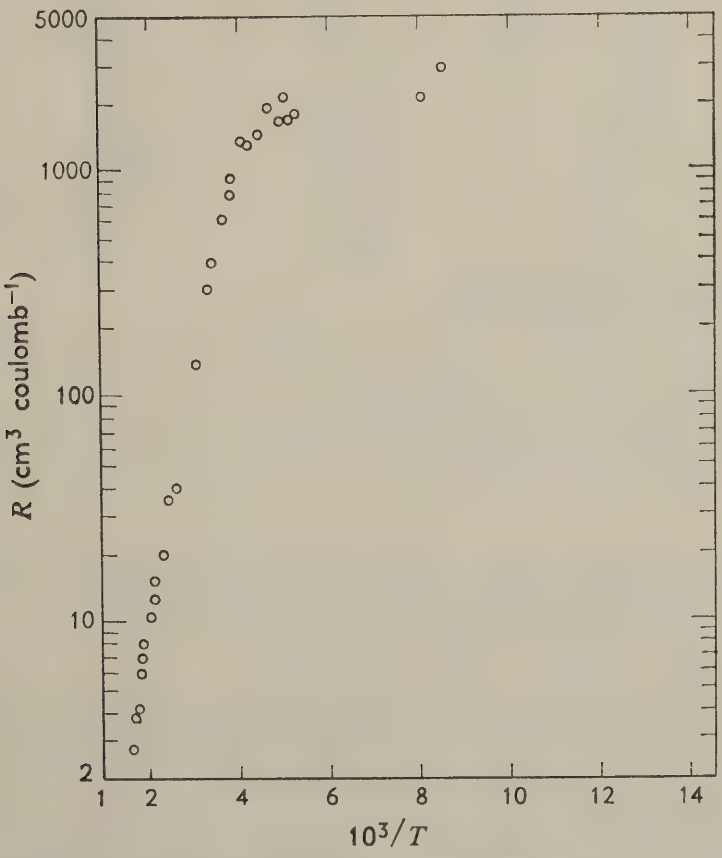

FIG. 14.—The Hall constants ($R$) of several samples of black phosphorus as a function of the reciprocal of the temperature

## THERMODYNAMIC PROPERTIES

Much of the information on the thermal properties of phosphorus is based on experimental data obtained before 1920. In some instances this has been checked by calculations using spectroscopic and other physical data of more recent origin. For the earlier observations the standard state of the element is the α- or cubic form of white phosphorus. In more recent reports,[171–2] however, the reference state for thermodynamic properties is the crystalline, triclinic form (Form V) of red phosphorus.

### Heats of Formation

Data on the heats of formation of various forms of phosphorus as given by the National Bureau of Standards[299] are reproduced in Table XXXI; the values given in column 5 refer to the formula weight indicated in column 3.

*Table XXXI.—Heats of Formation of Phosphorus*[299]

| Form | Temp. (°C.) | Formula | Physical state | Heat of formation (kcal. mole$^{-1}$) | Ref. |
|---|---|---|---|---|---|
| α-White | 25 | $P_4$ | Crystal | 0 | — |
| α-White | 25 | $P_4$ | Liquid | 0·601 | 193 |
| α-White | 25 | $P_4$ | Gas | 13·12 | 182, 191 |
| β-White(a) | −2·4 | $P_4$ | Crystal | −5·40 | 168 |
| Violet | 25 | P | Crystal | −4·4 | 300 |
| Violet(b) | 590 | P | Liquid | 3·85(c)(d) | 168, 169 |
| Violet(b) | 590 | P | Gas | 6·35(c) | 169 |
| Black | 25 | P | Crystal | −10·3 | |
| Monatomic | 25 | P | Gas | 75·18(e) | 68, 73, 74 |
| Diatomic | 25 | $P_2$ | Gas | 33·82(e) | 74, 202, 153 |
| Ion | 25 | $P^+$ | Gas | 329·81 | 59 |
| | 25 | $P^{2+}$ | Gas | 784·51 | 59 |
| | 25 | $P^{3+}$ | Gas | 1481·43 | 59 |
| | 25 | $P^{4+}$ | Gas | 2667·2 | 59 |
| | 25 | $P^{5+}$ | Gas | 4167·9 | 59 |

(a) At a pressure of $4{\cdot}4 \times 10^6$ mm. Hg.
(b) At a pressure of 32,760 mm. Hg.
(c) Heat of formation referred to solid violet phosphorus.
(d) This figure is erroneously given as 4·85 in the National Bureau of Standards Circular 500.[299] See ref. 169, p. 293.
(e) See pages 166, 189, where use of the heat of sublimation of 14 kcal. mole$^{-1}$ $P_4$ for white phosphorus[195] gives $\Delta H_f = 75{\cdot}5$ kcal./g. atom for monatomic gas and 34·25 kcal. mole$^{-1}$ $P_2$ for diatomic gas.

The violet form in Table XXXI is Hittorf's 'metallic' phosphorus, which appears to be identical with triclinic red phosphorus Form V (see page 157). The values given for the ions were calculated from the ionization potentials given in Table II. These data supersede those of Bichowsky and Rossini.[301]

Data on the heat and free energy of formation of phosphorus referred to red phosphorus Form V are summarized in Table XXXII. The heat of formation of red Form V from α-white phosphorus (on which the values in the Table were calculated) is −4·18 kcal. per gram atom. The corresponding free energy is 2·886 kcal./g.-atom, both values being at 25°C.

The reference state for Table XXXII was taken as red, triclinic phosphorus from 298°K. to 704°K. and as ideal diatomic vapour ($P_2$) at higher temperatures.

Table XXXIII gives the corresponding data for solid, cubic, α-white phosphorus.

### Heat of Atomization

The heat of formation of phosphorus atoms $\frac{1}{4}(\Delta H_1+\Delta H_2+2\Delta H_3)$, has been computed[302] to be 75·3 kcal./g.-atom at 25°C. from the following data:

$$\begin{array}{ll} 4P(g) \rightarrow P_4(g) & \Delta H_1 = 13{\cdot}2 \text{ kcal.} \\ P_4(g) \rightarrow 2P_2(g) & \Delta H_2 = 54{\cdot}5 \text{ kcal.} \\ P_2(g) \rightarrow 2P(g) & \Delta H_3 = 116{\cdot}8 \text{ kcal.} \end{array}$$

$\Delta H_1$ is the heat of sublimation of white phosphorus derived from vapour pressure measurements[182] and $\Delta H_2$ is the value obtained from the dissociation of tetratomic phosphorus vapour.[155, 201] $\Delta H_3$ is based on a spectroscopic dissociation energy of 5·031 e.v. (116·0 kcal. at 0°K.).[75, 203–4] This energy has also been reported to be 5·008 e.v. (115,450 kcal. at 0°K.).[72–4] The higher value is generally accepted as the more reliable.

A more accurate value of the heat of sublimation $\Delta H_1$ is 14·00 kcal./mole $P_4$ at 25°C.[194–5] This yields a value of 75·5 kcal./g. atom for the heat of atomization.

### Heat of Combustion

The heat of formation of the gaseous molecule PO is given as $-9{\cdot}7$ kcal. mole$^{-1}$ at 298·16°K.[76, 299]

The heat of combustion of white phosphorus to form phosphorous oxide, $P_4O_6$, has been reported to be $-486{\cdot}4$[303] and $-538$[300] kcal. per mole of $P_4O_6$. Both of these values appear to be too large and almost certainly refer to a combustion product containing a large proportion of the tetroxide $P_4O_8$. More recent data, based on the oxidation of $P_4O_6$ to $P_4O_{10}$, gives a heat of combustion of phosphorus of $-390$ kcal./mole of $P_4O_6$,[304] giving an enthalpy of formation of $-392$ kcal./mole for the oxide.

The earlier data[301, 305, 299] give the heats of combustion at 298·16°K. of $P_4$ to $P_4O_{10}$ (hexagonal) as $-717$ kcal. mole$^{-1}$ and to amorphous $P_4O_{10}$ as $-731$ kcal. mole.$^{-1}$ More recent determinations give $-710{\cdot}2$ kcal./mole $P_4$ for white phosphorus at 298·16°K. The corresponding data for red phosphorus, form IV, and amorphous red phosphorus are $697{\cdot}7 \pm 0{\cdot}4$ and $703{\cdot}2 \pm 0{\cdot}5$ kcal. mole$^{-1}$ respectively, both values referring to $P_4$ at 298·16°K.[306]

Data on the heat, free energy and entropy have been reported[307–8] for some oxidation reactions of phosphorus. These are summarized in Table XXXIV in the form of the values of the various constants to be used in the equations

$$\begin{aligned}
\Delta H_T &= \Delta H_0 - 10^{-3}bT^2 + 2\times 10^5 cT^{-1}\\
\Delta G_T &= \Delta H_0 + 2{\cdot}303aT\log_{10} T + 10^{-3}bT^2 + 10^5 cT^{-1} + IT\\
\Delta S_T &= -a - 2{\cdot}303a\log_{10} T - 2\times 10^{-3}bT^2 + 10^5 cT^{-2} - I\\
\Delta C_p &= -a - 2\times 10^{-3}bT - 2\times 10^5 cT^{-2}
\end{aligned}$$

*Table XXXIV.—Thermodynamic Data for Some Oxidation Reactions of White Phosphorus*

| Reaction | Temp. (°K.) | $\Delta H_0$ (g.-cal. mole$^{-1}$) | *a* | *b* | *c* | *I* |
|---|---|---|---|---|---|---|
| $P(s)+\frac{1}{2}O_2(g) = PO(g)$ | 298·16–317·4 | −9,370 | +1·10 | — | — | −25·40 |
| $P(l)+\frac{1}{2}O_2(g) = PO(g)$ | 317·4–553 | −9,390 | +1·50 | — | — | −27·63 |
| $P(g)+\frac{1}{2}O_2(g) = PO(g)$ | 553–1500 | −12,640 | +1·00 | — | — | −18·61 |
| $P_4(s)+5O_2(g) = P_4O_{10}(s)$ | 298·16–317·4 | −711,520 | +41·55 | −51·50 | −1·00 | −28·24 |
| $P_4(l)+5O_2(g) = P_4O_{10}(s)$ | 317·4–553 | −711,800 | +42·55 | −51·50 | −1·00 | −33·13 |
| $P_4(g)+5O_2(g) = P_4O_{10}(s)$ | 553–631 | −725,560 | +37·98 | −51·07 | −2·405 | +20·87 |
| $P_4(g)+5O_2(g) = P_4O_{10}(g)$ | 631–1500 | −722,330 | −18·87 | +2·93 | −2·405 | +348·2 |
| $2P(l)+2\frac{1}{2}O_2(g) = P_2O_5(s)$ | 298–631 | −379,000 | — | — | — | 138·4 |
| $2P(g)+2\frac{1}{2}O_2(g) = P_2O_5(g)$ | 631–1400 | −370,000 | — | — | — | 123·3 |

The free energies for $P_2O_5$ and $P_4O_{10}$ calculated from the data in Table XXXIV are not in agreement with one another. This is unavoidable because the entropy of phosphorus pentoxide had not been determined at the time the data were compiled. Later work has given for this entropy[309] a value of $54{\cdot}68 \pm 0{\cdot}1$ g.-cal. deg.$^{-1}$ mole$^{-1}$ for $P_4O_{10}$ at 25°C.

At high temperatures the rate of change of free energy of formation with temperature approaches a constant value. The free energies of formation of some of these reactions have been represented by empirical linear equations. The equations, which are given below, fit the data to within ± 600 g.-cal. per mole of oxide.[306]

$$\begin{array}{lll}
P(l)+\frac{1}{2}O_2(g) = PO(g) & \Delta G_T^\circ = -10{,}000 - 17{\cdot}11T & (298\text{–}553^\circ\text{K.})\\
P(g)+\frac{1}{2}O_2(g) = PO(g) & \Delta G_T^\circ = -13{,}500 - 10{\cdot}73T & (553\text{–}1500^\circ\text{K.})\\
P_4(l)+5O_2(g) = P_4O_{10}(s) & \Delta G_T^\circ = -722{,}530 + 227{\cdot}11T & (298\text{–}553^\circ\text{K.})\\
P_4(g)+5O_2(g) = P_4O_{10}(s) & \Delta G_T^\circ = -722{,}530 + 227{\cdot}11T & (553\text{–}631^\circ\text{K.})\\
P_4(g)+5O_2(g) = P_4O_{10}(g) & \Delta G_T^\circ = -707{,}490 + 205{\cdot}02T & (631\text{–}1500^\circ\text{K.})
\end{array}$$

Owing to their empirical nature, these equations are not suitable for calculating the entropy or heat of formation at any particular temperature.

## Latent Heat of Fusion

$\alpha$-White phosphorus has a latent heat of fusion of 601 g.-cal./mole $P_4$ at the melting point (44·2°C.). The variation with temperature is given by the equation[192]

$$L_{t^\circ\text{C.}} = 506+3{\cdot}02t-19{\cdot}121\times10^{-3}t^2-1{\cdot}309\times10^{-5}t^3 \text{ g.-cal./mole } P_4$$
$$t = 0^\circ \text{ to } 100^\circ\text{C.}$$

The effect of pressure on the latent heat of fusion ($\lambda$) is reported to be given by the equation

$$\frac{\mathrm{d}\lambda}{\mathrm{d}p} = \frac{\mathrm{d}T}{\mathrm{d}p}(C_1-C_s)+\delta V-T\left[\left(\frac{\partial V_e}{\partial T}\right)_p - \left(\frac{\partial V_s}{\partial T}\right)_p\right]$$

where $C_1$ and $C_s$ are the specific heats of liquid and solid phosphorus, $\delta V$ is the change in volume on melting and $V_e$ and $V_s$ are the specific volumes of the liquid and solid states.[310]

It has been pointed out that the entropy of fusion of white phosphorus (i.e. the molar heat of fusion of $P_4$ in calories divided by the melting point on the absolute scale of temperature) is very nearly equal to the gas constant $\boldsymbol{R}$.[311, 312] This has been interpreted as indicating no new degree of freedom between the atoms of the molecule in the liquid state.[312]

The latent heat of fusion of violet phosphorus (red phosphorus form V) is given as 15·6 kcal./mole $P_4$ at 590°C.[169] This high value is not a true heat of fusion, because violet phosphorus on melting changes to liquid white phosphorus containing $P_4$ molecules. The observed heat therefore includes the heat of depolymerization and other transitions which occur on melting. It should be noted that the latent heat of fusion has been incorrectly reported as 19·4 kcal./mole $P_4$.[299]

No value appears to have been reported for the latent heat of fusion of crystalline black phosphorus. However, the heat of sublimation at 580°C. is 33·6 ± 2 kcal./mole $P_4$.[170] By subtracting from this 10·6 kcal./mole $P_4$ for the heat of vaporization of liquid phosphorus at 580°C.,[169] the approximate value of 23 ± 2 kcal./mole $P_4$ is obtained for the latent heat of fusion.

## Latent Heat of Vaporization

Data on the latent heat of vaporization of liquid white phosphorus are derived from vapour pressure measurements. There is some variation in the values given in the literature, and the best figure seems to be 13·47 kcal./mole $P_4$ at 25°C.[171–2] This is derived from the latent heat of fusion (0·57 kcal./mole $P_4$ calculated as $L_{25^\circ\text{C.}}$ from the equation given above) and the heat of sublimation at 25°C. (14·0 ± 0·3 kcal./mole $P_4$).[194–5] The variation in the reported values has already been discussed (see pages 164–166).

In the temperature range 317° to 629°K. the latent heat is given by the equation[155]

$$\Delta H^\circ = 14{,}714-7{\cdot}7603T+4{\cdot}9122\times10^{-3}T^2 \text{g.-cal. mole } P_4$$

This equation is derived from the earlier vapour pressure measurements[145, 182, 185] and slight modifications are necessary to take account of more recent observations.[194–5] The values of the latent heat of vaporization calculated from this equation are 12·84 kcal./mole $P_4$ at 25°C. and 11·92 kcal./mole $P_4$ at the boiling point (280·5°C.). The corresponding values given by the Bureau of Standards are 12·62 and 11·88 kcal./mole $P_4$, respectively.[299]

The latent heat of vaporization of violet phosphorus has been reported as 10·2 kcal./mole $P_4$ at 590°C.[169] It is probable that this is actually the heat of vaporization of liquid white phosphorus.

## Heats of Transition

Several measurements have been made of the heat changes involved in the transitions between the various forms of phosphorus. The data are summarized in Table XXXV.

The accuracy of some of these data is uncertain,[306] and from an examination of the heats of transition it has been suggested[195] that the calorimetric data may be in error.

The heats of transition of white phosphorus to red, crystalline black and amorphous black phosphorus are derived from the heats of reaction of the appropriate allotropes with bromine in carbon disulphide.[164] These values (−69, −91 and −62 kcal./mole $P_4$, respectively, at 20°C.) appear to be much too large. However, the data were calculated on the assumption that the red and black phosphorus had formed phosphorus pentabromide on bromination. The heats of reaction were compared with previous data[315–16] on the bromination of white phosphorus to form phosphorus pentabromide. If in fact the red and black forms gave the tribromide, and the heat of formation of the latter from white phosphorus and bromine in carbon disulphide solution is taken to be 47·5 kcal./mole $PBr_3$,[155, 299] the above values become −21, −44 and −14 kcal./mole $P_4$, respectively.

*Table XXXV.—Heats of Transition of Phosphorus Allotropes*

| Initial form | Final form | Temp. (°C.) | $\Delta H$ transition (kcal./mole $P_4$) | Ref. |
|---|---|---|---|---|
| α-White | β-White | −76·9 | −3·8±0·2 | 133, 195 |
| α-White | Violet | 25 | −16·6±0·8 | 195, 313, 314 |
| α-White | Red amorphous | 25 | −7·0±1·1 | 306 |
| α-White | Red form IV | 25 | −12·5±1·1 | 306 |
| α-White | Black (cryst.) | 25 | −24·7±2·3 | 195 |
| Violet | Black (cryst.) | 25 | −8·1±2·5 | 195 |
| Red | Black (cryst.) | 350 | −18·2 | 133, 164, 183 |
| Black (amorph.) | Black (cryst.) | 20 | Approx. −30 | 164 |

## Heats of Sublimation

Data on the heats of sublimation of phosphorus allotropes are given in Table XXXVI. The values are referred to the $P_4$ molecule irrespective of the vapour phase shown in column 2; hence, in order to obtain values for $P_2$ and P the figures should be divided by two and four, respectively.

*Table XXXVI.—Heats of Sublimation of Phosphorus*

| Form | Vapour phase | Temp. (°C.) | $\Delta H$ sublimation (kcal./mole $P_4$) | Ref. |
|---|---|---|---|---|
| α-White | $P_4$ | 25 | 14·0±0·3 | 194, 195 |
| α-White | $P_2$ | 25 | 68·5 | 171, 172 |
| α-White | P | 25 | 302·5* | 171, 172 |
| Violet | $P_4$ | 25 | 30·6±0·5 | 169, 195 |
| Violet | $P_4$ | 360–590 | 25·9 | 155 |
| Violet | $P_4$ | 413 | 25·6±2·5 | 317 |
| Red form I | $P_4$ | 320–500 | 19·7 | 155 |
| Red form II | $P_4$ | 310–500 | 24 | 155 |
| Red form IV | $P_4$ | 380–560 | 28 | 155 |
| Red form V | $P_4$ | 320–510 | 28·8 | 155 |
| Red form V | $P_4$ | 25 | 30·8 | 171 |
| Red form V | $P_2$ | 25 | 85·5 | 171, 172 |
| Red form V | P | 25 | 319 | 171, 172 |
| Black (cryst.) | $P_4$ | 25 | 38·7±2·0 | 195 |
| Black (cryst.) | $P_4$ | 453 | 33·1±2·5 | 133, 317 |
| Black (cryst.) | $P_4$ | 552–578 | 33·6±2·0 | 170 |

* Based on $\Delta H = 14{\cdot}0$ for α-white phosphorus.

The values reported for white phosphorus have already been discussed (see pages 164–166). There are some differences in the data given for red phosphorus and it should be noted that the heats of sublimation for forms I to V are average values derived from vapour pressure equations. Except for form V it is possible that heating may have caused changes in the phosphorus which have an effect on its vapour pressure.[155]

The heat of sublimation at 25°C. for violet phosphorus is a value calculated from high temperature vapour pressure data,[169] and corrected to 25°C. using published values[318] for the heat capacities of phosphorus vapour and solid red phosphorus. The heat of sublimation of black phosphorus is obtained in a similar manner, also using the heat capacity data for solid red phosphorus. The latter are considered to be a sufficiently good approximation in the absence of experimental heat capacity values for black phosphorus.[195]

The heat of sublimation of $\alpha$-white phosphorus to monatomic vapour has been calculated to be $292{\cdot}6 \pm 8$ kcal./mole $P_4$.[319] An earlier calculated value of 424 kcal./mole $P_4$ seems to be too large.[320]

The value of 79 kcal./mole $P_4$ reported[319] for the sublimation of red phosphorus to diatomic vapour agrees with that given in Table XXXV when it is corrected for the more recent and more accurate values of the separate heats used in the earlier calculation.

## Atomic and Specific Heats

The atomic heat of solid white phosphorus at 25°C. has been given as 5·55,[299] 5·62[318] and 5·69[321] g.-cal./g. atom. The values given for liquid white phosphorus at 44·1°C. are 5·88,[318] 6·05[299, 322] and 6·24[321] g.-cal./g.atom.

The value of the expression $A/\alpha T_m$, where $A$ is the atomic heat, $\alpha$ the coefficient of cubical expansion and $T_m$ is the melting point in °K., is reported to be 48 g.-cal. deg.$^{-1}$ for solid white phosphorus and 36 g.-cal. deg.$^{-1}$ for the liquid.[323]

The molar specific heat of solid white phosphorus has been calculated by considering the unit cell to consist of $P_4$ molecules having a total of 48 degrees of freedom. Of these, 24 were identified with the internal vibrations of the $P_4$ molecule as specified by the observed Raman frequencies and their degeneracies, 12 were associated with the inactive frequency of a triply degenerate oscillation of each of four $P_4$ molecules, and 9 were associated with the observed low-frequency vibration due to hindered translations of $P_4$ molecules in the unit cell; this low-frequency was taken to be 36 cm.$^{-1}$ and the three hindered rotations of the $P_4$ molecules were assumed to correspond to a frequency of 67 cm.$^{-1}$ The remaining three degrees of freedom were considered to be due to simple translations of the unit cell.[324] In the assignment of the observed Raman frequencies, the 606 cm.$^{-1}$ frequency is identified as single and due to the symmetrical vibration, the 363 cm.$^{-1}$ is doubly degenerate and the 465 cm.$^{-1}$ one is triply degenerate.[69, 70] From these data the following equation expressed in Einstein terms was derived for the molar specific heat at constant volume

$$C_v = \tfrac{1}{4}E(\theta_{36}/T)+\tfrac{3}{4}E(\theta_{36}/T)+E(\theta_{67}/T)+\tfrac{1}{3}E(\theta_{606}/T)+\tfrac{2}{3}E(\theta_{363}/T)+E(\theta_{465}/T)$$

The difference in specific heats, $C_p - C_v$, at room temperature was calculated from thermodynamic data to be 3·06. At other temperatures Gruneisen's law[325]

$$C_p - C_v = \alpha^2 VT/\beta$$

where $\alpha$ = coefficient of cubical expansion, $\beta$ = coefficient of compressibility, $V$ = specific volume, was used. Since $\alpha$ is proportional to $C_v$ and the specific volume and compressibility vary little with temperature,

$$C_p - C_v = A\, C_v^2\, T$$

In this expression, $A$ is a constant which can be calculated from a known value of $C_p - C_v$ and the value of $C_v$ at 300°K.

The values of $C_p$ found in this way are compared in Table XXXVII with the mean specific heat data found by Dewar[326] at 50°K. and by Ewald[327] at 82° to 290°K. In this Table $U = E(\theta/T)$.

*Table XXXVII.—The Calculated Mean Molar Specific Heat of White Phosphorus (in* g.*-cal./mole* $P_4$*) at* 23° *to* 290°K.

| Parameter | Temperature—°K. | | | | | | | |
|---|---|---|---|---|---|---|---|---|

## Heat Capacity

The molar heat capacity of solid white phosphorus between 273·16°K. and 317·26°K. is given by the expression

$$C_p = 13{\cdot}615 + 28{\cdot}72 \times 10^{-3}T \text{ g.-cal. (mole P}_4)^{-1} \text{ deg.}^{-1}$$

This gives molar heat capacities of 22·18 and 22·73 at 25° and 44·2°C., respectively.[192]

For liquid and supercooled white phosphorus the molar heat capacity equation is

$$C_p = 24{\cdot}151 + 11{\cdot}932 \times 10^{-3}T - 3{\cdot}927 \times 10^{-5}T^2 \text{ g.-cal. (mole P}_4)^{-1} \text{ deg.}^{-1}$$

which represents measurements made between 298·16° and 370·16°K.[192]

Calculations by separate thermodynamic paths of the free energy of vaporization of white phosphorus indicate that the above heat capacity equation for liquid phosphorus is probably reliable up to 623·16°K.[155] (see, however, page 203).

The molar heat capacity of tetratomic phosphorus vapour is closely represented between 298° and 1500°K. by[155, 191]

$$C_p = 19{\cdot}227 + 0{\cdot}509 \times 10^{-3}T - 2{\cdot}975 \times 10^{5}T^{-2} \text{ g.-cal. (mole P}_4)^{-1} \text{ deg.}^{-1}$$

This equation is derived from values of the heat content $H_T^\circ - H_0^\circ$ obtained by a statistical mechanical calculation.[77]

For diatomic phosphorus vapour the molar heat capacity between 298° and 2000°K. is represented to within 0·02 g.-cal. by the equation

$$C_p = 6{\cdot}9545 + E(1114/T) + 5{\cdot}84 \times 10^{-5}T$$

where $E$ is the Einstein function corresponding to a vibration frequency of 778 cm.$^{-1}$ ($E = x^2e^x/(e^x-1)^2$ where $x$ is $1114/T$).[328–9] This is equivalent to

$$C_p = 8{\cdot}86 + 0{\cdot}08 \times 10^{-3}T - 1{\cdot}20 \times 10^{5}T^{-1}$$

Two other equations which represent the data[65, 172] less closely are[191]:

$$C_p = 8{\cdot}643 + 0{\cdot}202 \times 10^{-3}T - 1{\cdot}03 \times 10^{5}T^{-2}$$

and[155]

$$C_p = 8{\cdot}44 + 0{\cdot}38 \times 10^{-3}T - 0{\cdot}836 \times 10^{5}T^{-2}$$

The heat capacity of monatomic phosphorus vapour is constant at 4·97 g.-cal./g.atom P up to 1500°K. It increases to 5·06 at 2000°K. and 5·62 at 3000°K. (see page 196, Table XXXIX).[65, 172]

In the temperature range 300° to 1500°K. the molar heat capacities of diatomic and tetratomic phosphorus vapour at constant volume are represented by the equations[320]:

$$P_2:\quad C_v = 4{\cdot}04 + 7{\cdot}17 \times 10^{-3}T - 6{\cdot}3 \times 10^{-6}T^2 + 1{\cdot}85 \times 10^{-9}T^3$$
$$P_4:\quad C_v = 8{\cdot}33 + 25{\cdot}9 \times 10^{-3}T - 24{\cdot}2 \times 10^{-6}T^2 + 7{\cdot}41 \times 10^{-9}T^3$$

The data available on the heat capacity of red phosphorus appear to be rather less precise than those for the white modification. The earlier measurements[327, 330] are represented to within ±10% between 273° and 473°K. by the equation[322]

$$C_p = 0{\cdot}21 + 18 \times 10^{-3}T \text{ g.-cal./mole P}$$

The data are not considered to be reliable enough for thermochemical calculations.[331] Measurements[332] of the mean specific heat between 295·16 and 873·16°K. give the following molar heat capacity equation[322] in g.-cal./g.atom

$$C_p = 2{\cdot}67 + 7{\cdot}8 \times 10^{-3}T; \qquad T = 573° \text{ to } 773°\text{K.}$$

This agrees fairly well with the specific heat obtained by Regnault (Mellor, VIII, 760).

### Heat Content, Free Energy and Entropy

From a critical examination of the information available up to 1948, Kelley[318, 333] compiled data on the heat content and entropy of phosphorus. These are summarized in Table XXXVIII which gives the values of the constants to be used in the equations which follow. The data refer to calories per mole of the species indicated in column 2 of the Table.

$$\begin{aligned} C_p &= a + b \times 10^{-3}T + c \times 10^5 T^{-2} \\ H_T - H_{298} &= aT + \tfrac{1}{2}b \times 10^{-3}T^2 - c \times 10^5 T^{-1} - d \\ S_T - S_{298} &= 2{\cdot}303a \log_{10} T + b \times 10^{-3}T - \tfrac{1}{2}c \times 10^5 T^{-2} - e \end{aligned}$$

*Table XXXVIII.—Heat Content and Entropy of Phosphorus*

| Form | Formula | Temp. (°K.) | *a* | *b* | *c* | *d* | *e* | Relative Accuracy (%) | $S_{298}$ |
|---|---|---|---|---|---|---|---|---|---|
| White (liquid) | $P_4$ | 317–400 | 23·5 | 0·8 | — | 6425 | 132·4 | 1 | 44·4 |
| Red (solid) | P | 298–800 | 4·74 | 3·9 | — | 1587 | 28·12 | 5 | 7·4 |
| Ideal gas | P | 298–1500 | 4·97 | — | — | 1482 | 28·33 | 0·1 | 38·99 |
| Ideal gas | $P_2$ | 298–2000 | 8·31 | 0·46 | −0·72 | 2740 | 47·91 | 0·5 | 52·11 |
| Ideal gas | $P_4$ | 298–1500 | 18·93 | 0·86 | −2·81 | 6625 | 109·7 | 1 | 66·85 |

It should be noted that these are empirical equations. Although they represent the data within the accuracy stated, the equations must not be confused with those quoted elsewhere (e.g., page 194) which are derived by statistical mechanical methods or are based on calculations from spectroscopic data.

A more recent survey[334, 335] gives the same data, except for the entropy of liquid white phosphorus for which the value $S_{298} = 41{\cdot}2$ is considered to be more accurate. It has been shown experimentally that the enthalpy of liquid phosphorus varies in a smooth and continuous fashion from −1°C. through the melting point at 44°C.[479] It shows no anomaly near the melting point, such as would be associated with the changes in molecular association postulated by previous authors on the basis of the viscosity behaviour of supercooled liquid phosphorus.[231–2, 230]

Table XXXIX.—Thermodynamic Properties of Phosphorus Vapour[171]

| Temp. (°K.) | P—ideal gas (g.-cal./g. atom) | | | | $P_2$—ideal gas (g.-cal./mole) | | | | $P_4$—ideal gas (g.-cal./mole) | | | |

| $H_{298\cdot15}^\circ - H_0^\circ$ | 1481 | | | | 2133 | | | | 3368 | | | |

Expressions for the heat content have been derived[155] from the heat capacity equations given above (pages 194–195) for diatomic and tetratomic phosphorus vapour. These are[155]

$$P_2:\quad H^\circ - H^\circ_0 = -678 + 8{\cdot}44T + 0{\cdot}19\times10^{-3}T^2 + 0{\cdot}836\times10^5T^{-1}\,\text{g.-cal. mole}^{-1}$$
$$P_4:\quad H^\circ - H^\circ_0 = -3380 + 19{\cdot}23T + 0{\cdot}255\times10^{-3}T^2 + 2{\cdot}980\times10^5T^{-1}\,\text{g.-cal. mole}^{-1}$$

The entropy at 298·16°K. of solid α-white phosphorus has been given as 10·6 ± 0·5 g.-cal.(g.atom)$^{-1}$ deg.$^{-1}$ [333] and 9·8 g.-cal.(g.atom)$^{-1}$ deg.$^{-1}$ [172, 334]; the second is regarded as the better value.[334] The corresponding data for crystalline violet and crystalline black phosphorus are 7·4 ± 0·5 and 5·3 ± 0·5 g.-cal.(g. atom)$^{-1}$ deg.$^{-1}$ [333] A later determination of the heat capacity of black phosphorus from 13·0 to 293·8°K. gave values of $S^\circ_{298{\cdot}15} = 5{\cdot}457 \pm 0{\cdot}010$ g.-cal./g. atom/deg. and $H_{298{\cdot}15} - H^\circ_0 = 882{\cdot}6 \pm 1{\cdot}5$ g.-cal./g. atom, in good agreement with previous work.[480]

Thermodynamic properties referred to triclinic red phosphorus form V have been reported[171] for temperatures up to 3000°K. These data, which are given in Table XXXIX and Table XL, were compiled[172] from the heat capacities given by Kelley[318] in conjunction with other relevant information.[155, 336]

*Table XL.—Thermodynamic Properties of Triclinic Red Phosphorus and Cubic α-White Phosphorus*

| Temp. (°K.) | Red, triclinic (g.-cal./g. atom) | | | | α-White, cubic solid (g.-cal./g. atom) | | | |
|---|---|---|---|---|---|---|---|---|
| | $C^\circ_p$ | $H^\circ_T - H_{298}$ | $S^\circ_T$ | $-\left(\frac{G^\circ - H_{298}}{T}\right)$ | $C^\circ_p$ | $H^\circ_T - H_{298}$ | $S^\circ_T$ | $-\left(\frac{G^\circ - H_{298}}{T}\right)$ |
| 298·15 | 4·98 | 0 | 5·46 | 5·46 | 5·63 | 0 | 9·80 | 9·80 |
| 300 | 4·98 | 9 | 5·49 | 5·46 | 5·63 | 10 | 9·83 | 9·80 |

| 3000 | 4·54 | 33,320 | 36·03 | 24·93 | | | | |

The reference state for the above Tables is red triclinic phosphorus from 298° to 704°K. and ideal gas above this. The following additional enthalpy data were used in compiling the tables:

Heat of sublimation of red phosphorus to $P_4$ = 30·82 kcal./mole $P_4$ at 298°K.
Sublimation of red phosphorus to $P_2$ gas = 42·725 kcal./mole $P_2$ at 298°K.
$\left\{\begin{array}{l}\text{Dissociation } P_4 \rightarrow 2P_2 = 54{\cdot}630 \text{ kcal./mole } P_4 \text{ at } 298^\circ\text{K.}\\ \text{Dissociation } P_2 \rightarrow P \text{ gas} = 116{\cdot}0 \text{ kcal./mole } P_2 \text{ at } 0^\circ\text{K.}\end{array}\right.$
Sublimation of red to P gas = 79·5 kcal./g. atom at 298°K.

Heat of sublimation of red phosphorus to $P_4$ at 704°K. = 7·2 kcal./g. atom.
Heat of sublimation of α-white phosphorus to $P_4$ = 14·1 kcal./mole $P_4$ at 298°K.
Heat of vaporization of liquid white phosphorus = 2·960 kcal./g. atom at 554°K.
Formation of α-white phosphorus from red phosphorus = 4·18 kcal./g. atom at 298°K.

It should be noted that in one compilation[77] of the free energy functions of monatomic phosphorus vapour, the entropy values are all too low by 3·4 g.-cal./g.-atom/deg.

Thermodynamic functions of phosphorus vapour as ideal gas at one atmosphere pressure, without nuclear spin effects, have been calculated[337] using an I.B.M. 704 digital computer. The results for monatomic and diatomic phosphorus vapours up to 3000°K. agree to within one in the second place of decimals with the values given in Table XXXIX and Table XL. The data for temperatures above 3000°K. are given in Table XLI in which the data agree with other and simplified calculations,[338] when allowance is made for changes in the values of fundamental constants and approximations made in the previous calculation.[338]

*Table XLI.—Thermodynamic Functions of* $P(g)$ *and* $P_2(g)$ *in the Ideal Gas State*
(All entropy data in g.-cal. mole$^{-1}$ deg.$^{-1}$)

| Temp. (°K.) | $P(g)$ | | | $P_2(g)$ | | |

For tetratomic phosphorus vapour the values vary slightly from those given above and complete data are shown in Table XLII.

For the $P_4$ data (Table XLII) the information available was sufficient only to make a rigid rotator-harmonic oscillator approximation in the calculation of the internal partition function. The figure of 103·652 given in the original paper for the entropy at 2000°K. appears to be in error.

For data in Table XLII the $P_4$ frequencies used were 363, 461 and 606 cm.$^{-1}$, with a moment of inertia of $251{\cdot}17 \times 10^{-40}$ g. cm.$^2$ The spectroscopic data for the $P_2$ molecule are given in Table XLIII.

The heats of formation to be used with the functions given in Tables XLI and XLII are given in Table XLIV. These are referred to crystalline, white β-phosphorus

as the standard state. They are based on a heat of sublimation of α-white phosphorus of 14,040 g.-cal.[194] and the value of $H_{298}^\circ - H_0^\circ$ allowing for the α to β transition.

Slightly different values for the free energy of monatomic phosphorus gas have been reported[339] for temperatures up to 8000°K. These were calculated by the method

*Table XLIV.—Heats of Formation of Phosphorus referred to Crystalline, β-White Phosphorus at* 0°K.

The value of $H^\circ_{298\cdot16} - H^\circ_0$ was 1481·7 g.-cal./mole P.

It has been reported[341] that the assumption of a simple valency field force is not satisfactory for the calculation of the thermodynamic functions of the $P_4$ molecule (see also ref. 336, p. 299). An attempt was made to correct the anharmonicity in a semi-quantitative manner. The corrected values of $\omega_1 + 2x_{11} + x_{12} = 604$, $\omega_2 + \frac{1}{2}x_{12} = 381$ and $\omega_3 = 506$ were obtained[341] instead of the usual vibration frequencies of $\nu_1 = 606$ cm.$^{-1}$, $\nu_2 = 363$ cm.$^{-1}$ and $\nu_3 = 464\cdot5$ cm.$^{-1}$ The thermodynamic properties of $P_4$ gas have been calculated for ideal gas at 1 atmosphere pressure, by using these corrected frequencies and a rigid rotator-harmonic oscillator model.[342] However, this procedure has been criticized[343] and it would seem that it gives less accurate values of the thermodynamic functions than those obtained[171–2] directly from the uncorrected, observed vibrational wave numbers.

## Thermodynamics of Sublimation

There is some uncertainty in the earlier data[155] for the thermodynamics of sublimation of white phosphorus owing to various values which had been reported for the heat of sublimation of α-white phosphorus (see pages 165–166 and 192–193).

The thermodynamic constants at 298·16°K. for the sublimation of α-white phosphorus, based on a heat of sublimation of 13·47 kcal./mole $P_4$, have been given as[155]

$$\begin{aligned}\Delta H^\circ &= 13{,}470 \text{ g.-cal./mole } P_4\\ \Delta G^\circ &= 5784 \pm 8 \text{ g.-cal./mole } P_4\\ \Delta S^\circ &= 25\cdot78 \pm 0\cdot03 \text{ g.-cal./mole } P_4\text{/deg.}\end{aligned}$$

The corresponding thermodynamic equations are:

$$\begin{aligned}\Delta C^\circ_p &= 5\cdot515 - 28\cdot210 \times 10^{-3}T - 2\cdot98 \times 10^5 T^{-2}\\ \Delta H^\circ &= 12{,}080 + 5\cdot515T - 14\cdot105 \times 10^{-3}T^2 + 2\cdot98 \times 10^5 T^{-1}\\ \Delta G^\circ &= 12{,}080 + 4\cdot396T - 12\cdot699T \log_{10} T + 14\cdot105 \times 10^{-3}T^2 + 1\cdot49 \times 10^5 T^{-1}\\ \Delta S^\circ &= 1\cdot119 + 12\cdot699 \log_{10} T - 28\cdot21 \times 10^{-3}T + 1\cdot49 \times 10^5 T^{-2}\end{aligned}$$

These expressions are derived from the heat capacity equations for solid white phosphorus[192] and for $P_4$ vapour[191] (see page 194). The figure of 12,080 was calculated from the heats of fusion[192] and vaporization[182] of 601 and 12,750 g.-cal./mole $P_4$ respectively at the melting point, 44·1°C. The constant 5·515 is in error and should be 5·612.

More reliable equations may be derived by using the later and more accurate heat of sublimation of 14,040 g.-cal.(mole $P_4$)$^{-1}$ at 25°C.[194] Entropy values at 25°C. of 39·2 g.cal.(mole $P_4$)$^{-1}$ deg.$^{-1}$ for solid α-white phosphorus[172, 335] and 66·93 g.-cal.(mole $P_4$)$^{-1}$ deg.$^{-1}$ for $P_4$ vapour[335] give an entropy of sublimation of 27·73 g.-cal.(mole $P_4$)$^{-1}$ deg.$^{-1}$, and the following equations:

$$\begin{aligned}
\Delta C_p^\circ &= 5{\cdot}612 - 28{\cdot}210 \times 10^{-3}T - 2{\cdot}975 \times 10^{5}T^{-2} \\
\Delta H^\circ &= 12{,}623 + 5{\cdot}612T - 14{\cdot}105 \times 10^{-3}T^{2} + 2{\cdot}975 \times 10^{5}T^{-1} \\
\Delta G^\circ &= 12{,}623 - 12{\cdot}922 \log_{10} T + 3{\cdot}123T + 14{\cdot}105 \times 10^{-3}T^{2} + 1{\cdot}488 \times 10^{5}T^{-1} \\
\Delta S^\circ &= 2{\cdot}489 + 12{\cdot}922 \log_{10} T - 28{\cdot}21 \times 10^{-3}T + 1{\cdot}488 \times 10^{5}T^{-2}
\end{aligned}$$

The thermodynamic constants at 25°C. are:

$$\begin{aligned}
\Delta H^\circ &= 14{,}040 \text{ g.-cal.(mole } P_4)^{-1} \\
\Delta G^\circ &= 5{,}773 \text{ g.-cal.(mole } P_4)^{-1} \\
\Delta S^\circ &= 27{\cdot}73 \text{ g.-cal.(mole } P_4)^{-1} \text{ deg.}^{-1}
\end{aligned}$$

The sublimation pressure at 25°C. as measured by Centnerszwer[190] gives a free energy value of 5,792 g.-cal.(mole $P_4$)$^{-1}$.[154]

### Thermodynamics of Dissociation

The experimental data[201] for the dissociation $P_4 \rightleftharpoons 2P_2$ fit the following equation for the dissociation constant in the temperature range 900° to 1200°C.

$$\log_{10} K_{\text{atm.}} = 7{\cdot}5787 - 11{\cdot}489T^{-1}$$

(see page 168 and ref. 155, p. 16).

This gives an average heat of dissociation $\Delta H^\circ = 52{,}550$ g.-cal. The expression for the free energy of dissociation is

$$\Delta G^\circ = 52{,}550 - 34{\cdot}665T$$

Calculations based on spectroscopic data[77] give the following equations:

$$\begin{aligned}
\log_{10} K_{\text{atm.}} &= 7{\cdot}582 - 11{,}505T^{-1} \\
\Delta G^\circ &= 52{,}650 - 34{\cdot}690T
\end{aligned}$$

The heat of dissociation at 0°K. was calculated[77] to be $\Delta H_0^\circ = 53{,}600$ g.-cal. Using this value and the thermodynamic properties of $P_4$ and $P_2$ given in Table XLII and Table XXXIX, the data in Table XLVI are obtained.

*Table XLVI.—Thermodynamics of the Dissociation* $P_4 \rightleftharpoons 2P_2$

| Temp. (°K.) | $\Delta G^\circ$ (g.-cal. mole$^{-1}$) | $\Delta H^\circ$ (g.-cal. mole$^{-1}$) | $\Delta S^\circ$ (g.-cal. mole$^{-1}$ deg.$^{-1}$) | $K_p$ (atm.) | % dissociation |
|---|---|---|---|---|---|
| 298·1 | 43,375 | 54,498 | 37·29 | $1{\cdot}6 \times 10^{-32}$ | $6 \times 10^{-15}$ |

| 1373 | 4,880 | 52,630 | 34·78 | 0·167 | 20·0 |
| 1400 | 3,910 | 52,570 | 34·76 | 0·245 | 24·1 |
| 1473 | 1,380 | 52,440 | 34·66 | 0·624 | 36·7 |
| 1500 | 425 | 52,390 | 34·64 | 0·867 | 42·1 |
| 1600 | −3,006 | 52,210 | 34·51 | 2·58 | 62·6 |
| 1800 | −9,900 | 51,860 | 34·31 | 15·95 | 89·4 |
| 2000 | −16,720 | 51,500 | 34·11 | 91·75 | 97·9 |

Similar calculations for the $P_2 \rightleftharpoons 2P$ dissociation, using a heat of dissociation of 116,000 g.-cal. mole$^{-1}$ (5·031 e.v.)[171–2] at 0°K. give the results shown in Table XLVII.

The thermodynamic properties used for the above calculation were taken from Table XXXIX and Table XLI.

*Table XLVII.—Thermodynamics of the Dissociation* $P_2 \rightleftharpoons 2P$

| Temp. (°K.) | $\Delta G°$ (g.-cal. mole$^{-1}$) | $\Delta H°$ (g.-cal. mole$^{-1}$) | $\Delta S°$ (g.-cal. mole$^{-1}$ deg.$^{-1}$) | $K_p$ (atm.) | % dissociation |
|---|---|---|---|---|---|
| 298·1 | 109,125 | 116,830 | 25·85 | $1·1 \times 10^{-80}$ | $5 \times 10^{-39}$ |
| 1000 | 90,090 | 117,870 | 27·78 | $2 \times 10^{-20}$ | $7 \times 10^{-9}$ |

| 4000 | 3,560 | 123,410 | 29·97 | 0·64 | 37·2 |
| 4500 | −11,560 | 125,400 | 30·44 | 3·64 | 69·1 |
| 5000 | −26,890 | 127,660 | 30·91 | 14·9 | 88·8 |

The data of Table XLVII fit the following equation for the equilibrium constant:

$$\log_{10} K_{\text{atm.}} = 6·426 - 26{,}230T^{-1}$$

which gives an average heat of dissociation of $\Delta H° = 120{,}200$ g.-cal.(mole $P_2$)$^{-1}$.

The corresponding free energy equation is

$$\Delta G° = 120{,}200 - 29·4T$$

The dissociation of the tetratomic and diatomic vapour is shown graphically in Fig. 15.

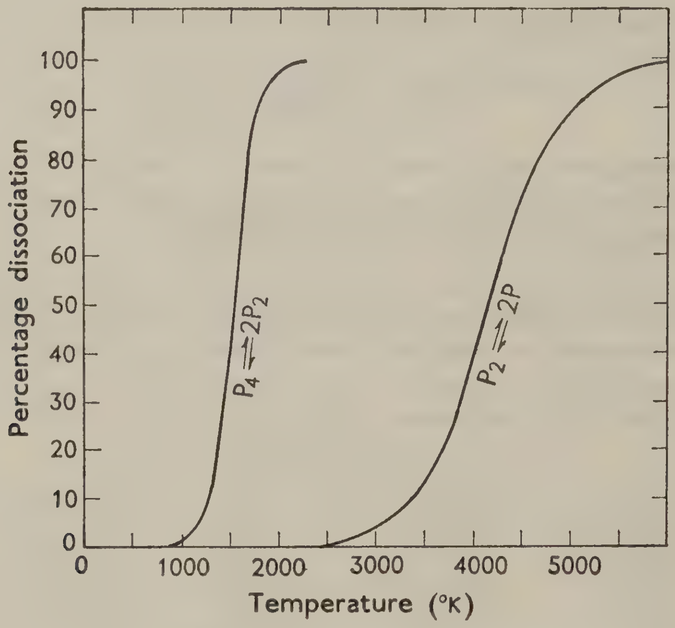

FIG. 15.—Dissociation of phosphorus vapour

## Thermodynamic Properties of Liquid Phosphorus

The vapour pressure of liquid phosphorus between 44° and 360°C. is represented by the equation[155]

$$\log_{10} p_{\text{mm.}} = 18·8192 + 1·074 \times 10^{-3}T - 3·906 \log_{10}T - 3216·7T^{-1}$$

From this, by means of the relation

$$\frac{d(\log_e p)}{dT} = \frac{\Delta H}{RT^2}$$

the latent heat of vaporization is given by

$$\Delta H^\circ = 14{,}714-7{\cdot}7603T+4{\cdot}9122\times10^{-3}T^2 \text{ g.-cal.(mole } P_4)^{-1}$$

The corresponding free energy and entropy equations are:

$$\Delta G^\circ = 14{,}714-72{\cdot}918T-4{\cdot}912\times10^{-3}T^2+17{\cdot}872T\log_{10}T$$
$$\Delta S^\circ = 65{\cdot}158+9{\cdot}826\times10^{-3}T-17{\cdot}872\log_{10}T$$

The heat capacity equation for liquid phosphorus in the temperature range 25°C. to 97°C. is[192]

$$C_p^\circ = 24{\cdot}151+11{\cdot}932\times10^{-3}T-3{\cdot}927\times10^{-5}T^2 \text{ g.-cal.(mole } P_4)^{-1}\text{ deg.}^{-1}$$

A summary of the data derived from these equations is given in Table XLVIII.

*Table XLVIII.—Thermodynamic Properties of Liquid Phosphorus*[155]

| 473·1 | 0·158 | 1730 | 1740 | 12,140 | 22·0 | 74·8 | 52·8 | 21·0 |
| 523·1 | 0·538 | 640 | 660 | 12,000 | 21·7 | 76·6 | 54·9 | 19·6 |
| 553·7 | 1·0 | 0 | 0 | 11,920 | 21·5 | 77·7 | 56·2 | 18·7 |
| 573·1 | 1·467 | −440 | −420 | 11,880 | 21·5 | 78·3 | 56·8 | 18·1 |
| 623·1 | 3·378 | −1510 | −1500 | 11,790 | 21·3 | 79·9 | 58·6 | 16·3 |

The entropy values for $P_4(g)$ used in the above Table were derived from the free energy and heat content data of Stevenson and Yost.[77]

The free energy of vaporization has also been obtained[155] from the heat capacity equation for liquid phosphorus given above, and the heat capacity equation for phosphorus vapour,[191] i.e.,

$$C_p^\circ\text{ (gas)} = 19{\cdot}23+0{\cdot}510\times10^{-3}T-2{\cdot}980\times10^{5}T^{-2} \text{ g.-cal.(mole } P_4)^{-1}\text{ deg.}^{-1}$$

This gives the following free energy equation

$$\Delta G_c^\circ = 13{,}638+11{\cdot}331T\log_{10}T-57{\cdot}358T+5{\cdot}711\times10^{-3}T^2 \\ -0{\cdot}6545\times10^{-5}T^3+1{\cdot}490\times10^{5}T^{-1}$$

the values of which are given in column 4 of Table XLVIII. The agreement between the two sets of free energy data has been taken as evidence that the heat capacity equation for liquid phosphorus is reliable up to 350°C.[155] On the other hand the following heat content and entropy equations may be derived from the heat capacity equations:

$$\Delta H^\circ = 13{,}638-4{\cdot}92T-5{\cdot}71\times10^{-3}T^2+2{\cdot}98\times10^{5}T^{-1}+1{\cdot}31\times10^{-5}T^3$$
$$\Delta S^\circ = 52{\cdot}44-11{\cdot}33\log_{10}T-11{\cdot}42\times10^{-3}T+1{\cdot}49\times10^{5}T^{-2}+1{\cdot}964\times10^{-5}T^2$$

These expressions have the property of giving minimum values for the heat content and entropy at about 600°K.

The vapour pressure equation of supercooled red phosphorus is[182]

$$\log_{10}p_{\text{atm.}} = 8{\cdot}6886-2898{\cdot}1T^{-1}-1{\cdot}2566\log_{10}T$$

The following thermodynamic expressions may be derived from this equation:

$$\begin{aligned}
\Delta G^\circ &= 13{,}256 - 39{\cdot}74T + 5{\cdot}748T \log_{10} T \\
\Delta H^\circ &= 13{,}256 - 2{\cdot}893T \\
\Delta S^\circ &= 36{\cdot}85 - 5{\cdot}748 \log_{10} T
\end{aligned}$$

These give the data shown in Table XLIX.

*Table XLIX.—Thermodynamic Properties of Supercooled Red Phosphorus*

| Temp. (°K.) | Vapour pressure (atm.) | Free energy of vaporization ($\Delta G^\circ$) (g.-cal./mole) | Heat of vaporization ($\Delta H^\circ$) (g.cal./mole) | Entropy | | |

## Bond Energies and Related Properties

Since 1950 many thermochemical investigations which provide information on phosphorus bonds and bond energies have been made on phosphorus compounds. Most of the thermochemical data are derived from reaction calorimetry. Combustion measurements, especially with high-precision calorimeters, are relatively rare. Because of this, the accuracy in phosphorus thermochemistry is lower than that for other elements such as carbon. In addition, revisions or more accurate measurements of some of the earlier data necessitate alterations in the values of some of the thermochemical properties of phosphorus. Critical reviews[117, 344] of the subject have given assessments of the accuracy and reliability of the information at present available.

The term 'bond energy' is sometimes used without precise definition, so that confusion arises over its meaning and interpretation. In the present account the concept is used to indicate the strength of a bond in two ways.[302] The bond strength may be measured by determining how much energy is required to break the bond. This value is referred to as the bond dissociation energy, $D_0^\circ$. The latter is defined[345] as the change in energy, $\Delta E_0^\circ$ at absolute zero in the ideal gas state, required to break the bond $X$–$Y$ according to the reaction

$$XY \rightarrow X + Y$$

with the products in their ground state. In polyatomic molecules the bond dissociation energy may include energy associated with changes in the spatial arrangement of the remaining atoms or adjustment of the other bonds in the molecule, consequent upon the breaking of a particular bond.

The alternative is to use a quantity which, when summed over all the bonds, gives the heat of formation of a molecule from atoms. This quantity is referred to as the thermochemical bond energy term $E$. Unlike the bond dissociation energy, the thermochemical bond energy term is referred to 298·16°K. and not to 0°K. This is because data are not always available to enable the zero-point energy to be calculated (see ref. 302, pp. 103–6). The bond energy term is therefore defined as the quantity obtained by summation over all bonds and is the heat of atomization in the ideal gas state at 298·16°K. to the atomic elements in their ground state at this temperature.[123, 302] It should be noted that this definition refers only to the gaseous state. If, therefore, the heat of atomization is given for a solid or liquid, the latent heat of fusion and vaporization must be subtracted in order to allow for the Van der Waals forces which take no part in bond formation. For a gaseous compound the heat of atomization is obtained by adding to its heat of formation, $-\Delta H_1$ (in the ideal gas state from its elements in their standard state), the sum of the heats of formation, $\Sigma\Delta H_2$ (from the elements in their standard states), of the monatomic gaseous elements.

In a diatomic molecule the bond energy term is equal to the bond dissociation energy, but for polyatomic molecules the bond energy terms are not usually equal to one another. For example the bond dissociation energy for P–O in phosphorus monoxide is 140 kcal. mole$^{-1}$ but in phosphorous oxide ($P_4O_6$) the bond energy term $E$(P–O) is 86 kcal. mole$^{-1}$.

The literature contains some bond energy values which have since been revised in the light of more reliable data. For example, the P–P bond energy term has been reported[123] to be 18·9 kcal. mole$^{-1}$. This was based on an early value of 42 kcal. mole$^{-1}$ for the heat of dissociation of diatomic phosphorus vapour. Correction for the more accurate value of 116 kcal. mole$^{-1}$ gives[108] a bond energy of 48 kcal. mole$^{-1}$. The bond energy data given below have been selected from what is considered to be the most reliable information.

The bond-dissociation energies of the diatomic molecules PC,[302, 346] PP,[76, 302, 346] PN[344, 347] and PO,[302, 344, 348] in kcal. mole$^{-1}$ are $138 \pm 23$, $117 \pm 1$, $164 \pm 2$ and $140 \pm 20$, respectively. The value for PN replaces those previously given.[76, 302, 346]

For polyatomic molecules, difficulties arise in assigning values to the various bonds involved. For simple compounds resulting from the combination of only two kinds of atoms, e.g., $PH_3$, $PCl_3$, an average value $\bar{E}$ of the bond energy terms can be obtained from heats of formation as described above. The figure obtained in this way is based on the assumption that the same energy is required to break each bond in succession. This assumption may not be valid where the molecular configuration alters with the breaking of the initial bond. Table L gives average bond energy terms for a number of phosphorus bonds.[344]

*Table L.—Average Bond Energy Terms in Phosphorus Compounds*

| Compound | Bond | $\bar{E}$ (kcal. mole$^{-1}$) | Compound | Bond | $\bar{E}$ (kcal. mole$^{-1}$) |
|---|---|---|---|---|---|
| $PH_3$ | P–H | 77 | $PI_3$ | P–I | 44 |
| $PF_3$ | P–F | 117 | $P_4O_6$ | P–O | 86 |
| $PCl_3$ | P–Cl | 76 | $P_4$ | P–P | 48 |
| $PBr_3$ | P–Br | 62 | | | |

Some of the above values differ slightly from those reported elsewhere[302] through the use of more accurate data, which are summarized in Table LII. A few of the data for phosphorus halides are either incomplete or depend on very early investigations. In particular, the heat of sublimation of phosphorus tri-iodide is an estimate. The bond energy term for P–O is based on a recent determination of the heat of formation of phosphorous oxide[304] which is considered to be more reliable than the earlier value.[300] The value of $\bar{E}$(P–P) refers to the $P_4$ tetrahedron with a bond angle of 60°. Several attempts have been made to correct this for the so-called strain energy. The normal angle between the *p*-orbitals in the phosphorus tetrahedron is 90°. By assuming an overlap of wave functions, the angle of strain is 15°, i.e., $\frac{1}{2}(90° - 60°)$. The bond energy for a normal or unstrained bond is therefore $\bar{E}\sec.^2 15$ or 51·5 kcal. This gives a strain energy of 3·5 kcal. per P–P bond or 21 kcal.(mole $P_4$)$^{-1}$.[108] The observed bond angle for phosphorus is, however, very nearly 101° and from this a strain energy of 22·8 kcal. (mole $P_4$)$^{-1}$ has been calculated,[64] thus making $\bar{E} = 51{\cdot}8$ kcal. The strain energy has also been calculated to be 42 kcal.(mole $P_4$)$^{-1}$, i.e $\bar{E} = 55$ kcal.[109]

An estimated value of 53 kcal has been obtained for an unstrained P–P bond.[124]

This is based on the heat of sublimation of red phosphorus to diatomic vapour and is therefore not comparable with the values discussed above. It assumes that the $P_2$ molecule is triple-bonded. A thermochemical bond energy $\bar{E} = 46{\cdot}8$ kcal. has been obtained from the heat of formation (+5 kcal. mole$^{-1}$) of $P_2H_4$ and the P–H bond energy given in Table L.[349]

*Table LI.—Heats of Atomization of Elements at* 298°K.[302]

| Element | Standard state | $\Delta H_{\text{at.}}$ (kcal. per g. atom) | Element | Standard state | $\Delta H_{\text{at.}}$ (kcal. per g. atom) |
|---|---|---|---|---|---|
| Hydrogen | $H_2(g)$ | 52·09 | Chlorine | $Cl_2(g)$ | 28·94 |
| Carbon | graphite($c$) | 170·9 | Bromine | $Br_2(l)$ | 26·71 |
| Nitrogen | $N_2(g)$ | 112·9 | Iodine | $I_2(c)$ | 25·48 |
| Oxygen | $O_2(g)$ | 59·54 | Phosphorus | $P(c)$ | 75·5 |
| Fluorine | $F_2(g)$ | 18·5 | Sulphur | $S(c)$ | 57 |

Of the above values, that for sulphur is the only doubtful one.

*Table LII.—Thermochemical Data for Phosphorus Compounds*[344]

Notes: (a) $\Delta H^\circ_f$ for solid; (b) Estimated.

The heats of atomization used in deriving $\bar{E}$ values for some gaseous atoms are given in Table LI.

Thermochemical data for a number of phosphorus compounds are summarized in Table LII, at a temperature of 298°K.

Average values of the thermochemical bond energies ($\bar{E}$) have been calculated[344] for some tervalent organic phosphorus compounds. These were evaluated by deducting from the heat of formation of the compound the heat of formation of the organic group. The values so obtained are given in Table LIII.

*Table LIII.—Average Bond Energy Terms for Organo-phosphorus Compounds*[344]

| Compound | Bond | $\bar{E}$ (kcal. mole$^{-1}$) |
|---|---|---|
| $(CH_3O)_3P$ | P–O | 91 |
| $(C_2H_5O)_3P$ | P–O | 92 |
| $(iso\text{-}C_3H_7O)_3P$ | P–O | 92 |
| $(CH_3)_3P$ | P–C | 65 |
| $(C_6H_5)_3P$ | P–C | 71 |
| $[(CH_3)_2N]_3P$ | P–N | 70 |
| $[(C_2H_5)_2N]_3P$ | P–N | 67 |

Using the data given in Table LII the bond dissociation energy for the phosphoryl group P=O in a number of compounds has been evaluated.[344] This was done by considering heats of formation of compounds differing in composition by a single oxygen atom, or by using heats of reaction where direct oxidation reactions had been studied. The results are shown in Table LIV.

*Table LIV.—Average Bond Dissociation Energy of* P=O *in Phosphorus Compounds*[344]

| Compound | $D$(P=O) (kcal. mole$^{-1}$) |
|---|---|
| $P_4O_{10}$ | 138 |
| $POF_3$ | 130 |
| $POCl_3$ | 128 |
| $POBr_3$ | 125 |
| $PO(CH_3)_3$ | 139 |
| $PO(n\text{-}C_3H_7)_3$ | 138 |
| $PO(n\text{-}C_4H_9)_3$ | 137 |
| $PO(C_6H_5)_3$ | 128 |
| $PO(C_2H_5O)_3$ | 151 |
| $PO(iso\text{-}C_3H_7O)_3$ | 146 |
| $PO[(CH_3)_2N]_3$ | 139 |
| $PO(C_2H_5)_2N)_3$ | 156 |

A method of assigning bond energies in which allowance is made for changes in the environment of the bonds has been suggested.[344] On the basis that each P=O link involves one $\pi$ bond and each P–O link involves $\frac{1}{3}\pi$ bond, values of the average *in situ* bond energy $\bar{\epsilon}$(P=O) have been computed. These are summarized in Table LV.

Other procedures for calculating bond energies have been suggested,[372, 373] but these do not provide close agreement with known data. It has been reported that the bond moment, $\mu$, of a molecule can be expressed by the equation

$$\mu = C^2 er$$

where $e$ is the electronic charge, $r$ is the bond distance and

$$\frac{1}{C^2} = 1 - \left(\frac{H_t - E}{H_c - E}\right)$$

*Table LV.*—In situ *Bond Energies of Phosphorus Compounds*[344]

| Compound | *In situ* bond energy (kcal. mole$^{-1}$) | | | |
|---|---|---|---|---|
| | $\bar{\epsilon}$(P=O) | $\bar{\epsilon}$(P–O) | $\bar{\epsilon}$(P–Halogen) | $\bar{\epsilon}$(P–N) |
| $P_4O_{10}$ | 112 | 94·7 | — | — |
| $P_4O_6$ | — | 94·7 | — | — |
| $POF_3$ | 112 | — | 123 | — |
| $POCl_3$ | 108·5 | — | 82·5 | — |

| $PO[N(CH_3)_2]_3$ | 105 | — | — | 81 |
| $PO[N(C_2H_5)_2]_3$ | 105 | — | — | 84 |
| $PO(OC_2H_5)_3$ | 107·5 | 106·5 | — | — |
| PO(O-*iso*-$C_3H_7)_3$ | 107 | 105 | — | — |

where $E$ is the bond energy and $H_i$ and $H_c$ are the energies of the ideal ionic and ideal covalent bonds respectively.[374] Calculated values agree with those observed for P–Cl, but not for P–Br and P–I bonds.

The force constants $k_1$, $k_2$ and $k_3$ for the tetrahedral $P_4$ molecule have been calculated to be 2·08, −0·12 and 0·08 × 10$^5$ dynes cm.$^{-1}$, respectively.[375] These are based on the vibration frequencies $\nu_1 = 606$, $\nu_2 = 363$ and $\nu_3 = 468$ cm.$^{-1}$ corresponding to the relation

$$\nu_1{}^2 + 8\nu_2{}^2 = 6\nu_3{}^2$$

The value of $k_2$ is negative, in agreement with the idea of a restoring force for angular deformation.

## Bond Refraction

Data on the bond-refraction properties of phosphorus, based on experimentally determined molecular refractions of several trialkyl phosphites and phosphates, have been reported.[376] The bond refraction for the P=O group was found by subtracting the molecular refraction of a phosphite from that of the corresponding phosphate. The value for P–O bonds was derived from refraction data for the phosphites by subtracting the refraction due to other bonds in the molecule and dividing by three. For this purpose the following bond values were used:

C–H = 1·676, C–C = 1·296, C–O = 1·460

The average values of the bond refraction, $R_D$, obtained in this way are 3·18 for the P–O bond and −1·23 for the P=O bond, both referred to sodium *D* lines at 20°C. The bond refraction for P–C is 3·71 based on data for alkyl phosphines. The information for the individual molecules is summarized in Table LVI.

The bond refractions of these phosphorus bonds are considered[376] to be evidence supporting the formulation of the phosphoryl linkage, P=O, as a co-ordinate bond P → O.

There are numerous data on the density and refractive index of organic phosphorus compounds in the recent literature.[378, 381–92] This information may be used to calculate molar refractivities $R_D$ for the sodium *D*-line, according to the expression

$$R_D = \frac{n^2-1}{n^2+2} \cdot \frac{M}{d}$$

where $n$ is the refractive index, $M$ the molecular weight and $d$ is the density. The $R_D$ values can then be used to estimate the bond refraction for various phosphorus

*Table LVI.—Bond Refractions in Phosphorus Compounds*

| Compound | Density $d_4^{20}$ | Refractive index $n_D^{20}$ | Molar refraction | Bond refraction | | | | Ref. |

bonds. This is illustrated by the data given in Table LVII, which shows the bond refraction of the P=S bond as derived from data for trivalent phosphorus compounds and the corresponding thiophosphates.

These data give an average P=S bond refraction value of 6·5. Various summaries of the atomic, molecular and bond refractions for phosphorus have been given.[406–8] Representative values are shown in Table LVIII.

*Table LVIII.—Bond Refractions for Various Phosphorus Bonds*[408]

| Bond | $R_D$ | Bond | $R_D$ |
|---|---|---|---|
| P—H | 4·27 | P—S | 7·31 |
| P—C | 3·64 | P—Cl | 8·79 |
| P—N | 3·46 | P=Se | 9·95 |
| P—O | 3·12 | P—Br | 12·05 |
| P—F | 3·63 | P=S | 6·3 |
| P—Si | 5·29 | P=O | −1·22 |

Values of bond refractions for several non-phosphorus bonds have been reported.[409] These may be used in conjunction with the values in Table LVIII to estimate molar refractivities of phosphorus compounds for which experimental data are not available.

## MISCELLANEOUS PHYSICAL PROPERTIES

### Thermal Conductivity

The thermal conductivities of liquid and supercooled white phosphorus have been measured at temperatures up to 80°C., with the following results (Table LIX):

*Table LIX.—Thermal Conductivity of White Phosphorus*[410]

| Temp. (°C.) | Thermal conductivity $\lambda \times 10^3$ g.-cal. cm.$^{-1}$ sec.$^{-1}$ deg.$^{-1}$ |
|---|---|
| 16 | 1·0015 |
| 20 | 1·0130 |
| 25 | 1·1246 |
| 31 | 1·1980 |
| 33 | 1·2120 |
| 35 | 1·4160 |
| 36 | 1·4725 |
| 37 | 1·5293 |
| 40 | 1·6240 |
| 50 | 1·7820 |
| 60 | 1·9556 |
| 69 | 2·1985 |
| 80 | 2·3125 |

Later results for solid and liquid white phosphorus in the range 25–60°C., obtained by a similar method, are in broad agreement with the values in Table LIX. Simple 'quasi-lattice' theories predict thermal conductivities in good agreement with experimental values.[477]

The thermal conductivity of mono-, di and tetratomic phosphorus has been estimated for the ground state at 1 atm. pressure for temperatures from 100° to 5000°K. These calculations are based on the Lennard-Jones potential and the following equation:

$$\lambda = \frac{\eta R}{M}\left[3{\cdot}75 + 1{\cdot}32\left(\frac{C_p}{R} - \frac{5}{2}\right)\right]$$

where $\lambda$ is the thermal conductivity, $R$ is the gas constant, $C_p$ is the heat capacity, $M$ is molecular weight and $\eta$ is the viscosity in poises.[411] Selected values are given in Table LX.

*Table LX.—Thermal Conductivity of Phosphorus Vapour*[411]

| Temp. (°K.) | Conductivity $\lambda \times 10^6$ (g.-cal. cm.$^{-1}$ sec.$^{-1}$ deg.$^{-1}$) | | |

| 5000 | 236·5 | 154·0 | 178·3 |

## Viscosity

The viscosity of mono-, di- and tetratomic phosphorus has been calculated[411] from the expression

$$\eta = \frac{26{\cdot}693\sqrt{MT}}{\sigma^2 \Omega}$$

where $\eta$ is viscosity in poises, $M$ is molecular weight, $T$ is absolute temperature, $\sigma$ the collision diameter in Ångström units and $\Omega$ is the reduced collision integral. Values of the last parameter have been tabulated.[412] Selected viscosity data are given in Table LXI.

## Electronegativity and Bond Properties

Values of bond distances, bond energies and electronegativity differences quoted by Van Wazer[50] are given in Table LXII. The bond energy values should be compared with the more recent values discussed on pages 204–208 above.

The force constant for the P–H bond is reported to be $3{\cdot}10 \times 10^5$ dynes cm.$^{-1}$ [413]

## Spectroscopic Properties

The residual ray or reststrahlen frequency of phosphorus has been calculated[414] from Lindemann's equation

$$\nu = 2{\cdot}8 \times 10^{12} \sqrt{\frac{Tm}{MV^{2/3}}}$$

*Table LXI.—Calculated Viscosity of Phosphorus Vapour*[411]

| Temp. (°K.) | Viscosity $\eta \times 10^6$ (poises) | | |
|---|---|---|---|
| | P | $P_2$ | $P_4$ |
| 200 | 45 | 45·1 | 49·6 |
| 300 | 64·8 | 64·9 | 71·0 |

| P–I | 2·38 | 2·420 | 48 | 0·50 |

where $T_m$°K. is the melting point, $M$ is molecular weight and $V$ is molecular volume. $\nu$ must be divided by the velocity of light to convert it to a frequency in wave-numbers. The value of $\nu$ is given as 27·5 cm.$^{-1}$ as compared with an observed value of 36 cm.$^{-1}$ However, although the calculated value appears to apply to monatomic phosphorus, it is not clear whether the calculation applies to white or red phosphorus. Also, the figure 27·5 cm.$^{-1}$ does not agree with those previously reported (Mellor, I, 829) for either variety of phosphorus, even when allowance is made for the factor $3{\cdot}08 \times 10^{12}$ instead of $2{\cdot}8 \times 10^{12}$. If the calculation is made for tetratomic white phosphorus a frequency of 36·6 cm.$^{-1}$ is obtained.

Molecular vibration frequencies have been calculated[415] for the $P_2$ and other diatomic molecules containing phosphorus, using the equation

$$\nu(\text{cm.}^{-1}) = 3959{\cdot}4 \sqrt{\frac{K}{\mu r^3}}$$

where $\mu$ is the reduced mass in atomic mass units, $r$ is the interatomic distance in A. and $K$ is a constant. The calculated and observed values are given in Table LXIII.

*Table LXIII.—Calculated and Observed Molecular Frequencies of Diatomic Phosphorus Molecules*[415]

| Molecule | $K$ | $r$(A.) | $\nu$ (cm.$^{-1}$) | |
|---|---|---|---|---|
| | | | Calculated | Observed |
| $P_2$ | 3·670 | 1·894 | 739 | 780 |
| PC | 3·345 | 1·562 | 1261 | 1240 |
| PN | 3·345 | 1·491 | 1281 | 1337 |
| PO | 3·345 | 1·449 | 1279 | 1231 |

A relation between the energy of the ground state of the $P_4$ molecule and the temperature of melting has been discussed with reference to the hole theory of liquids.[416]

## Parachor and Thermochor

The average value of the atomic parachor of phosphorus was given originally as 37·7.[417] Later values have been given as 39·2[418] and 40·5,[419] of which the last appears to be the more generally accepted.[420] On the assumption that bond constants in a molecule should remain unchanged and that the parachor alters with the valency state of an atom, values of 37·1 and 18·3 respectively have been calculated for the atomic parachor of trivalent and pentavalent phosphorus.[421] Similar values were obtained by comparing atoms in the same iso-steric state, i.e., containing equal numbers and kinds of complete electron shells, lone pairs and bonding electrons.[422]

Much higher values, 73·5[423] and 70·5,[424] have been reported for the atomic parachor. These values are based on the observation[423] that, for elements of the same electron configuration around the central nucleus, an increase of one unit in the positive charge on the nucleus lowers the atomic parachor by a constant amount of 5·7. Molecular parachor values may be calculated from atomic parachors by simple addition and subtracting 19 for every bond in the molecule, irrespective of whether this is a single, double, triple or a co-ordinate bond. Parachor values derived in this way for phosphorus compounds are somewhat nearer the observed parachors than those calculated according to the procedure of Sugden. The $P_4$ molecule, however, gives a value of 170[425] as compared with the observed figure of 204·8.[234, 235]

Several other methods of calculating the parachor of the $P_4$ molecule have been examined. The molecular volume $V$ of $P_4$ at absolute zero is 61·6 ml.[175] and the relationship $V = 0{\cdot}346\,P$ gives a value of 178 for the parachor, $P$.[425]

By eliminating the surface tension term in the Sugden equation[426]

$$P = \frac{M\gamma^{1/4}}{D-d}$$

and a modified Eötvös equation[427]

$$\gamma\left(\frac{M}{D-d}\right)^{2/3} = k(T_c-T)$$

the equation

$$\left(\frac{D-d}{M}\right)^{10/3} P^4 = k(T_c-T)$$

is obtained, where $M$ is molecular weight, $T_c$ is critical temperature in °K., $T$ the temperature at which the parachor is determined, $D$ and $d$ are the densities of liquid and gas, respectively, and $k$ is a constant. This constant $k$ has a value of 2·09 for spherical or near-spherical unassociated molecules. A plot of $(D-d)^{10/3}$ against $T$ gives a straight line of slope $-kM^{10/3}/P^4$ from which the parachor can be easily calculated. Using published values[176, 177] for the density of liquid white phosphorus between 45° and 80°C. a parachor value of 205·9 is obtained.[425] Density measurements at temperatures between $-195°$ and $+40°$C.[175, 178] for solid phosphorus give 203·2 for the parachor.

The expression[425]

$$P = 2{\cdot}09^{1/4}\, T_c^{1/4} V_0^{5/6}$$

where $T_c$ is the critical temperature (968°K.) and $V_0$ is the molecular volume of the $P_4$ molecule at 0°K. (61·6 ml.) gives a parachor of 208. The compressibility $X$ is related to the parachor by the equation[428]

$$P = \frac{M}{21(D-d)\, X^{1/6}}$$

where $M$ is the molecular weight. Using a compressibility of $20{\cdot}3 \times 10^{-12}$ cm.$^2$ dyne$^{-1}$ for white phosphorus (Mellor, VIII, 759), the parachor is 197.

The term 'thermochor' has been proposed[429] for the property given by the equation

$$[T] = V^{5/6} T^{1/4}$$

where $[T]$ is the thermochor and $V$ is the molecular volume at the boiling point, $T$°K.; the parachor is 1·055 times the thermochor. These relationships give a parachor of 199·5 for white phosphorus.[430]

## Molecular and Critical Volumes

The density of liquid phosphorus at 580° to 680°C. is given in Table LXIV.

*Table LXIV.—Density of Liquid Phosphorus at High Temperature*[431]

| Temp. (°C.) | Density (g. ml.$^{-1}$) |
|---|---|
| 580 | 1·16 |
| 600 | 1·12 |
| 620 | 1·09 |
| 640 | 1·07 |
| 650 | 1·04 |
| 680 | 0·96 |

The molecular volume of the $P_4$ molecule, based on the above data, varies as shown in Fig. 16, which also includes data for red and black phosphorus.[431] The volume expansion of red phosphorus on melting is unusually large. This indicates a complete change in the structure on melting.[432] The figures give a critical volume of 133 ml. for the $P_4$ molecule at a critical temperature of 695°C.

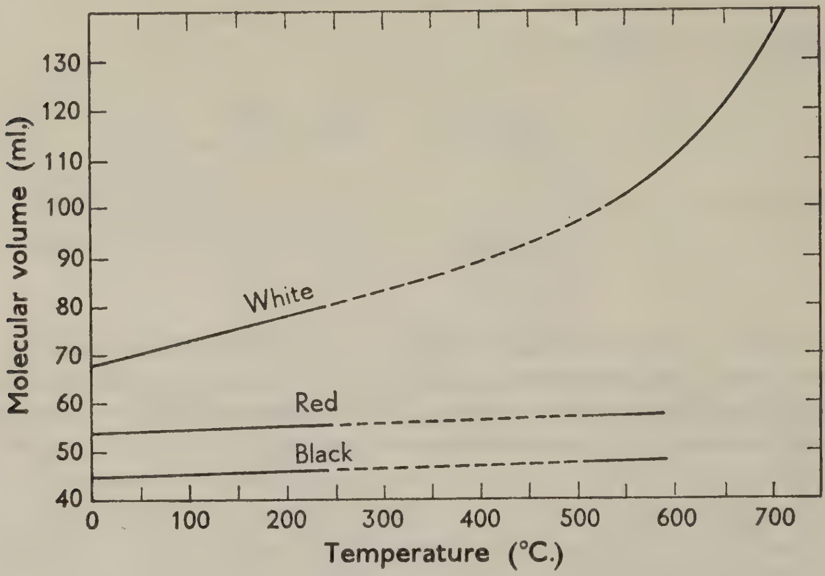

FIG. 16.—Molecular volume of phosphorus

## Other Properties

The velocity of condensation of phosphorus vapour on the solid is a linear function of the temperature difference between the solid and vapour. The rates of condensation

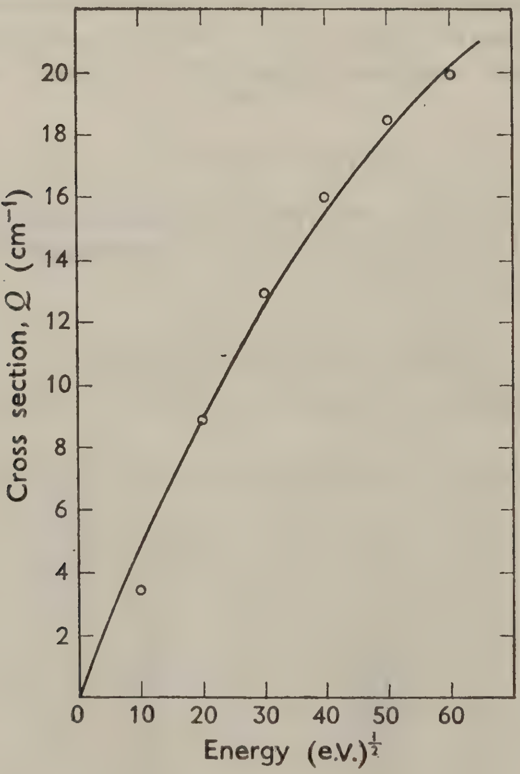

FIG. 17.—Detachment cross-section of $P^-$ ions

in mm. hr.$^{-1}$ are 0·0015, 0·0060, 0·025 and 0·030, respectively, for temperature differences of 0·037°, 0·15°, 0·45° and 0·76°C.[433]

The detachment cross-section $Q$ cm.$^{-1}$ for inelastic collisions, in a neon atmosphere, between negative ions and atoms of phosphorus according to the equation

$$P^- + Ne \rightarrow P + Ne + e - 0{\cdot}3 \text{ e.v.}$$

has been measured[434] with the results shown in Fig. 17.

Phosphorus depresses the freezing point of the platinum metals and a eutectic phase has been observed in rhodium– and ruthenium–phosphorus alloys containing 0·5% P.[435]

Red phosphorus inhibits the rapid crystallization of amorphous sulphur at room temperature. Measurements of the elasticity of sulphur stabilized with 0·8 to 10% of phosphorus indicate a molecular weight of between 18,000 and 73,000 for the $\mu$-phase.[436]

## THE ATOMIC WEIGHT OF PHOSPHORUS

The early work on the atomic weight of phosphorus has previously been discussed (Mellor, VIII, 801). In 1925 the International Union of Pure and Applied Chemistry adopted an atomic weight of 31·027 for phosphorus[437] (oxygen 16). This was based on values of 31·04, 31·027 and 31·018 derived from the ratios $3AgBr:Ag_3PO_4$, $3AgBr:PBr_3$ and $3AgCl:PCl_3$, respectively.[438–40] This value was accepted by the American Chemical Society,[441] but was changed to 31·02 in 1929 because the third decimal place was considered unreliable.[442] The same view was taken by the German Chemical Society.[443]

In the same year, the British Chemical Society considered that the best value for phosphorus was 30·982, the last figure being somewhat uncertain.[444] This value was based largely on measurements made by Aston using the mass spectrograph.[21, 445–6] Observations on the compressibility and density of phosphine confirmed this, giving an atomic weight of 30·977.[447] The reproducibility of this was estimated to be 1 part in 10,000.[448]

The discovery of the isotopes of oxygen in 1929[449–50] resulted in the adoption of two atomic weight scales. On the physical scale, atomic weights were referred to the $^{16}O$ isotope of mass exactly 16. On the chemical scale the standard was naturally-occurring oxygen, the atomic weight of which was defined as 16·0000. Because of the existence of isotopes of masses 16, 17 and 18 in naturally-occurring oxygen, its atomic weight is greater than 16. Consequently, atomic weights based on 'chemical' oxygen are smaller than those referred to 'physical' oxygen. These two scales required the use of a conversion factor derived from measurements of the relative abundance of the three isotopes in naturally-occurring oxygen. For a number of years there was uncertainty as to the magnitude of this factor and some confusion arose over atomic weight values on the two scales. Babcock[451] and Naudé[452] obtained a conversion factor of 1·000125, a value used later by the International Union of Chemistry.[453–4] Mecke and Childs[455] found that the ratio $^{16}O:^{18}O:^{17}O$ was 630:1:0·2 which gave $16{\cdot}0035 \pm 0{\cdot}0003$ for the atomic weight of chemical oxygen and a conversion factor of 1·00022. The ratio $^{18}O:^{17}O = 5:1$ was generally accepted, but the $^{16}O:^{18}O$ ratio was reported to have various values. Aston[456] obtained an approximate value of 536:1 which gives an oxygen atomic weight of 16·0041 and a conversion factor of 1·000256. A later measurement[457] gave a ratio of $(514 \pm 13):1$, corresponding to $O = 16{\cdot}0043$ and a conversion factor of 1·00027. What are probably the most reliable data[458] give the isotopic composition of oxygen as $^{16}O$ 99·76%, $^{17}O$ 0·04% and $^{18}O$ 0·20%. Allowing for the packing fractions,[459] $^{17}O = +2{\cdot}7 \times 10^{-4}$ and $^{18}O = +2{\cdot}1 \times 10^{-4}$, the atomic weight of chemical oxygen is 16·00441 which gives a conversion factor of 1·000275. This value has been accepted since 1938.[460]

During the decade following 1929 evidence accumulated,[461–2] which showed that the value of 31·02 for the chemical atomic weight of phosphorus was too high. Spectrographic measurements indicated a chemical atomic weight of 30·9844[463] or

Refs. p. 218

30·9836 ± 0·0006.[464] A chemical determination of the ratios $POCl_3$:3Ag and $POBr_3$:3Ag gave atomic weights of 30·978[465–6] and 30·974,[467] respectively, but the latter value was considered to be slightly less certain. A chemical atomic weight of 30·98 was adopted by the International Union of Chemistry in 1939[468–9] and 30·975 in 1951.[470]

Owing to the greater precision in determining atomic weights by spectrographic and similar procedures, and for other reasons, the International Union of Pure and Applied Physics in 1960[471] adopted an atomic weight scale based on $^{12}C = 12{\cdot}0000$. On this basis the atomic weights of phosphorus and naturally-occurring carbon and oxygen are 30·9738, 12·01115 ± 0·00005 and 15·9994 ± 0·00010, respectively.[471–2] The uncertainty in the values for oxygen and carbon is caused by variations in the isotopic compositions of these elements.

With the new atomic weight scale the differentiation into 'physical' and 'chemical' atomic weights no longer applies. A factor is required, however, for converting atomic weights on the old physical scale to those based on the $^{12}C$ scale. This factor is calculated as follows:

On the old physical scale, which is based on $^{16}O = 16{\cdot}0000$, the atomic weight of the $^{12}C$ isotope of carbon is 12·0038150.[20, 24, 48] Dividing this by 12 gives the divisor $1{\cdot}000317917 \pm (17 \times 10^{-9})$ by which the physical atomic weights must be divided to convert them to the $^{12}C$ scale.[471–2] Chemical atomic weights reported since 1939 must be multiplied by 1·000275 before carrying out the above conversion.

It should be noted that the atomic weight of carbon was revised when the change to the $^{12}C$ scale was made, the new value being 12·01115 ± 0·00005.[471] This was due to the observation that naturally-occurring carbon contained between 1·1088% and 1·1151% of the $^{13}C$ isotope,[473] and the mass of this isotope is 13·003354 on the $^{12}C$ scale.[20, 24]

The new atomic weight of oxygen (15·9994) was derived from the isotopic composition of 99·7587% of $^{16}O$, 0·0374% of $^{17}O$ and 0·2039% of $^{18}O$ for naturally-occurring oxygen.[474] On the $^{12}C$ scale the isotopic masses are[48] 15·994915 for $^{16}O$, 16·999134 for $^{17}O$ and 17·999160 for $^{18}O$.

## SECTION V

# THE CHEMICAL PROPERTIES OF PHOSPHORUS

BY D. R. PECK

Phosphorus forms binary compounds with all the other elements with the exception of the inert gases of the helium group, antimony, bismuth and possibly a few of the rare earths. For these elements either compounds with phosphorus have not been reported, or their existence is doubtful.

The reactions of phosphorus with oxygen and with the halogens are spontaneous at room temperature and highly exothermic. At temperatures below about 250°C. vigorous reactions occur with sulphur and the alkali metals. Phosphides are formed with metallic elements, usually by heating with phosphorus vapour or with red phosphorus. In some of these reactions, e.g. with iron, nickel, copper or platinum, the reacting mass may become incandescent.[1]

Helium is the only inert gas for which any evidence of reaction with phosphorus has been reported. At liquid-air temperatures, under the influence of electron bombardment, helium is absorbed by, or forms an interstitial compound with, phosphorus. The product decomposes suddenly at $-125$°C. with evolution of helium.[2]

## THE REACTIONS OF PHOSPHORUS WITH NON-METALLIC ELEMENTS

### Hydrogen and its Isotopes

Hydrogen is one of the least reactive of the non-metals in that it does not combine directly with phosphorus at normal temperatures and pressure. Atomic hydrogen, however, readily converts phosphorus into phosphine.[3]

The PH molecule does not exist at room temperature but a band at 3400 A., corresponding to a $^3\Pi \rightarrow {}^3\Sigma$ transition, has been observed in the spectra of mixtures of hydrogen and phosphorus vapour.[4-7] The emission spectrum of the $PH^+$ molecule has been observed in a cathode discharge through helium containing phosphorus vapour and hydrogen.[8]

There is no reaction between red phosphorus and hydrogen at 400°C. and only small amounts of phosphine are formed at 550°C.[9] The equilibrium between hydrogen and phosphorus under pressure has been studied,[10] some phosphine being obtained by heating the elements in a closed tube at 360°C.[11] However, very high pressures are necessary to obtain any significant yield of phosphine.[12] From the experimental data the following results have been calculated[13-4]:

$$\begin{aligned} P_4 + 6H_2(g) &= 4PH_3(g) & \Delta H_0^\circ &= 1530 \text{ g.-cal.} \\ P_{(\text{white})} + \tfrac{3}{2}H_2(g) &= PH_3(g) & \Delta G_{298}^\circ &= -3140 \text{ g.-cal.} \end{aligned}$$

The heat of formation of phosphine is uncertain (see Section VI) and $\Delta H_0^\circ = 1530$ g.-cal. is an estimated 'best' value. Using a free energy $\Delta G_{298} = -18{,}370$ g.-cal. for the first of the above reactions, values of the equilibrium constant

$$K = \frac{P_{PH_3}^4}{P_{P_4} \cdot P_{H_2}^6}$$

shown in Table I have been reported.[13]

*Table I.—Equilibrium Constant, $K_{\text{atm.}}$, for the Reaction* $P_4+6H_2(g) = 4PH_3(g)$

| Temp. °K. | Equilibrium constant $K_{\text{atm.}} \times 10^{12}$ |
|---|---|
| 627 | 10 |
| 677 | 5·6 |
| 731 | 2·5 |
| 771 | 1·9 |

Values of $\Delta H°$, $\Delta G°$, $\Delta S°$ and $K_{\text{atm.}}$ for this reaction are given in Table II.

*Table II.—Thermodynamic Properties of Phosphine*[15]

| Temp. °K. | $-\Delta H°$ g.-cal.mole$^{-1}$ | $\Delta G°$ g.-cal.mole$^{-1}$ | $-\Delta S°$ g.-cal.mole$^{-1}$ deg.$^{-1}$ | $K_{\text{atm.}} \times 10^{10}$ |
|---|---|---|---|---|
| 298·1 | 4,300 | 11,590 | 53·3 | 32 |
| 400 | 6,390 | 17,330 | 59·3 | 3·4 |
| 600 | 9,540 | 29,940 | 65·8 | 0·12 |
| 800 | 11,340 | 43,380 | 68·4 | 0·014 |
| 1000 | 12,040 | 57,260 | 69·3 | 0·0031 |
| 1200 | 11,920 | 71,120 | 69·2 | 0·0011 |

Values of the equilibrium constants $K_{\text{I}}=p_{P_4}^{1/4}\cdot p_{H_2}^{3/2}/p_{PH_3}$ for the dissociation

$$PH_3 \rightarrow \tfrac{1}{4}P_{4(\text{vap.})}+\tfrac{3}{2}H_2 \quad (K_{\text{I}} = K^{-0\cdot 25})$$

and $K_{\text{II}}=p_{H_2}^{3/2}/p_{PH_3}$ for the dissociation $PH_3 \rightarrow \frac{1}{4}P_{4(\text{solid})}+\frac{3}{2}H_2$, are given by the equations[309]

$$\begin{aligned} \log_{10} K_{\text{I}} &= -275/T+2{\cdot}46 \log_{10} T-4{\cdot}0\times 10^{-4}T-3{\cdot}74 \\ \log_{10} K_{\text{II}} &= 387/T+0{\cdot}272 \log_{10} T+1{\cdot}32\times 10^{-3}T \\ (T &= 300\text{–}1300°\text{K.}) \end{aligned}$$

For the reaction $\frac{1}{4}P_4(\alpha\text{-white})+\frac{3}{2}H_2=PH_3(g)$ the following values have been calculated[15] for 25°C. and 1 atm.:

$$\Delta H_f^\circ = 2{\cdot}29 \text{ kcal.} \qquad \Delta G_f^\circ = 4{\cdot}34 \text{ kcal.}$$
$$\Delta S_f^\circ = -6{\cdot}88 \text{ g.-cal./deg./mole}$$

Some thermodynamic data for phosphine vapour are given in Table III.

*Table III.—Thermodynamic Properties of Phosphine Vapour*[15]

| Temp. °K. | $H°-H_0^\circ$ g.-cal./mole | $-(G°-H_0^\circ)/T$ g.-cal./mole/deg. | $S°$ g.-cal./mole/deg. |
|---|---|---|---|
| 298·1 | 2,420 | 42·10 | 50·22 |
| 400 | 3,390 | 44·54 | 53·02 |
| 600 | 5,610 | 48·13 | 57·48 |
| 800 | 8,220 | 50·95 | 61·23 |
| 1000 | 11,160 | 53·34 | 64·50 |
| 1200 | 14,360 | 55·45 | 67·42 |
| 1400 | 17,670 | 57·34 | 69·96 |
| 1500 | 19,400 | 58·24 | 71·17 |

The formation of phosphine by the hydrolysis of phosphorus is discussed below. Its preparation by the reaction of phosphides or phosphonium halides with water, and by the thermal decomposition of the lower oxyacids of phosphorus, is described in Section VI (page 272).

Other hydrides of phosphorus have been reported but none of these is formed by direct combination of the elements. The best characterized of these is diphosphine, $P_2H_4$, a water-white liquid,[16] m.p. $-98$°C. and b.p. 51·7°C.[17] Yellow to red solids, corresponding empirically to $P_2H$, $P_5H_2$ and $P_9H_4$, have been described. These compounds result from the decomposition of diphosphine under anhydrous conditions in a sealed system at room temperature. Moisture stabilizes the composition of the product at $P_{12}H_6$.[16] The latter is a yellow powder,[18] stated to be an adsorption compound of phosphine on yellow amorphous phosphorus, formed by the reaction:

$$3P_2H_4 = 4PH_3 + 2P$$

in which 16–20% of the phosphine is adsorbed.[19] The formula has been given as $2PH_3,10P$.[20]

Solid hydrides have been reported to be formed when an electric discharge is passed through a mixture of argon, hydrogen and phosphorus at 25° to 100°C. under pressures of 1 mm.[21] Solid products of formula $(PH)_x$ result from the decomposition of lithium phosphide, LiP, by water[22] or from the reaction of ether solutions of phosphorus trichloride or tribromide and lithium hydride, aluminium hydride or lithium aluminium hydride[23] at temperatures between 0° and $-115$°C.

Liquid polymeric hydrides or phosphanes are said to exist and for these ring $P_nH_n$ or chain $P_nH_{n+2}$ structures are suggested, as well as others ($P_nH_{n-2}$, $P_nH_{n-4}$, etc.) less readily explicable in classical structural terms.[310–2] When heated in nitrogen at 300°C. in the presence of quartz, the chain compounds decompose according to the equation[24]:

$$3P_nH_{n+2} = (n+2)PH_3 + (2n-2)P$$

Deuterium compounds of phosphorus have been prepared, mainly for examination of their spectra. The deuterium analogue of phosphine, $PD_3$, is made by decomposing calcium phosphide with deuterium oxide[25]:

$$Ca_3P_2 + 6D_2O = 2PD_3 + 3Ca(OD)_2$$

or by the reaction of deuterium oxide with phosphorus triiodide.[26] The compound $PH_2D$ has been obtained in an exchange reaction between phosphine and deuterium at temperatures between 20° and 600°C. under pressures of 100–500 mm.:

$$PH_3 + HD \rightleftharpoons PH_2D + H_2$$

The calculated equilibrium constant for this reaction is 1·37 at 0°C. and 1·05 at 700°C.[27] The free radicals $PH_2$ and $PD_2$ have been identified in absorption spectra resulting from the flash photolysis of phosphine and $PD_3$, respectively.[26] The compounds $PHD_2$ and $PH_2D$ have been obtained by equilibrating phosphine with water and deuterium oxide.[28] Deuterio–diphosphine, $P_2D_4$, has been made by reacting calcium phosphide with deuterium oxide.[29] The infra-red and Raman spectra have been examined.[30, 29] Fractional distillation of this material leaves a residue of $P_3H_5$ and other chain $P_nH_{n+2}$ compounds.[24]

Thermodynamic functions have been calculated for $PH_2D$, $PHD_2$,[31–2] $PH_2T$, $PHT_2$,[31] $PD_3$,[33–4] $PT_3$,[35] $PD_2T$ and $PDT_2$,[31] with the results shown in Tables IV–VI. All values are given in g.-cal./deg./mole and refer to the ideal gas state at 1 atm. pressure. Data for phosphine,[33] obtained by the same method of calculation, are given for comparison. Further data for $PH_2D$, $PHD_2$, $PH_2T$, $PHT_2$, $PDT_2$ and PHDT have been reported subsequently.[313] Spectroscopic and other data for some of these compounds have been reported.[25, 28, 36–7]

## Boron and Carbon

Red phosphorus and amorphous boron react to form boron phosphide, BP, when heated in a sealed silica tube at 1100° to 1200°C.[38] The pressure is 1–2 atm.[39] The heat of formation from boron and phosphorus:

$$B_{(c)} + P_{(white)} = BP_{(c)}$$

is

$$\Delta H^\circ_{298} = -19{,}900 \text{ g.-cal./mole}$$[40]

The formation of boron phosphide at temperatures up to 10,000°C. and pressures of 15,000 atm. has been studied.[41]

At 1000°C. under 1 mm. pressure, boron phosphide decomposes to form a lower phosphide, $B_{13}P_2$.[42–3] This compound was previously formulated as $B_5P_3$[44] and $B_6P$,[40] both of which appear to be incorrect.[43]

Phosphorus and carbon combine at high temperatures to form the CP molecule[45] which is identified by its band spectrum.[46] Thermodynamic functions for the molecule in the ideal gas state at 1 atm. pressure are given in Table VII. These were calculated from spectroscopic data by statistical mechanical methods. The heats of formation at 0°K. and 25°C., referred to the $\beta$-form of white phosphorus at 0°K. as standard, are $\Delta H^\circ_0 = 107{,}380$ g.-cal./mole and $\Delta H^\circ_{298\cdot15} = 107{,}940$ g.-cal./mole.[47] A yellow carbide, $P_2C_6$, has been reported.[48]

## Nitrogen

Previous references to the reaction between phosphorus and nitrogen (Mellor, VIII, 122–3) described compounds having P/N mole ratios between 0·6 and 1·1. Yellow phosphorus and nitrogen under the influence of an electric discharge of 4000–15,000 volts at less than 200 mm. pressure give a material having the empirical composition PN. At pressures of less than 20 mm. some red phosphorus is formed and this interferes with the reaction.[49] Phosphorus nitrides have also been obtained using a silent electrical discharge.[50] At 250°C. in the presence of nickel oxide and platinized asbestos as catalyst $P_3N_5$ is said to be formed in this way.[51] At 800°C. it decomposes to give phosphorus and nitrogen, and reacts with water according to the equation[51]:

$$P_3N_5 + 12H_2O = 3H_3PO_4 + 5NH_3$$

The products obtained from an electrical discharge are usually amorphous, but by heating these *in vacuo* or in a stream of nitrogen or ammonia a crystalline product,

$P_3N_5$, is obtained.[52] At about 750°C. *in vacuo*, this material decomposes according to the equation[53]:

$$P_3N_5 = 3PN + N_2$$

The crystalline pentanitride appears to have been confused originally with a polymeric form of the mononitride, $(PN)_n$,[52, 54] obtained by heating phospham, $PN_2H$, *in vacuo* at 450° to 720°C.

The mononitride or its polymeric form is readily obtained by passing phosphorus vapour and nitrogen, at about 1 atm. total pressure, through an electric arc of several thousand volts between tungsten electrodes. As an alternative the gases can be heated at 400° to 500°C. and passed over a tungsten wire heated electrically to about 1500°C.[55] The reaction was originally given as:

$$nP_2(g) + nN_2(g) \rightleftharpoons 2nPN(g) \rightleftharpoons 2(PN)_n(s)$$

but it was later found that at temperatures above 800°C. the nitride is completely dissociated into its elements[56]:

$$(PN)_n \xrightarrow{450°C.} PN \xrightarrow{800°C.} P + N$$

From a calculation of the equilibrium constant[57] the reaction:

$$P_2(g) + N_2(g) = 2PN(g)$$

was found to be favourable for the synthesis of the mononitride at 600° to 800°C. The relevant data are shown in Table VIII and Table IX.

*Table VIII.—Thermodynamic Properties of the* PN *Molecule in the Ideal Gas State at* 1 *atm.*[57]

| Temp. °K. | $C_p$ g.-cal./mole | $S$ g.-cal./mole/deg. | $H-H_0$ g.-cal./mole | $-(G-G_0)$ g.-cal./mole |
|---|---|---|---|---|
| 100 | 6·9544 | 42·824 | 694·6 | 3588 |
| 298·1 | 7·0973 | 50·448 | 2079·1 | 12959·8 |
| 500 | 7·6474 | 54·235 | 3565·1 | 23553·6 |
| 750 | 8·1759 | 57·450 | 5546·6 | 37538·7 |
| 1000 | 8·4774 | 59·842 | 7633·8 | 52209·0 |

*Table IX.—Equilibrium Constants for the Reaction* $P_2(g) + N_2(g) = 2PN(g)$[57]

| Temp. °C. | $K_p e^{+\Delta E_0/RT}$ | $e^{-\Delta E_0/RT}$ | $K_p$ atm. |
|---|---|---|---|
| 800 | 6·09 | 7·87 | 47·9 |
| 900 | 5·94 | 6·58 | 39·1 |
| 1000 | 5·82 | 5·68 | 33·1 |

The above calculation does not agree with the experimental results[56] but the discrepancy can be accounted for by a difference of only a few tenths of an electron-volt in the dissociation energy, $E_0$, of PN.

An investigation into the rate of reaction of the hot-wire synthesis has been made.[58] When equi-atomic mixtures of nitrogen and phosphorus are heated for 42 hr. at 900°C. or for 44 hr. at 950°C. and then quenched at 500°C., no nitrogen is found in the condensed product. Measurements of the degree of dissociation of phosphorus nitride (31·36% N, 67·60% P) at 900°C. give a dissociation energy of 7·1 ± 0·05 e.v.

per PN mole. The equilibrium constant, $K_{\text{atm.}}$, was $10^{-2}$ at 900°C. and 0·20 at 2000°C., giving an average heat of reaction of 14·2 kcal. for the reaction:

$$P_2 + N_2 = 2PN$$

The rate of decomposition of PN is shown in Fig. 1, from which the activation energy of decomposition is 24 kcal./mole. Adding the activation energy of synthesis (7 kcal./mole) gives an apparent activation energy of 31 kcal./mole for the homogeneous synthesis of the PN molecule. This indicates that neither free phosphorus atoms nor free nitrogen atoms represent the activated state or enter into the formation of PN from its elements.

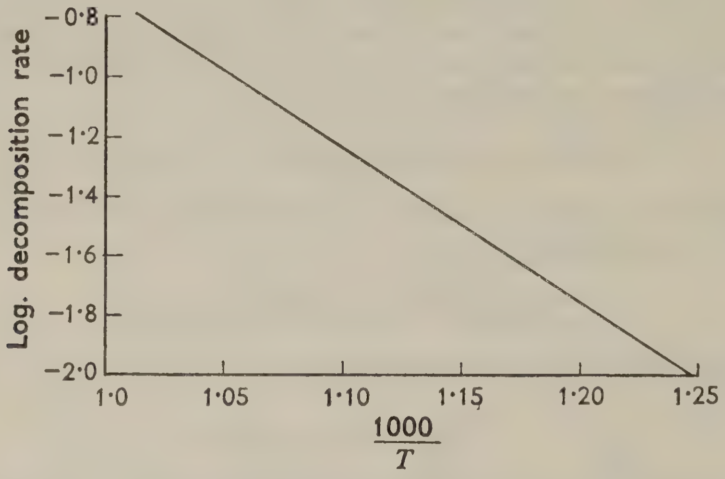

FIG. 1.—Rate of decomposition of PN at 800° to 1000°C.

Observations of the rate of synthesis[58] from phosphorus vapour and nitrogen at atmospheric pressure in the presence of tungsten as catalyst gave a rate constant which agreed with the expression $-\mathrm{d}C_{P_2}/\mathrm{d}t = kC_{P_2}^{1/2}$, where $C_{P_2}$ is the concentration of $P_2$ molecules in moles/c.c. Some data are given in Table X where $k$ is in units of moles$^{1/2}$ c.c.$^{1/2}$ sec.$^{-1}$ cm.$^{-2}$

*Table X.—Rate Constants for the Tungsten-catalyzed Reaction* $P_2 + N_2 = 2PN$ *at Constant Pressure*[58]

| Temp. °C. | Rate constant in moles$^{1/2}$ c.c.$^{1/2}$ sec.$^{-1}$ cm.$^{-2}$ |
|---|---|
| 2080 | $1{\cdot}9 \times 10^4$ |
| 2097 | $2{\cdot}0 \times 10^4$ |
| 2165 | $3{\cdot}5 \times 10^4$ |
| 2212 | $3{\cdot}8 \times 10^4$ |

These data give an activation energy of 59 kcal./mole PN for the catalyzed reaction at temperatures above 1800°C. Since the dissociation energies at 0°K. for $P_2$ and $N_2$ are 58 kcal./g.-atom and 112 kcal./g.-atom respectively, the rate controlling process is the catalyzed dissociation of diatomic phosphorus. This may involve the adsorption of $P_2$ molecules on the tungsten, followed by release from the catalyst surface of phosphorus atoms, which then react with the nitrogen in the gas phase.

A polymerized nitride, $(PN)_n$, is formed when active nitrogen reacts with phosphine at 80° to 290°C. The suggested mechanism is[59]:

$$N + PH_3 = PH_2 + NH$$
$$PH_2 + N = PN + H_2$$

Addition of phosphorus trichloride to liquid ammonia in the presence of nitrogen at $-78$°C. is reported[60] to give an amorphous, pale yellow product having a composition corresponding to PN.

Thermodynamic functions for the PN molecule have been calculated[47] with the results shown in Table XI. The data are for the ideal gas state at 1 atm. The heats of formation at 0°K. and 25°C. referred to the $\beta$-form of white phosphorus are $\Delta H_0 = 22{,}020$ g.-cal./mole and $\Delta H_{298} = 21{,}790$ g.-cal./mole.

Phosphorus–nitrogen compounds, such as $P_2NH_3$,[61] $P_4N_6$,[62] $P_3N_5$[63–5] and $P_4(NH_3)$,[65] which are not formed by direct combination, have been described.[66] The properties of these compounds have been discussed in some detail.[66–9] Sections VIII, XI and XVIII should also be referred to.

## Oxygen

White phosphorus combines spontaneously and exothermically with oxygen, and with excess of oxygen forms the pentoxide. Since the discovery of this reaction by Robert Boyle in 1680, oxides with the empirical formulae $P_4O$, $P_2O$, $P_2O_3$, $P_2O_5$ and $P_2O_6$ have been reported[66] (Mellor, VIII, 866), as well as two mixed oxide systems of variable stoicheiometry between $P_4O_{7\cdot7}$ and $P_4O_{9\cdot2}$.[314]

The diatomic molecule PO is unstable under ordinary conditions, but has been identified in band spectra of its vapour.[70–3] Thermodynamic functions for the ideal gas state at 1 atm. pressure have been calculated and are shown in Table XII.[47, 74] The heats of formation at 0°K. and at 298°K. referred to $\beta$-white phosphorus as standard state are $\Delta H_0^\circ = -5710$ g.-cal./mole and $\Delta H_{298\cdot15}^\circ = -5780$ g.-cal./mole. The dissociation energy has been variously given as 5·4 e.v. (125 kcal./mole),[73] 6·07 e.v. (140 kcal./mole)[75] and 6·2 e.v. (143 kcal./mole).[76]

The PO molecule has been observed in the vapour above melts of sodium tripolyphosphate, $Na_5P_3O_{10}$, at temperatures above 700°C.[77]

A number of products exist which are generally referred to as lower oxides of phosphorus. These vary in colour from yellow to red and contain oxygen, possibly hydrogen, and a high percentage of phosphorus. In the earlier literature (Mellor, VIII, 866) there are reports of compounds of the formula $P_4O$[78] and $P_2O$.[79] These have been said[80] to be mixtures of simple compounds, but it is probable that they are complex materials containing P–O, P–P and P–H bonds. $P_4O$ is reported to be present in the reaction products of phosphorus trichloride and either water or aqueous solutions of various salts at temperatures between −20° and −70°C.[81] Its structure is similar to, but more ordered than, that of red phosphorus.[315]

The autoxidation of suspensions of white phosphorus in carbon tetrachloride gives products which may contain $P_2O$, $(P_2O_3)_n$ or possibly $P_4O_8$.[82]

The oxidation of white phosphorus to the trioxide, $P_4O_6$, is best carried out by burning it at 46° to 50°C. in a quartz tube in a stream of air containing 75% of oxygen and 25% of nitrogen at a pressure of 90 mm. Hg and a flow rate of 30 l./hr.[83] The product is purified by distillation and by irradiating with a mercury arc to convert unchanged white phosphorus to a red form.[84–5] Good yields of the trioxide are also obtained by the oxidation of yellow phosphorus by nitrous oxide at 70 mm. Hg and 550–625°C.[316]

When phosphorus trioxide is heated *in vacuo* it dissociates to a red involatile residue, and a sublimate of large colourless crystals, once thought to be phosphorus tetroxide, $P_4O_8$[86] (Mellor, VIII, 922). This has now been shown to contain two oxide systems of variable stoicheiometry, α-P(III/V) oxide $P_4O_{8\cdot 1}$–$P_4O_{9\cdot 2}$ and β-P(III/V) oxide $P_4O_{8\cdot 0}$–$P_4O_{7\cdot 7}$.[314] The α oxide comprises mixed crystals of the molecules $P_4O_9$ and $P_4O_8$,[317] while the β oxide is a similar mixed crystal of $P_4O_8$ and $P_4O_7$.[318] The structure of the two oxides is discussed further in Section IX.

When a mixture of oxygen and phosphorus pentoxide at a pressure of 1 mm. Hg is passed through a discharge at 3 kv. and 150 ma. between aluminium electrodes, a blue-violet material condenses immediately after the discharge.[87] The product decomposes when heated above 130°C. and is insoluble in chloroform. Its aqueous solution behaves as a peroxyphosphoric acid.[88] In a corona discharge, both the violet and colourless materials are formed. The latter is stable only up to 120°C. and its composition agrees with the formula $P_4O_{11}$.[89] The various oxides of phosphorus are fully discussed in Sections IX and X.

### THE GLOW AND SLOW OXIDATION OF PHOSPHORUS

The oxidation of phosphorus at ordinary temperatures has been studied very extensively since the discovery of the element in 1669. There are two distinct oxidation reactions, both accompanied by the emission of light. When the element oxidizes slowly by reacting in the vapour phase near the solid, it emits a characteristic greenish glow. If rapid oxidation occurs, a yellow flame is produced and this may extend some distance from the solid. The previous observations (Mellor, VIII, 771–81) may be summarized qualitatively as follows.

A greenish glow is observed when white phosphorus is exposed to air or oxygen in the presence of moisture at temperatures of 16° to 30°C., and below atmospheric pressure. No light appears if the oxygen pressure is above about 600 mm. As the pressure decreases, the intensity of the glow increases to a maximum at about 300 mm. pressure and then decreases to zero at zero pressure. Vapours of a number of substances (Mellor, VIII, 775) either stop the glow altogether or necessitate a higher temperature to obtain the same intensity of light. The ignition temperature of the phosphorus is lowered by increasing the water content of the gas. Organic vapours generally raise the ignition temperature (Mellor, VIII, 772). The intensity of the glow varies with the temperature and the partial pressures of water vapour and oxygen. In a closed system of phosphorus and oxygen the rate of decrease in the partial pressure of oxygen increases as $p_{O_2}$ decreases.

In the earlier quantitative measurements of the oxidation of solid white phosphorus it was found that the reaction rate was greatest when only a small amount of water was present. Slower oxidation occurred when very dry or very moist oxygen was used. A partial pressure of 16–20 mm. of water vapour had a very marked inhibiting effect. With oxygen dried by concentrated sulphuric acid the rate of oxidation at 13° to 19°C. agreed with the first order equation $-\mathrm{d}p_{O_2}/\mathrm{d}t = kp_{O_2}$ for pressures between 850 and 2000 mm. At lower pressures $k$ was not constant. When nitrogen was also present, $-\mathrm{d}p_{O_2}/\mathrm{d}t$ passed through a maximum at $p_{O_2} = 250$ mm. This effect was thought to be due to diffusion effects in the gas phase. It was also established that ozone or hydrogen peroxide was formed during the oxidation only if water was present.[90] These data have been examined mathematically.[91]

The formation of ozone, as detected by the liberation of iodine from potassium iodide solution, has been explained by the presence of ultra-violet radiation of wavelength 1200–1800 A. in the spectrum of the glow. This is supported by the observation that ozone is formed during the oxidation of phosphorus trioxide, $P_4O_6$, and the fact that the glow from this reaction oxidizes oxygen. There is, however, evidence that pure $P_4O_6$ does not glow during oxidation and that any glow previously observed was due to the presence of elemental phosphorus in the trioxide.[92] Ozone is also formed in oxygen separated by a quartz window from a glowing phosphorus–oxygen mixture.[93] Some of the radiation has been shown to be emitted by the excited molecule PO.[94] The emission spectrum of the glow shows bands due to three different electronically excited states. One, a state of an unknown physical species of PO, emits a greenish glow in the visible region. Another, the $A^2\Sigma$ state, emits radiation on dropping to the $X^2\Pi$ state. The third, $B^2\Pi$ state radiates by dropping to the ground state. The reaction postulated for the production of these states is[95]:

$$P(^4S) + O(^3P) + PO(X^2\Pi) = PO^* + PO(X^2\Pi)$$

The spectrum of the glow of phosphorus shows a series of lines and bands between 2370 A. and 3420 A.[96–9] and also between 5200 A. and 8000 A.[100–1] Other observations are reported in reference 102.

The effect of nitrogen dioxide on the glow of solid white phosphorus has been determined by measuring the pressure at which the phosphorus begins to glow in the presence of mixtures of the gas with air and oxygen. The pressure, in mm. Hg, is given by the expression $p(a+x) = K$, where $x$ is the ratio $[NO_2]/[O_2]$ and $a$ and $K$ are constants. At 20°C. the values of $a$ and $K$ are 0·00135 and 0·80 respectively for oxygen.[103] It is reported[104] that phosphorus does not[18] glow in pure sulphur dioxide. The pressure at which the glow begins in mixtures of oxygen with sulphur dioxide or hydrogen sulphide increases with temperature. Hydrogen sulphide has a weak inhibiting action similar to that of nitrogen, whereas sulphur dioxide is comparable with benzene and carbon tetrachloride. The pressure limits for both gases are defined by the equation given above.[105] At room temperature the constants in this equation for various gases are as shown in Table XIII. These refer to pressure in mm. Hg and $x$ in volume per cent.

*Table XIII.—Constants in the Equation $p_{\text{mm.}}(a+x)=K$ for the Pressure at which Various Gases Inhibit the Oxidation of White Phosphorus in Air or Oxygen*[106]

| Inhibitor | Constant $a$ | | Constant $K$ | |
|---|---|---|---|---|
| | $O_2$ | air | $O_2$ | air |
| Sulphur dioxide | 23 | — | 1,350 | — |
| Benzene | 21 | 32 | 10,805 | 4912 |
| *cyclo*Hexane | 20 | 14 | 10,107 | 2113 |
| Acetylene | 11·3 | 4·8 | 7,017 | 1249 |
| Methyl*cyclo*hexane | 8·2 | 6·2 | 4,577 | 1023 |
| Ethylene | 1·75 | 0·66 | 1,073 | 177 |
| Propylene | 0·35 | 0·15 | 168 | 26 |
| *cyclo*Hexene | 0·11 | 0·08 | 58 | 9 |
| Isoprene | 0·025 | 0·01 | 20 | 2·6 |
| Iron carbonyl, $Fe(CO)_5$ | 0·0033 | 0·0019 | 1·7 | 0·21 |

The pressure necessary to prevent luminous oxidation at 20°C. in the absence of chemical inhibitors is 588 mm. for oxygen and 1195 mm. for moist air.[107] The inhibiting action of ethylene, chlorine and bromine is less than that of nitrogen dioxide.[108] The inhibiting effect of some compounds has been expressed by an equation of the form:

$$p_{\text{mm.}} = p_0 - Ax$$

where $p_0$ is the pressure which prevents oxidation in pure oxygen, $A$ is a constant and $x$ is the volume percentage of inhibitor in the gas phase.[106, 109] Some data are given in Table XIV.

*Table XIV.—Constants in the Equation $p=p_0-Ax$ for the Inhibition of the Oxidation of Solid White Phosphorus by Oxygen*[106, 109]

| Inhibitor | Temp. °C. | $p_0$ | $A$ |
|---|---|---|---|
| Nitrogen | 15–16 | 670 | 3·6 |
| Hydrogen | 17·5 | 732 | 6·2 |
| Carbon monoxide | 6·5 | 400 | 3·5 |
| Carbon dioxide | 12 | 510 | 4·6 |
| Nitrous oxide | 14 | 480 | 4·25 |
| Chloroform | 20 | 549 | 10·4 |
| Carbon tetrachloride | 15 | 533 | 8·35 |
| | 20 | 678 | 12·45 |
| Ethyl bromide | 17·5 | 540 | 8·0 |
| Ethylene dibromide | 14·5 | 540 | 10·0 |
| Methyl acetate | 18·2 | 543 | 41·5 |

The data for a number of vapours, particularly those of aromatic compounds, agree better with an equation of the form[106–7]:

$$p = p_0 - Ax + Bx^2$$

Phosphorus oxychloride vapour is anomalous in that it catalyzes the glow, the pressure at 20°C. agreeing with the equation:

$$p = \frac{1650}{2{\cdot}1 - x}$$

for the low concentrations investigated.[109]

In the earlier literature (Mellor, VIII, 772) various values were reported for the ignition temperature of phosphorus. More recent data[110] show that the true ignition temperature in dry air is 38·5°C. This value was obtained by determining the lower and upper limits of air pressure between which a phosphorus flame was obtained at various temperatures. The data are given in Table XV, from which it will be seen that the lower pressure limit varies only slightly with temperature, whereas the upper limit increases rapidly as the temperature is raised.

*Table XV.—Pressure Limits in the Hot Flame Oxidation of White Phosphorus*[110]

| Temp. °C. | Lower limit mm. | Upper limit mm. |
|---|---|---|
| 2 | 70 | 75 |
| 7 | 66 | 100 |
| 19 | 65 | 200 |
| 22 | 64 | 300 |
| 25 | 62–64 | 400 |
| 28 | 62–64 | 500 |
| 31·5 | 62–64 | 600 |
| 35·5 | 62 | 700 |
| 38·5 | 60–62 | 760 |
| 41·5 | 60–62 | 800 |
| 47·0 | 60–62 | 900 |
| 50·0 | 60 | — |

These data are shown in Fig. 2, which includes other observations defining the boundary between the glow and flame regions in the oxidation.

Hydrocarbons have a marked influence on the boundaries, the effect varying with temperature. The pressure–composition diagram for these at a temperature of 44·5°C. is shown in Fig. 3.

A change of 10°C. in the temperature considerably alters the shape of the diagram. As the temperature is lowered, the flame region becomes smaller and the region of no reaction shown in Fig. 3 moves to the left.[110]

It is reported[111] that the inflammability, *I*, of a substance is given by the expression:

$$I = \frac{\text{heat of combustion} \times \text{specific heat}}{\text{ignition temperature}}$$

On this basis the inflammability of white phosphorus is 834 and that of the red variety is 128, as compared with 25–35 for hydrogen and 63 for carbon disulphide.

The vapour phase oxidation of white phosphorus has been studied in great detail, and more precise data have been obtained than has been possible in the study of the solid element. In the earlier stages of this work it was found that for a given pressure of phosphorus there is an upper limit to the oxygen pressure, above which only slow oxidation occurs and below which ignition takes place.[112] The upper pressure limit is directly proportional to the pressure of phosphorus vapour[113] and is independent of temperature between −40°C. and +15°C. This pressure has been considered to be the lower limit of explosion[114–5] in mixtures of phosphorus vapour and oxygen.

There is also a lower pressure limit, below which the oxidation is very slow and above which ignition occurs. The lower critical pressure is independent of temperature and is inversely proportional to the pressure of phosphorus vapour and the

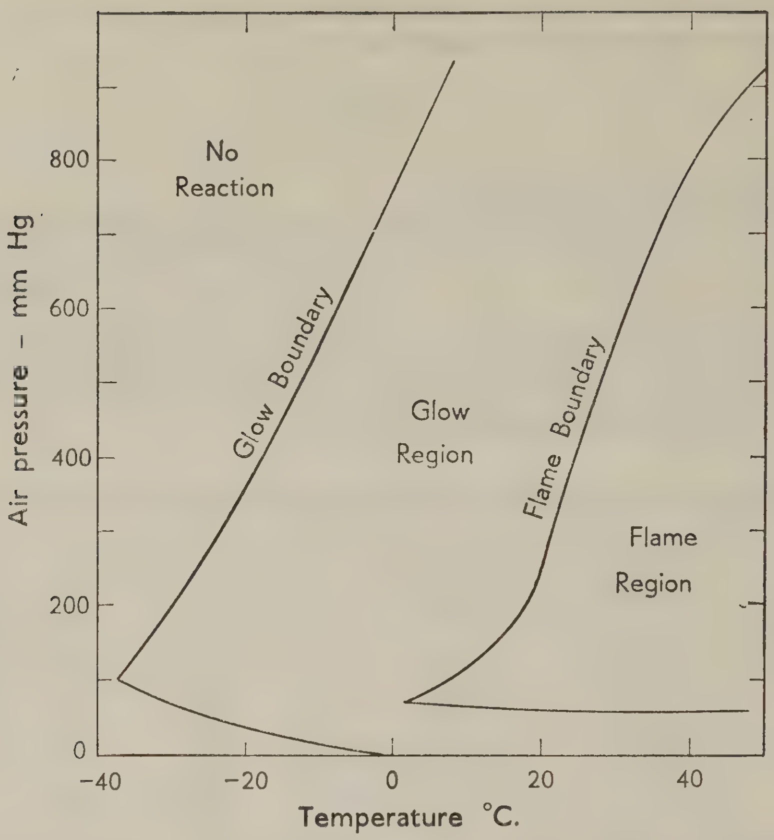

FIG. 2.—The glow and flame regions in the oxidation of solid white phosphorus in air[110]

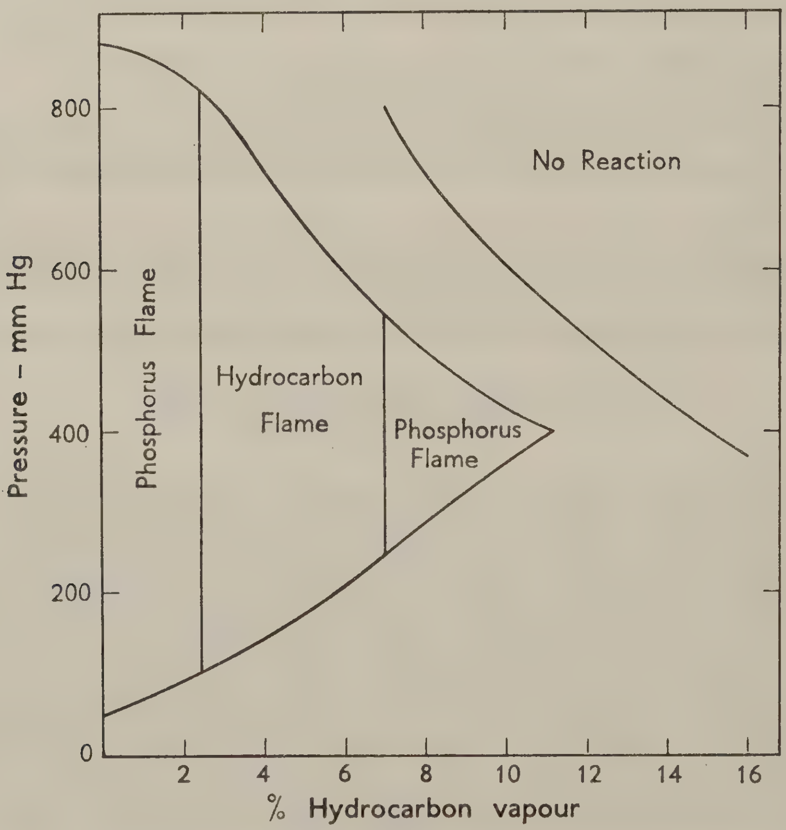

FIG. 3.—The effect of hydrocarbons on the oxidation of solid white phosphorus in air at 44·5°C.[110]

**Refs. p. 264**

square of the diameter of the containing vessel. It is also lowered by the addition of inert gases such as argon. Earlier data[116–7] were in approximate agreement with Semenoff's expression[118]:

$$p_{\mathrm{P}}\, p_{\mathrm{O}} \left(1 + \frac{p_{\mathrm{A}}}{p_{\mathrm{O}}+p_{\mathrm{P}}}\right) d^2 = \text{constant}$$

where $p_{\mathrm{A}}$, $p_{\mathrm{P}}$ and $p_{\mathrm{O}}$ are the pressures of inert gas, phosphorus vapour and the critical pressure of oxygen, respectively, and $d$ is the diameter of the vessel.

The two pressure limits were shown[113] to be limiting cases of a general equation which determines the explosion conditions of phosphorus–oxygen mixtures, i.e.

$$k_1 - p_{\mathrm{P}}\, p_{\mathrm{O}} + k_2 p_{\mathrm{O}}^2 = 0$$

where the constants are $k_1 = 3{\cdot}2 \times 10^{-4}$ and $k_2 = 2{\cdot}8 \times 10^{-5}$. The lower $p_1$ and the upper $p_2$ critical oxygen pressures are then given by:

$$p_1 = \frac{p_{\mathrm{P}} - \sqrt{p_{\mathrm{P}}^2 - 4k_1k_2}}{2k_2} \quad \text{and} \quad p_2 = \frac{p_{\mathrm{P}} + \sqrt{p_{\mathrm{P}}^2 - 4k_1k_2}}{2k_2}$$

This result is shown in Fig. 4, where the curve is derived from the above equations and the points represent the experimental data. Pressures are in mm. Hg and the area inside the curve is the region of fast reaction.[115, 119, 120]

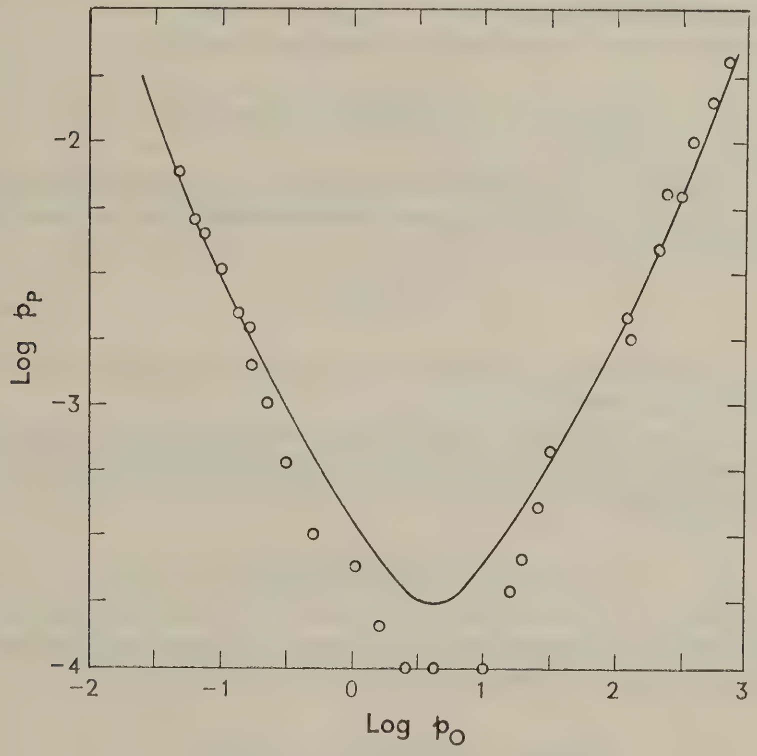

FIG. 4.—Critical pressures in the oxidation of phosphorus vapour

These observations were explained[120–1] by a chain mechanism in which it is considered that oxygen atoms provide the reaction centres. Chain propagation spreads until ignition occurs, unless the chains are terminated by the walls of the containing vessel. The reactions postulated are:

$$\begin{aligned} \mathrm{O_2} &= \mathrm{O + O} \\ \mathrm{O + P_4} &= \mathrm{P_4O} \\ \mathrm{O_2 + P_4O} &= \mathrm{P_4O_2 + O} \end{aligned}$$

Consecutive reactions of $P_4O_2$ could cause chain branching:

$$\begin{aligned} P_4O_2+2(n-1)O_2 &= P_4O_{2n} \\ P_4O_{2n}+O_2 &= P_4O^*_{2n+2} \\ P_4O^*_{2n+2}+O_2 &= P_4O_{2n+2}+2O \end{aligned}$$

where $P_4O^*{}_{2n+2}$ is an activated molecule. The last reaction occurred only when the kinetic energy of the oxygen molecule and the excess energy $\phi$ of the $P_4O^*_{2n+2}$ molecule exceeded 160,000 g-cal. The probability of this is $e^{-E/RT}$ where

$$E = 160{,}000-\phi$$

The chain length $\nu$ at which ignition occurs is $\nu=\frac{1}{2}e^{+E/RT}$. The addition of an inert gas increases the rate of oxidation by hindering the diffusion of the chains to the walls of the vessel, thus increasing the chain length.

The hypothesis that the reaction centres are formed spontaneously in the gas phase has been criticized because it does not explain why the formation of the centres ceases abruptly with small changes in pressure. It seems that the chain theory should be modified in favour of a heterogeneous initiation of inflammability.[122]

A study of the effect of hydrogen, helium, neon, argon, nitrogen, carbon monoxide and dioxide, hydrogen sulphide, nitrous oxide, sulphur dioxide, and the vapours of acetone, acetylene, ethylene, benzene, hexane, methylene chloride and mesitylene on the lower oxidation pressure gives results which agree with Semenoff's equation. This indicates that the inert gas effect should be independent of the nature of the gas. However, the slope of the curve obtained by plotting $1/p_O$ against $1+[p_A/(p_O+p_P)]$ varies with the nature of the gas.[123]

A better approximation is obtained by using the equation:

$$p_P\, p_O \left(1 + \frac{\mu p_A}{p_O+p_P}\right) d^2 = \text{constant}$$

where $\mu$ is the reciprocal of the diffusion coefficient of oxygen through the inert gas. In the upper pressure limit the termination of the chains is in the gas phase and

$$p_O = \frac{k}{a+p_A/p_O}$$

The ratio $k/a$, which should be independent of the inert gas, varies from 350 for acetylene to 800 for isoprene.[124]

Values of $\mu$ have been obtained in two ways. In one of these the acceleration of the chain reaction velocity by an inert gas is measured. If $R_X$ and $R_O$ are the rates with and without the gas, then:

$$\mu = \left(\frac{R_X-R_O}{R_O}\right)\left(\frac{p_O+p_P}{p_X}\right)$$

In the second method the depression of the lower pressure limit on adding an inert gas is measured. For these circumstances:

$$p'_O\, p'_P = p_O\, p_P \left(1 + \frac{\mu p_X}{(p_O+p_P)}\right)$$

where $p'_O$ and $p'_P$ are the pressure limits in the absence of inert gas.[125] Some values of $\mu$ are given in Table XVI.

For hydrogen and deuterium values of $\mu=0{\cdot}10$ and $\mu=0{\cdot}128$, respectively, have been obtained.[126, 125]

Illumination of the vapour with a zinc spark or a mercury arc, at pressures below the lower limit, displaces the latter towards smaller pressures and also causes the reaction between phosphorus vapour and oxygen to occur at below the critical limit. The displacement is a wall effect, said to be due to dissociation of $P_4$ into $P_2$ molecules. Illumination with ultra-violet light raises the upper pressure limit, but this is not a

*Table XVI.—Constants for the Effect of Inert Gases on the Oxidation of Phosphorus Vapour*[125]

| Inert gas | Constant $\mu$ |
|---|---|
| Helium | 0·13 |
| Neon | 0·20 |
| Argon | 0·46 |
| Nitrogen | 0·37 |
| Carbon dioxide | 0·48 |
| Sulphur dioxide | 0·52 |
| Nitrous oxide | 0·46 |
| Chloroform | 0·84 |
| Carbon tetrachloride | 0·84 |

wall effect. The kinetics of the stable oxidation at pressures below the lower limit in the presence of ultra-violet light are represented by the equation:

$$\frac{-\mathrm{d}[O_2]}{\mathrm{d}t} = kI[O_2]^2[P_4]$$

where $k$ is a constant and $I$ is the intensity of illumination. This experimental result does not agree with the prediction of the chain theory of reaction, according to which the rate of reaction should be proportional to the oxygen pressure and the square of the phosphorus vapour pressure. The observed rate equation would result if the production of one of the chain carriers were due to the formation of a lower phosphorus oxide on the walls of the apparatus rather than the dissociation or deactivation of phosphorus molecules by ultra-violet light.[126]

A slow oxidation reaction is induced by platinum or tungsten at 200° to 500°C. at pressures below the lower critical limit. With a platinum filament no glow is emitted and the reaction velocity at 200°C. is proportional to the oxygen pressure. Introduction of argon does not affect the reaction rate. At 500°C. with a tungsten filament the reaction velocity is proportional to both the oxygen and the phosphorus vapour pressures. It is increased by using wider reaction tubes and by adding neon or argon. The rate equation is:

$$-\frac{\mathrm{d}p_O}{\mathrm{d}t} = kp_O\,p_P\left(1 + \frac{\mu p_X}{p_O + p_P}\right)d^2\,\mathrm{e}^{-E/RT}$$

where $d$ is the diameter of the tube, $p_O$, $p_P$, and $p_X$, are the pressures of oxygen, phosphorus vapour and inert gas, respectively, $\mu$ has the values given in Table XVI and the activation energy is $E = 16$ kcal. Silver, gold and molybdenum have a similar effect.[127]

The glow-type oxidation of phosphorus has been explained in terms of branched chain reactions, and this theory accounts for the temperature dependence of the glow limits.[128] A more recent and detailed discussion examines the factors affecting the lower and upper limits of the cool-flame reaction.[129] The proposed scheme for the oxidation is:

| | | |
|---|---|---|
| (1) | $P_4 + O_2 \rightarrow P_4O + O$ | Initiation |
| (2) | $P_4 + O + M \rightarrow P_4O + M$ | Propagation |
| (3) | $P_4O_n + O_2 \rightarrow P_4O_{n+1} + O$ | Chain branching |
| (4) | $O + O_2 + M \rightarrow O_3 + M$ | Termination |
| (5) | $O + X \rightarrow$ stable product | Termination |
| (6) | $O +$ wall $\rightarrow$ adsorption | Termination |

This is a slight modification of the mechanism previously given[128] in that reaction (2), which requires no activation energy, is a three-body process with M as the third atom. The simpler reaction:

$$P_4 + O \rightarrow P_4O$$

involves the liberation of too much energy to explain the observed data.[128] In reaction (3), $n$ can have any integral value between 1 and 9, and the activation energy for reaction (4) is 4·3 kcal./mole. In reaction (5) X is a foreign gas which acts as an inhibitor by reacting with oxygen atoms, e.g. an unsaturated aliphatic hydrocarbon.[129]

The intensity of the glow of phosphorus has been measured with a photo-electric photometer. In oxygen at 40–350 mm. pressure the intensity is approximately constant at temperatures up to 380°C. At room temperatures ozone has no effect at concentrations below 0·14%. At higher concentrations the glow intensity is increased according to the equation:

$$I = 5+2{\cdot}95(x-0{\cdot}14)$$

where $x$ = percentage of $O_3$.

Chlorine and sulphur dioxide decrease the intensity and at high enough concentrations extinguish the glow. Chlorine is much the more effective in this respect, the equations being:

$$\begin{aligned} Cl_2: &\quad I = 6{\cdot}7(1-0{\cdot}433R) \\ SO_2: &\quad I = 4{\cdot}25(1-0{\cdot}009R) \end{aligned}$$

where $R$ is the ratio $Cl_2/O_2$ or $SO_2/O_2$ as measured by the partial pressures.[130]

Investigation of the glow with a photoelectric counter[131] gave results in agreement with the originally proposed reaction mechanism.[118]

The band spectrum of the green flame of phosphorus[132] and the fluorescence and absorption spectra of superheated phosphorus vapour[133] have been investigated. Fluorescent emission has been observed in the 1900–3500 A. region on illuminating the vapour at 600° to 700°C. under 0·1 mm. Hg pressure with aluminium, cadmium and zinc light.[134]

The rate of oxidation of white phosphorus in air at temperatures between 125° and 450°C. shows that the reaction time has relatively little effect on the composition of the products. Table XVII shows the percentages of the various oxides formed at four temperatures.

*Table XVII.—Products obtained in the Air-oxidation of White Phosphorus*[135]

| Oxidation product | % composition at | | | |
|---|---|---|---|---|
| | 125°C. | 250°C. | 350°C. | 450°C. |
| $P_4O$ | 28 | 20 | 10 | — |
| $P_4O_2$ | 0·6–4·7 | 0·9–4·0 | 0·3–0·9 | — |
| $P_4O_6$ | 35 | 19 | 14 | 12 |
| $P_4O_{10}$ | 35 | 59 | 75 | 88 |

The first stage of the oxidation was represented by the equations:

$$\begin{aligned} P_4+O &= P_4O \\ P_4O+O_2 &= P_4O_2+O \\ P_4O_2+O_2 &= P_4O_4 \end{aligned}$$

At low pressure this was followed by:

$$\begin{aligned} P_4O_4 &= 4PO \\ PO+O_2 &= PO_3 \\ PO_3+O_2 &= PO_2+O_3 \\ 2PO_2 &= P_2O_4 \\ P_2O_4+O_3 &= P_2O_5+O_2 \end{aligned}$$

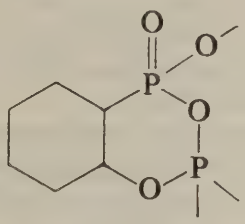
At high pressures $P_4O_4$ reacts with one, two and three molecules of oxygen to give $P_4O_6$, $P_4O_8$ and $P_4O_{10}$, respectively.[135]

The formation of substantial quantities of $P_4O$ has been doubted.[129] This product was not obtained in a previous detailed examination of the oxidation of phosphorus.[92] Careful repetition of this work failed to give any $P_4O$ which could be isolated as a separate product.[129] Later workers have proposed a detailed mechanism along similar lines for the oxidation of phosphorus via the trioxide to the pentoxide.[319]

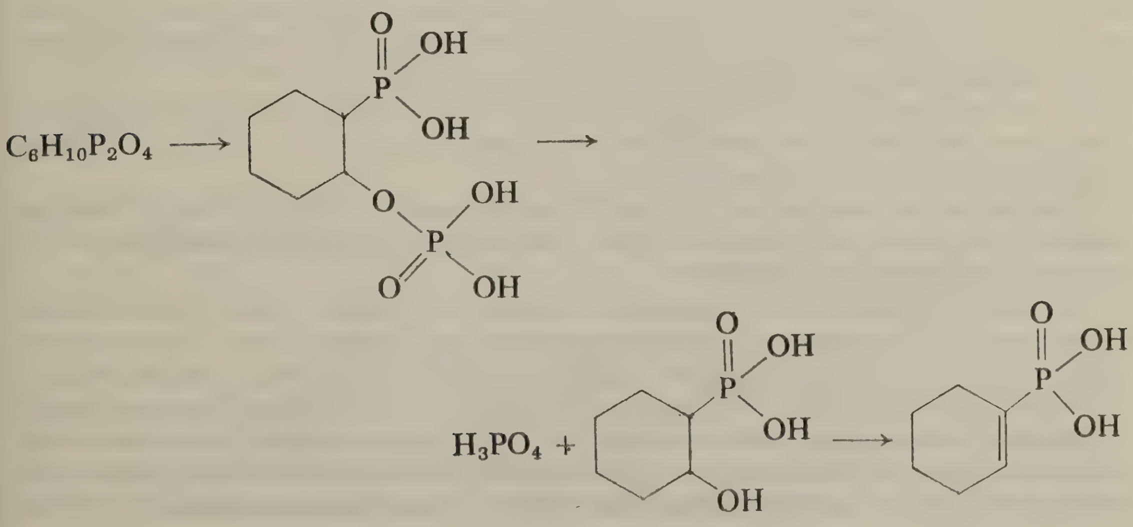
Oxidation of white phosphorus with oxygen at 100°C. in the presence of water vapour gives amorphous yellowish-red products. These contain hydrogen and oxygen, and 87 to 91% of phosphorus. The composition of the product with the lowest phosphorus content corresponds to $(P_4(OH))_n$. These materials are insoluble in water and decompose in an inert atmosphere at 250° to 300°C. to form red phosphorus and pentavalent phosphorus compounds. They oxidize slowly in air to give hypophosphorous acid, phosphorous acid, some phosphoric acid and traces of lower reduced acids of phosphorus.[136]

Orange-coloured products, which contain bromine atoms and may also contain $(P_4(OH))n$, are formed when pentaerythritol is converted to its tetrabromide by refluxing with phosphorus tribromide.[136A]

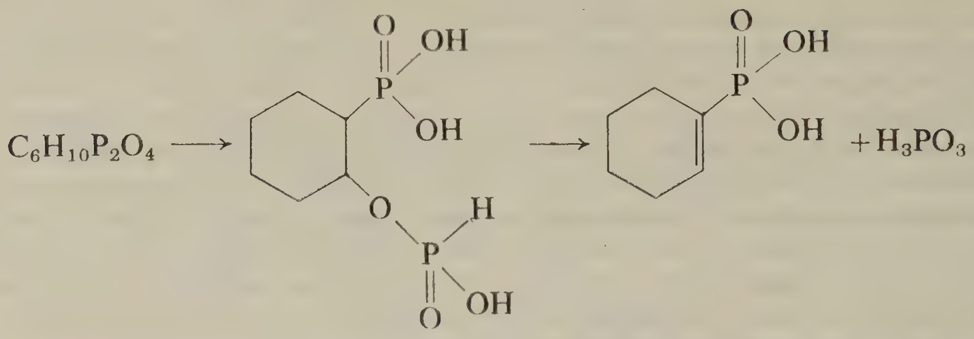
In the presence of olefins the oxidation of benzene solutions of white phosphorus with oxygen at 40° to 50°C. produces organic polymers.[137] The reaction in most cases attains 100% completion with the absorption of two atoms of oxygen to each atom of phosphorus. The oxidation is a free radical process, giving large molecules of kinetic chain length at least 7000. The reaction is inhibited by hydroquinone, but is accelerated by azobis–*iso*butyronitrile. The products are white or light-yellow crystalline solids, which react vigorously with water and alcohol. Analytical data of the materials correspond to $R.P_2O_5$ when R is hexadecene, octene and dodecene, and to $R.P_2O_4$ when R is *cyclo*hexene, styrene and ethylene. With *cyclo*hexene the polymeric structure is made up of the units:



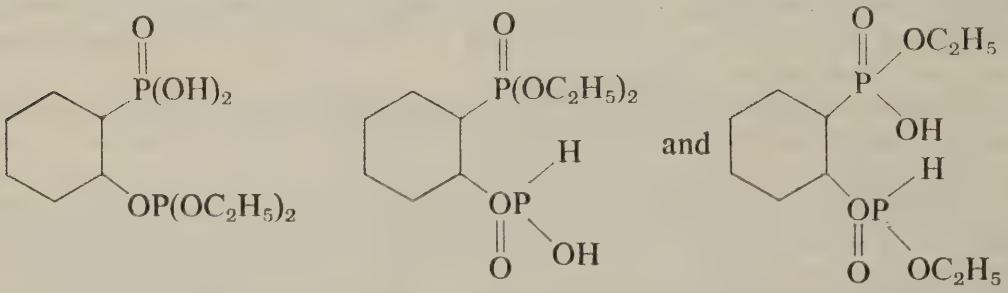
Oxidative hydrolysis of this material with 45% nitric acid proceeds according to the following scheme:



Hydrolysis with water proceeds as follows:



Aqueous alcohol forms esterified products, of which the most likely structures appear to be:



## Silicon, Sulphur, Arsenic, Selenium and Tellurium

Vapour pressure studies indicate the existence of a silicon phosphide, SiP, but no compound $Si_3P_4$, analogous to thorium phosphide, exists.[138] The monophosphide is formed by reaction of the elements at temperatures above 1100°C.[139]

A disilicon phosphide, $Si_2P$, has been prepared as a blue-black amorphous solid by heating phosphine and silane at 450°C. and 200 mm. total pressure. It decomposes at 600°C. into silicon and silicon monophosphide.[140] Further details of these phosphides are given in Sections VII and VIII.

Sulphur and white phosphorus form solid solutions on mixing the elements at temperatures below 100°C. Above this temperature a vigorous exothermic reaction occurs with the formation of $P_4S_3$, $P_4S_5$, $P_4S_7$ and $P_4S_{10}$ (ref. 66, p. 290). In addition less well-defined compounds of composition $P_4S_2$,[320] PS[321] and $PS_{5-7}$[322] have been described, as well as a phase of variable composition $P_4S_{6-7}$, which appears to be a defect form of the heptasulphide.[323] These products are described in detail in Section XI.

The band spectrum of the diatomic molecule PS has been studied.[73, 141] A polymeric form, $(PS)_n$, which is a yellow powder insoluble in common organic solvents, has been described.[142] The heat capacity of the PS molecule has been calculated from spectroscopic constants with the results shown in Table XVIII.[143]

Four phosphorus oxysulphides, $P_4O_6S_4$,[144-5] $P_4O_4S_6$,[146] $P_4O_4S_3$[147] and $P_6O_{10}S_5$,[145] have been described. The best-defined of these compounds is $P_4O_6S_4$.[144] These materials are described in Section XII.

Phosphorus and arsenic react to form a monophosphide, AsP, a black substance similar to graphite. The existence of this is shown by *X*-ray and thermal analysis of the phosphorus–arsenic system.[148]

Mixtures of selenium and phosphorus combine on heating to form the selenides $P_2Se_3$ and $P_2Se_5$ according to the proportion of the elements used. In carbon disulphide solution in the presence of naphthalene $P_4Se_3$, a yellow or orange product, is formed. It melts at 242°C.[149] The same material is produced slowly when selenium is dissolved in molten white phosphorus. Solid solutions are formed at temperatures below 50°C. and at 130°C. a slow reaction begins.[150] This selenide is also formed in about 30% yield by heating selenium and phosphorus in tetralin solution at 215° to

220°C.[151] The density is 1·31 and the structure is similar to that of $P_4S_3$ except that the unit cell is about twice as large.[152] In moist air it forms hydrogen selenide and aqueous sodium hydroxide gives phosphine and sodium selenide. Iodine in carbon disulphide produces $P_4Se_3I_2$, m.p. 154° to 155°C., which reacts explosively with nitric acid.[153]

*Table XVIII.—Calculated Heat Capacity of the* PS *Molecule*[143]

| Temp. °K. | $C_p$ g.-cal./mole | Temp. °K. | $C_p$ g.-cal./mole | Temp. °K. | $C_p$ g.-cal./mole |
|---|---|---|---|---|---|
| 100 | 6·963 | 1200 | 8·889 | 3200 | 9·116 |
| 200 | 7·246 | 1400 | 8·933 | 3400 | 9·129 |
| 300 | 7·740 | 1600 | 8·967 | 3600 | 9·143 |
| 400 | 8·118 | 1800 | 8·993 | 3800 | 9·155 |
| 500 | 8·368 | 2000 | 9·016 | 4000 | 9·169 |
| 600 | 8·531 | 2200 | 9·036 | 4200 | 9·183 |
| 700 | 8·643 | 2400 | 9·054 | 4400 | 9·195 |
| 800 | 8·722 | 2600 | 9·070 | 4600 | 9·207 |
| 900 | 8·780 | 2800 | 9·086 | 4800 | 9·221 |
| 1000 | 8·825 | 3000 | 9·102 | 5000 | 9·233 |

Powdered tellurium and white phosphorus form a tritelluride, $P_2Te_3$, by heating in a sealed tube at 320°C., but red phosphorus does not react. It is a black solid, *d* 4·13, which in moist air slowly evolves phosphine. In air it ignites at 330°C. forming phosphorus pentoxide and tellurium, but in a sealed tube tellurium and phosphorus result. Iodine in carbon disulphide gives $P_2Te_3I_2$, a black material which is also formed by reaction of carbon disulphide solutions of white phosphorus and tellurium iodide, $TeI_2$.[154]

No binary compounds of phosphorus and antimony exist according to phase diagram studies.[155]

### Halogens

The diatomic phosphorus halides PCl, PBr and PI are unstable under normal conditions but have been identified in band spectra.[156] Direct combination of phosphorus with the halogens is spontaneous and exothermic. Reactions with white phosphorus can be explosive, but those with red phosphorus are easier to control. Iodine does not form a pentaiodide, giving only $PI_3$ and $P_2I_4$. The other halogens form both penta- and trihalides but no dihalide, except for chlorine, though $P_2F_4$ has been prepared by an indirect procedure.[324] The preparation of $PF_3$,[157–8] $PCl_3$[159] and $PBr_3$[60] have been described in detail. The reaction between phosphorus and iodine in carbon tetrachloride solution to form $P_2I_4$ involves a chain mechanism which can be represented by the following stages:

(1) $P_4+I_2 = P_4I_2$
(2) $P_4I_2 = P_2I_2+P_2$
(3) $P_2I_2+P_4 = P_4I_2+P_2$
(4) $P_2+I_2 = P_2I_2$
(5) $P_2I_2+I_2 = P_2I_4$
(6) $2P_2I_2 = P_2I_4+P_2$

On the assumption (which is not completely justified by the data) that the concentrations of $P_2$, $P_2I_2$ and $P_4I_2$ reach a steady state during the reaction, the rate equation is:

$$\frac{-\mathrm{d}[I_2]}{\mathrm{d}t} = 4[I_2]\left(\frac{a[P_4][I_2]}{[I_2]-b[P_4]}\right) + c\left(\frac{a[P_4][I_2]}{[I_2]-b[P_4]}\right)^2$$

where $a=k_1$, $b=2k_3/k_5$ and $c=4k_6/k_5^2$; and $k_1$, $k_3$, $k_5$ and $k_6$ are the rate constants for the equations given above, in millimoles/litre/min. For a reaction carried out in the dark at 15°C. in an atmosphere of carbon dioxide the values of *a*, *b* and *c* are 100, 0·04 and 0·06, respectively.[161] Later workers have criticized the assumptions on which these experiments were based.[325]

Phosphorus forms a number of higher or poly-halides containing seven or more halogen atoms per atom of phosphorus. Several mixed halides, which are not simply mixtures, have been obtained by prolonged heating of the pure trihalides. The formulæ of these are $PXY_2$ and $PX_2Y$, where X and Y are halogen atoms. Raman spectra of heated mixtures of the trihalides show the existence of PFClBr. The oxyhalides $POX_3$ and thiohalides $PSX_3$ are well known and a number of more complex compounds of this type, e.g. $P_2O_3Cl_4$, $P_2S_3Br_4$, has been obtained. Mixed halides such as $POX_2Y$, $POXY_2$, $PSX_2Y$ and $PSXY_2$ have been described. These, and the simpler phosphorus halides, are discussed in more detail in Sections XIII to XVII.

Phosphorus pentahalides react with ammonia or ammonium halides to form the phosphonitrilic halides $(PNX_2)_n$, which are described in Section XVIII.

Some halogen-containing compounds of phosphorus are listed in Table XIX.

*Table XIX.—Some Halogen-containing Compounds of Phosphorus*

| Simple halides | Mixed halides | Oxy- and thio-halides | Complex halides | Higher halides | Mixed oxy- and thio-halides | Nitrogen–halogen compounds |
|---|---|---|---|---|---|---|
| $PF_5$ | $PF_4Cl$ | $POF_3$ | $PO_2F$ | $PCl_6I$ | $POF_2Cl$ | $(PNF_2)_3$ |
| $PCl_5$ | $PF_3Cl_2$ | $POCl_3$ | $PO_2Cl$ | $PCl_5Br_{10}$ | $POF_2Br$ | $(PNF_2)_4$ |
| $PBr_5$ | $PF_3Br_2$ | $POBr_3$ | $PO_2I_2$ | $PCl_5BrI$ | $POFCl_2$ | $(PNCl_2)_n$ |
| $PF_3$ | $PF_3I_2$ | $PSF_3$ | $P_2OF_4$ | $PCl_3Br_4$ | $POFBr_2$ | $(PNBr_2)_n$ |
| $PCl_3$ | $PF_2Cl_3$ | $PSCl_3$ | $P_2O_2Cl_5$ | $PCl_3Br_8$ | $POFClBr$ | $(PNFCl)_4$ |
| $PBr_3$ | $PF_2Br_3$ | $PSBr_3$ | $P_2O_3F_4$ | $PCl_3Br_{18}$ | $POCl_2Br$ | $P_3N_3Cl_2F_4$ |
| $PI_3$ | $PFCl_4$ | | $P_2O_3Cl_4$ | $PCl_2Br_7$ | $POClBr_2$ | $P_3N_3Cl_4F_2$ |
| $P_2F_4$ | $PFBr_4$ | | $P_2OS_2Cl_4$ | $PClBr_5I$ | $PSF_2Br$ | |
| $P_2Cl_4$ | $PCl_4Br$ | | $P_3O_8I_6$ | $PBr_{17}$ | $PSFBr_2$ | |
| $P_2I_4$ | $PCl_3Br_2$ | | $P_7O_{15}Cl_5$ | $PBr_7$ | $P_2O_3Cl_2F_2$ | |
| $PCl$ | $PCl_2Br_3$ | | $PSI$ | $PBr_6I$ | | |
| $PBr$ | $PClBr_4$ | | $PS_2Cl_5$ | | | |
| $PI$ | $PF_2Cl$ | | $PS_5Cl_2$ | | | |
| | $PF_2Br$ | | $PS_{24}I_3$ | | | |
| | $PF_2I$ | | $P_2SBr_6$ | | | |
| | $PFCl_2$ | | $P_2SI_4$ | | | |
| | $PFBr_2$ | | $P_2SI_2$ | | | |
| | $PFClBr$ | | $P_2S_3Br_4$ | | | |
| | $PCl_2Br$ | | $P_4S_3I_2$ | | | |
| | $PClBr_2$ | | | | | |
| | $PBr_2I$ | | | | | |
| | $PBrI_2$ | | | | | |

In addition to the above there are numerous other phosphorus compounds which contain halogens, including phosphonium halides $PH_4X$, chlorinated phosphines, fluorinated phosphines and phosphoranes, addition compounds of phosphorus trihalides and pentahalides with halides of other elements and organic phosphorus halogen compounds. For details of these reference should be made to Sections XIII to XVIII and XXXI to XXXIII, Mellor, VIII, 993–1041, and Van Wazer (ref. 66).

Compounds such as $P(CN)_3$, $P(NCO)_3$ and $P(NCS)_3$, which are similar to the phosphorus trihalides, also $PO(NCO)_3$ and $PO(NCS)_3$, similar to the oxyhalides, and $PS(NCO)_3$, resembling the thiohalides, have been described.[162–5]

The viscosities of phosphorus vapour and several diatomic phosphorus compounds have been estimated[143] for gases in the ground state and 1 atm. pressure, using the expression:

$$\eta = \frac{26{\cdot}693\sqrt{MT}}{\sigma^2\Omega}$$

where $\eta$ is the viscosity in micropoises, $M$ is molecular weight, $T$ is absolute temperature, and $\sigma$ is the collision diameter in Ångström units. $\Omega$ is the reduced collision integral, which is a function of the reduced temperature $kT/\epsilon$, where $k$ is Boltzmann's constant and $\epsilon$ ergs is the maximum energy of attraction between colliding molecules. Values of $\Omega$ have been tabulated.[166] Representative values of $\eta$ are given in Table XX.

*Table XX.—Calculated Viscosity of Molecules of Phosphorus and Some Phosphorus Compounds*[143]

| Temp. °K. | Viscosity in micropoises | | | | | | | |

Thermal conductivities have been estimated[143] in a similar way from the expression:

$$\lambda = \lambda_1 + \lambda_2 = \frac{R}{M}\left[\frac{15}{4} + 1{\cdot}32\left(\frac{C_p}{R} - \frac{5}{2}\right)\right]\eta$$

where $\lambda$ is the total thermal conductivity in g.-cal./cm. sec. °K., $\lambda_1$ and $\lambda_2$ are the coefficients for translational and internal conductivity, respectively. The viscosity $\eta$ is in poises. Selected conductivity values are given in Table XXI. The translational conductivity was calculated from the expression:

$$\lambda_1 = \frac{15R}{4M}\eta$$

## THE REACTIONS OF PHOSPHORUS WITH METALLIC ELEMENTS

Phosphorus under suitable conditions reacts with all metallic elements except bismuth, mercury and lead. The products of these reactions are phosphides, the preparation and properties of which are more fully described in Section VII.

Some metals, e.g. calcium, magnesium and beryllium, form only one phosphide, but in most cases more than one phosphide is known. The resulting compounds may be simple molecules which are readily volatilized, complex polymeric materials, or compounds having properties rather similar to those of hard metals such as iron. The binary compounds of phosphorus with metals of Group IA and Group IIA of the Periodic Table are described as being salt-like in properties, but there does not seem to be conclusive evidence in support of this. Elements of Groups IIIA, IVA and VA generally give covalently bonded molecules. The transition metal phosphides usually have a high melting point, are fairly resistant to chemical attack, and conduct heat and electricity to some extent.

Several general methods can be used for causing phosphorus to react with the metallic elements. The simplest is to heat the metal with red or white phosphorus, or with phosphorus vapour, in a non-oxidizing atmosphere. With some elements phosphorus can be added to a bath of the molten metal. The more volatile and easily oxidized elements, e.g. sodium, are often covered with an inert liquid such as paraffin during reaction with phosphorus. Thermally unstable phosphides have been made by heating the metal under pressure with excess of phosphorus in a closed system at temperatures up to 1000°C. At the end of the reaction the excess of phosphorus is condensed in another part of the apparatus.[167–8] When phosphorus reacts in more than one proportion with an element, advantage can be taken of the fact that some of the products may be thermally more unstable than others.[169]

The alkali metals react with phosphorus on heating in a vacuum at temperatures up to 450°C. to yield phosphides of the formula $M_2P_5$, where M is the alkali metal.[170] Liquid white phosphorus in an inert atmosphere reacts with alkali metals to give materials corresponding to $M_3P$. The existence of these as pure compounds has been doubted.[66] Lithium and liquid white phosphorus react in liquid ammonia, and on removing excess of phosphorus from the product by heating in a vacuum at 280°C. a product with the composition LiP is obtained. This compound is also formed by heating lithium in phosphorus vapour at temperatures below 400°C. It reacts with more lithium to give $Li_3P$.[22] Liquid ammonia reactions also form $Li_2P$, $Na_2P$ and $K_3P_2$.[171] The properties of these compounds suggest that they are dimeric, i.e. $Li_4P_2$, $Na_4P_2$ and $K_6P_4$.[172] For other alkali-metal phosphides, e.g. $Li_2PH$, $NaPH_2$, which are not formed by direct combination with phosphorus, Section VII should be consulted.

Phosphorus reacts with the lithium–aluminium alloy $Li_3Al$ on heating to form a mixed phosphide $Li_3AlP_2$. The same product results when phosphorus is heated with a mixture of aluminium metal and $Li_3P$.[173] The reaction of phosphorus, $Li_3P$ and a metal in a bomb at 500° to 1000°C. has been used to prepare $Li_3GaP_2$, $Li_5GeP_3$, $Li_5SiP_3$ and $Li_5TiP_3$.[174]

Direct combination of phosphorus with copper, silver and gold occurs less readily than with the alkali metals. At high temperatures and pressures, copper and phosphorus vapour form $CuP_2$. The latter decomposes according to the equation:

$$12CuP_2 = 4Cu_3P + 5P_4$$

The partial pressure of phosphorus vapour ($P_4$) for this reaction is given by[175, 168]:

$$\log_{10} p_{mm.} = -\frac{11{,}370}{T} + 13{\cdot}827$$

The phosphide $Cu_3P$ has also been made by heating the theoretical proportions of copper and red phosphorus for 20 hr. at 640°C. in a vacuum and then raising the temperature to 1000°C. for 5 hr.[175]

At temperatures above 500°C. phosphorus vapour reacts slowly with finely-divided silver and gold to form $AgP_3$, $AgP_2$ and $Au_2P_3$. These materials decompose when heated, according to the following equations[167–8]:

$$\begin{aligned} 4AgP_3 &= 4AgP_2 + P_4 \\ 2AgP_2 &= 2Ag + P_4 \\ 12Au_2P_3 &= 8Au_3P + 7P_4 \\ 4Au_3P &= 12Au + P_4 \end{aligned}$$

The partial pressures of $P_4$ are given by:

$AgP_3$ $$\log_{10} p_{mm.} = -\frac{7766}{T} + 12{\cdot}74$$

$AgP_2$ $$\log_{10} p_{mm.} = -\frac{7180}{T} + 11{\cdot}60$$

$Au_2P_3$ $$\log_{10} p_{mm.} = -\frac{9124}{T} + 12{\cdot}21$$

Red and white phosphorus react with beryllium, magnesium and the alkaline earth metals in the manner already described (Mellor, VIII, 833) to give phosphides of the type $M_3P_2$. Red phosphorus and barium, when heated at 400° to 450°C., are reported to form a crystalline material having the empirical formula $BaP_3$. At 750°C. this is converted into $BaP_2$ and at higher temperatures the normal phosphide $Ba_3P_2$ is obtained.[176]

Liquid ammonia solutions of the alkaline earth metals react with phosphorus to give products of somewhat uncertain composition, e.g. $Ca(PH_2)_2,6NH_3$.[177]

Zinc or cadmium reacts with red phosphorus when heated in a sealed tube to form the diphosphides $MP_2$. These melt at about 700°C. and sublime in an atmosphere of phosphorus vapour.[178] In a vacuum at 500°C. they decompose to give the lower phosphides $M_3P_2$.[179] Heating red phosphorus in a sealed tube with cadmium–lead alloys for several days at 565°C. forms $CdP_4$.[180] Mercury does not react directly with phosphorus.

Several aluminium phosphides have been reported (Mellor, VIII, 846), but more recent work indicates that on heating aluminium in a stream of phosphorus vapour and hydrogen only a monophosphide, AlP, is formed.[181] Phosphorus reacts slowly with gallium or indium in a vacuum at 700°C. forming GaP and InP.[182–3]

In the earlier literature (Mellor, VIII, 846) thallium phosphide was not thought to exist. However, a later phase study suggested that red phosphorus and thallium form $TlP_3$ at about 400°C.[184] High pressures are necessary for its formation. Theoretical amounts of thallium and white phosphorus form $Tl_3P$ in a sealed tube at 400°C.[185]

Germanium and tin react when heated with excess of phosphorus in an evacuated sealed tube at above 400°C. and below 350°C., respectively. The formula of the germanium phosphide is GeP[186] and that of the tin compound is $SnP_3$. The latter loses phosphorus at above 350°C. in a vacuum to give $Sn_4P_3$ (Mellor, VIII, 848).

More recently[187] a tin phosphide, SnP, has been obtained by heating a 1:3 atom weight ratio of tin and red phosphorus at 700°C. in a vacuum ($10^{-6}$ mm. Hg). The product is then cooled at about 40°C./hr. Lead does not appear to react directly with phosphorus to form a definite compound, although $PbP_2$ has been reported (Mellor, VIII, 849). Alloys of lead with zinc, cadmium and mercury form ternary compounds $MPbP_{14}$ when heated with phosphorus at 500° to 600°C. for up to ten days.[188]

Lanthanum reacts violently with phosphorus at 400° to 500°C. in a sealed tube to form LaP.[189] Scandium and yttrium phosphides, ScP and YP, have been prepared by heating the element with red phosphorus in an evacuated silica tube for 30 hr. at 1000°C.[190] A hafnium phosphide, HfP, has been reported,[191] as has a diphosphide, $HfP_2$.[326]

Zirconium, vanadium, niobium and tantalum all react with excess of red phosphorus on heating in evacuated sealed tubes for periods up to 30 days at temperatures between 550° and 1100°C.[192] They all form diphosphides, $MP_2$, which decompose to form monophosphides:

$$4MP_2 = 4MP + P_4$$

The partial pressure of phosphorus vapour over a mixture of the two phosphides, as derived from experimental data, is given for three of the metals by the following equations:

$ZrP_2$[193] $$\log_{10} p_{\text{mm.}} = 12{\cdot}05 - \frac{10{,}800}{T}$$

$VP_2$[169] $$\log_{10} p_{\text{mm.}} = 15{\cdot}37 - \frac{12{,}400}{T}$$

$TaP_2$[194] $$\log_{10} p_{\text{mm.}} = 14{\cdot}48 - \frac{13{,}200}{T}$$

A compound which may be $Zr_3P$ has been obtained by controlled heating of zirconium and phosphorus in a sealed tube for varying successive periods at 500° to 600°C., 800°C. and 900° to 1000°C., followed by cooling at a rate of 100°C./hr.[193]

Titanium diphosphide, $TiP_2$, does not appear to be obtained easily by direct synthesis.[192] The product formed by heating the elements in a sealed tube at 600° to 800°C. is the monophosphide TiP.[195] Phosphorus and excess of titanium form $Ti_3P$ when heated for 48 hr. at 800°C. in an evacuated silica tube.[196–8]

Niobium, like titanium, does not give a diphosphide by direct reaction with phosphorus. However, by heating niobium with excess of red phosphorus at 750°C. under pressure, the compound $NbP_{2\cdot4}$ is obtained. This decomposes to the diphosphide when heated at 430°C. in a vacuum.[199]

When red phosphorus is heated in a closed system with chromium, molybdenum or rhenium, diphosphides are formed.[192, 200–17] These reactions are generally slow and may require up to 100 hr. for completion. Chromium reacts in 75 hr. at 600° to 750°C.,[200] and the temperatures for molybdenum and tungsten are 550° to 1000°C. and 700° to 970°C., respectively.[200] Rhenium reacts only above 800°C., forming mainly the triphosphide $ReP_3$. Further heating at atmospheric pressure gives the diphosphide.[201] Manganese does not form a diphosphide.[202] It reacts with red phosphorus at 300° to 350°C., but temperatures of 1000°C. are necessary to form a homogeneous product.[202–3] The main product is the triphosphide, $MnP_3$. A monophosphide has been made directly by dropping pellets of red phosphorus into molten manganese in a sealed tube in an atmosphere of argon. The product is then heated with more red phosphorus in an evacuated silica tube at 900° to 1150°C.[204]

A tungsten monophosphide has been obtained by fused salt electrolysis,[205] by thermal decomposition of $W_3P$[205] or $WP_2$[200] and by direct synthesis.[200] At 950° to 1300°K. it decomposes into tungsten and mainly diatomic phosphorus. The $P_2$ decomposition pressure is given by the equation[205]:

$$\log_{10} p_{\text{atm.}}[P_2] = 8{\cdot}501 - \frac{16{,}534}{T}$$

Chromium, molybdenum and tungsten diphosphides decompose according to the equation:

$$4MP_2 = 4MP + P_4$$

The partial vapour pressures of $P_4$ over these phosphides are[200]:

$CrP_2$ $\qquad \log_{10} p_{\text{mm.}} = 11{\cdot}582 - \dfrac{8540}{T}$

$MoP_2$ $\qquad \log_{10} p_{\text{mm.}} = 12{\cdot}425 - \dfrac{12{,}000}{T}$

$WP_2$ $\qquad \log_{10} p_{\text{mm.}} = 13{\cdot}090 - \dfrac{13{,}800}{T}$

For manganese triphosphide obtained from its elements at 610° to 720°C. under pressure, the decomposition equation is[203]:

$$2MnP_3 = 2MnP + P_4$$

The $P_4$ partial pressure in this decomposition is given by:

$$\log_{10} p_{\text{mm.}} = 14{\cdot}948 - \frac{11{,}856}{T}$$

Heating manganese and red phosphorus in an evacuated sealed tube at 650°C. is reported to give $Mn_2P$ and $Mn_4P$.[204]

Rhenium triphosphide decomposes in the following stages to form lower phosphides[201]:

$$\begin{aligned} 4ReP_3 &= 4ReP_2 + P_4 \\ 4ReP_2 &= 4ReP + P_4 \\ 4ReP &= 2Re_2P + P_2 \end{aligned}$$

The vapour pressure equations for these reactions are:

$ReP_3$ $\qquad \log_{10} p_{\text{mm.}} = 16{\cdot}77 - \dfrac{17{,}060}{T}$

$ReP_2$ $\qquad \log_{10} p_{\text{mm.}} = 13{\cdot}37 - \dfrac{14{,}220}{T}$

$ReP$ $\qquad \log_{10} p_{\text{mm.}} = 10{\cdot}90 - \dfrac{13{,}780}{T}$

Red phosphorus and iron react when heated for periods up to 24 hr. at 600° to 1000°C. and 1–2 atm. pressure. The compounds $FeP_2$ and $FeP$ are formed, and these decompose when heated at atmospheric pressure, according to the equations[207]:

$$\begin{aligned} 4FeP_2 &= 4FeP + P_4 \\ 4FeP &= 2Fe_2P + P_2 \end{aligned}$$

The partial pressures of $P_4$ and $P_2$, respectively, for these reactions are given by[210]:

$FeP_2$ $\qquad \log_{10} p_{\text{mm.}} = 14{\cdot}469 - \dfrac{14{,}650}{T}$

$FeP$ $\qquad \log_{10} p_{\text{mm.}} = 13{\cdot}230 - \dfrac{17{,}580}{T}$

According to more recent data for the reactions[211]:

$$\begin{aligned} 2FeP_2 &= 2FeP + P_2 \\ 4FeP &= 2Fe_2P + P_2 \\ 6Fe_2P &= 4Fe_3P + P_2 \end{aligned}$$

the equations for the partial pressure of $P_2$ are:

$$\mathrm{FeP_2} \qquad \log_{10} p_{\mathrm{mm.}} = 13{\cdot}381 - \frac{15{,}400}{T}$$

$$\mathrm{FeP} \qquad \log_{10} p_{\mathrm{mm.}} = 14{\cdot}001 - \frac{18{,}700}{T}$$

$$\mathrm{Fe_2P} \qquad \log_{10} p_{\mathrm{mm.}} = 14{\cdot}161 - \frac{24{,}040}{T}$$

Cobalt and red phosphorus combine to form $CoP_3$, CoP and $Co_2P$ on heating for up to 200 hr. in a closed system at 600° to 650°C.[212–3] The triphosphide decomposes on heating according to the equation:

$$2\mathrm{CoP_3} = 2\mathrm{CoP} + \mathrm{P_4}$$

for which the $P_4$ partial pressure is given by[212]:

$$\log_{10} p_{\mathrm{mm.}} = 14{\cdot}397 - \frac{15{,}650}{T}$$

The compound $Co_2P$ has been obtained by heating red phosphorus with molten cobalt at reduced pressure in a closed system under argon. The product is then heated with more cobalt in a vacuum.[213] A similar technique was used for CoP, the product (largely $Co_2P$) then being heated with red phosphorus in evacuated sealed tubes at 900° to 1150°C.[212]

The phosphides $NiP_3$, $NiP_2$ and $Ni_6P_5$ are obtained on heating nickel and red phosphorus in a closed system for up to 100 hr. at 600° to 700°C.[214] The decomposition and $P_4$ partial pressure equations are:

$$\begin{aligned} 4\mathrm{NiP_3} &= 4\mathrm{NiP_2} + \mathrm{P_4} \\ \tfrac{24}{7}\mathrm{NiP_2} &= \tfrac{4}{7}\mathrm{Ni_6P_5} + \mathrm{P_4} \\ 2\mathrm{Ni_6P_5} &= 6\mathrm{Ni_2P} + \mathrm{P_4} \end{aligned}$$

$$\mathrm{NiP_3} \qquad \log_{10} p_{\mathrm{mm.}} = 12{\cdot}870 - \frac{9{,}350}{T}$$

$$\mathrm{NiP_2} \qquad \log_{10} p_{\mathrm{mm.}} = 14{\cdot}320 - \frac{12{,}450}{T}$$

$$\mathrm{Ni_6P_5} \qquad \log_{10} p_{\mathrm{mm.}} = 14{\cdot}965 - \frac{13{,}750}{T}$$

The cobalt and nickel phosphides are somewhat more easily obtained by heating red phosphorus at 600°C. with alloys of tin containing 5% of cobalt or nickel. The tin triphosphide, $SnP_3$, which is also formed, is then converted to $Sn_4P_3$ by heating in a vacuum at 350°C. and the $Sn_4P_3$ is removed by dissolving it in hydrochloric acid.[214–5]

Heating ruthenium and red phosphorus in evacuated sealed tubes at 500° to 1100°C. gives the phosphides $RuP_2$, RuP and $Ru_2P$.[216] Excess of phosphorus at 650° to 680°C. for 34–48 hr. forms $RuP_2$ and at 800° to 900°C. RuP results.[217–8] Excess of ruthenium gives $Ru_2P$.[213]

A diphosphide, $RhP_2$, is obtained when rhodium and red phosphorus are heated under pressure in a sealed tube at 800° to 1100°C.[218–20] A triphosphide, $RhP_3$, and the compound $Rh_5P_4$ have been obtained in a similar manner,[218] although the latter is more probably identical with $Rh_4P_3$.[220] Rhodium triphosphide decomposes at about 1000°C. according to the equation:

$$4\mathrm{RhP_3} = 4\mathrm{RhP_2} + \mathrm{P_4}$$

The $P_4$ partial pressure equation for this decomposition is[219]:

$$\log_{10} p_{\text{mm.}} = 11{\cdot}713 - \frac{12{,}850}{T}$$

At 900° to 1100°C. in evacuated sealed tubes the phosphides $Rh_4P_3$[220-1] and $Rh_2P$[220, 216] are formed from the elements.

The products obtained when red phosphorus and palladium are heated in various proportions in evacuated sealed tubes at 500° to 1100°C. have been shown to be $PdP_3$,[216, 220] $PdP_2$[218] and $Pd_5P_2$.[222] At 700°C. $Pd_3P$ is also formed[222-3]; the composition of this material appears to vary slightly[224, 222] but its existence has been confirmed by *X*-ray methods.[225] The compound $Pd_7P_3$ has been prepared by heating palladium and red phosphorus in an evacuated silica tube at 1200°C. and rapidly quenching from 750°C., and may be identical with $Pd_5P_2$ mentioned above.[226]

Osmium, iridium and platinum form diphosphides when heated with red phosphorus at temperatures above 700°C.[218] The osmium compound, $OsP_2$, is prepared by heating the metal with red phosphorus at 1000°C. and then condensing the excess of phosphorus at 500°C. Osmium also reacts with phosphorus vapour at 1190°C.[217]

Iridium and excess of red phosphorus form $IrP_2$ on heating for 280 hr. at 650°C. This product is also formed by heating the mixture for 96 hr. at 820°C. and then distilling off the excess of phosphorus at 427°C.[218] At 1000°C. in a vacuum the triphosphide $IrP_3$ is obtained.[227] Iridium diphosphide decomposes in a vacuum at 1150°C. to form $Ir_2P$, which is also obtained by heating red phosphorus with excess of iridium for 146 hr. at 990°C.

Platinum reacts with excess of red phosphorus when heated at 800° to 1100°C. in an evacuated tube to form $PtP_2$.[216, 218] It is also formed on heating the elements under pressure for 10 hr. at 600°C.[228] Phosphorus and excess of platinum heated for 2 hr. at 500°C. and then for one day at 750°C. form $Pt_{20}P_7$. A eutectic (m.p. 588°C.) of this compound and platinum is the cause of the embrittlement and corrosion of platinum crucibles by small amounts of phosphorus.[229]

The more usual compounds formed when the actinide elements are heated under pressure with red phosphorus are the phosphides MP and $M_3P_4$. Excess of phosphorus and thorium form $Th_3P_4$ at 650° to 700°C.[230-1] The monophosphide ThP also appears to exist.[232]

Uranium and excess of red phosphorus, under pressure at 800° to 900°C., form $U_3P_4$, $UP_2$ and UP.[233, 231] The diphosphide is also obtained by heating the elements for two days at 550°C.[234] The monophosphide forms when $U_3P_4$ is decomposed by heating in a vacuum at 1400°C.[235] On further heating at 1500° to 2000°C. under ordinary pressure, the monophosphide decomposes according to the equations:

$$\begin{aligned} UP(s) &= U(g)+\tfrac{1}{2}P_2(g) \\ UP(g) &= U(g)+P(g) \end{aligned}$$

The respective heats of reaction ($\Delta H^\circ$) at 1750°C. are $184{\cdot}4 \pm 3{\cdot}1$ kcal./mole and $251{\cdot}6 \pm 4{\cdot}9$ kcal./mole. The partial vapour pressure equations are[236]:

$$\log_{10} p_{\text{atm.}}\,[P] = 6{\cdot}41 - \frac{26{,}211}{T}$$

$$\log_{10} p_{\text{atm.}}\,[P_2] = 4{\cdot}26 - \frac{23{,}046}{T}$$

$$\log_{10} p_{\text{atm.}}\,[U] = 7{\cdot}80 - \frac{28{,}778}{T}$$

A phosphide $U_2P_3$ has been reported.[237] This was not obtained directly from the elements but by causing phosphine to react with uranium trihydride at 400°C.

Neptunium forms the phosphide $Np_3P_4$ on heating with red phosphorus for 16 hr. at 750°C. in a sealed tube, followed by sublimation of the excess of phosphorus in a

Rare earth elements

---

[a] $P_nH_{n+2}$ ($n=1$–6(7)): $P_nH_n$ ($n=2$–9(10)): $P_nH_{n-2}$ ($n=4$–7(8)(10)): $P_nH_{n-4}$ ($n=6$–9); also $P_2H$, $P_5H_2$, $P_9H_4$, $P_9H_3$, $P_{10}H_4$, $P_{10}H_2$, $P_{11}H_6$, $P_{11}H_3$, $P_{12}H_4$, $(P_{14}H)$.

[b] $Ni_7P_3$ (or $Ni_{12}P_5$), $Ni_3P_2$, $NiP$ and $NiP_4$ have also been reported by various workers.

vacuum at 800°C.[238] Plutonium and red phosphorus form PuP when heated in a vacuum or in helium under slightly reduced pressure.[239–40]

The reactions of phosphorus with the rare earth elements have not been exhaustively investigated, but all of them appear to form monophosphides.[241] Samarium reacts at 900°C.,[242] and at 400° to 500°C. in sealed tubes cerium, praseodymium and neodymium combine violently with red phosphorus.[189, 243]

The binary compounds of phosphorus, including those not formed by direct combination of the elements, are shown in Table XXII. The compounds given in parentheses are those on whose existence doubt has been cast, or which exist only under special conditions of temperature or pressure.

A number of ternary compounds, containing phosphorus and formed by direct union of the elements, have been reported. By sintering the components at 700° to 900°C. the compounds CuPS,[244] FePS,[245] CoPS, RhPS, IrPS, RuPS, OsPS, RhPSe, IrPSe, RuPSe and OsPSe have been made.[246, 245] Other compounds, such as PdPS, PtPS, NiPSe, PdPSe, PtPSe, RhPTe, IrPTe and PtPTe, are also considered to be possible.[246] Substances containing phosphorus and arsenic, e.g. PdPAs, PtPAs,[247] and phosphorus and silicon, e.g. $ZnSiP_2$, $CdSiP_2$,[248] have been synthesized in a similar manner.

Polyphosphides such as $HgPbP_{14}$, $CdPbP_{14}$ and $ZnPbP_{14}$ have been made by heating red phosphorus and alloys of lead with mercury, cadmium or zinc, for 8–10 days at 525° to 610°C.[249] Their structures have been discussed.[250]

## MISCELLANEOUS REACTIONS OF PHOSPHORUS

The earlier investigations (Mellor, VIII, 784) into the reaction between white phosphorus and water have been extended to higher temperatures and pressures. The initial observation[251] that small quantities of phosphorous acid are formed on heating at 200°C. in a sealed tube has been confirmed[252]:

$$P_4 + 6H_2O = 2H_3PO_3 + 2PH_3$$

This reaction is slow at 200°C. and goes to completion in 40 hr. at 240°C., in 20 hr. at 290°C. and in 10 hr. or less at 310°C. Above 240°C., increasing amounts of phosphoric acid are formed and the ratio of phosphine to hydrogen produced decreases. The reaction is catalyzed by phosphoric acid and in the presence of 63% of the latter the reaction time is reduced to a minimum of 1 hr. at 310°C. The mechanism proposed is represented by the equations:

$$\begin{aligned} &P_4 + 6H_2O + 6H_3PO_4 = 10H_3PO_3 && t < 250°C. \\ &4H_3PO_3 = 3H_3PO_4 + PH_3 && t > 250°C. \\ &H_3PO_3 + H_2O = H_3PO_4 + H_2 && t > 250°C. \end{aligned}$$

A slower reaction:

$$PH_3 + 4H_2O = H_3PO_4 + 4H_2$$

also occurs and at temperatures above 350°C. there is some evidence for the formation of phosphine according to the equation:

$$P_4 + 6H_2 = 4PH_3$$

At 290°C. under pressures of 40–50 atm., phosphine is formed according to the equation[11]:

$$2P_4 + 12H_2O = 3H_3PO_4 + 5PH_3$$

Surprisingly, phosphine of high purity, containing little hydrogen, is formed by the hydrolysis of finely divided red phosphorus in polyphosphoric acid, at atmospheric pressure and 280–310°C.[327]

White phosphorus reacts with aqueous sodium hydroxide under pressure to give various oxidation products. At 100°C. a slow reaction occurs with sodium hypophosphite as the main product:

$$P_4 + 4NaOH + 4H_2O = 4NaH_2PO_2 + 2H_2$$

At 200° to 300°C. formation of phosphite is rapid when enough 30% sodium hydroxide to form disodium phosphite is present:

$$P_4 + 8NaOH + 4H_2O = 4Na_2HPO_3 + 6H_2$$

With 30% sodium hydroxide and temperatures above 300°C., or with more dilute alkali (e.g., 4% NaOH) at about 250°C., orthophosphate is formed:

$$P_4 + 8NaOH + 8H_2O = 4Na_2HPO_4 + 10H_2$$

At 300°C. or above, and using alkali in excess of requirement for the disodium salt, oxidation of the phosphite is retarded.

The reaction of phosphorus at 200° to 250°C. with sufficient 30% alkali to form monosodium phosphite yields disodium phosphite and some phosphine. Only half of the phosphorus is oxidized to phosphite, the remainder giving red phosphorus which is slowly converted into phosphine.

The formation of phosphate in these reactions occurs through oxidation of phosphine. This is slow at 230°C. but very rapid at 300°C.:

$$2PH_3 + 4NaOH + 4H_2O = 2Na_2HPO_4 + 8H_2$$

Equimolar amounts of hypophosphorous acid and sodium hydroxide (as 30% solution) do not react under pressure at 200°C. but oxidation to phosphate is rapid above 250°C.:

$$NaH_2PO_2 + 2H_2O \overset{>250°C.}{=} NaH_2PO_4 + 2H_2$$

With 2 moles of sodium hydroxide the reaction is complete within a few minutes at 160°C. according to the equation[253]:

$$NaH_2PO_2 + NaOH = Na_2HPO_3 + H_2$$

The oxidation of white phosphorus with moist air under ordinary conditions of temperature and pressure is reported to yield in seven days a product containing approximately 1% of hypophosphorous acid, 18% of phosphorous acid, 6% of hypophosphoric acid and 75% of phosphoric acid.[254]

The reaction of red phosphorus with water at 175° to 420°C. and under 20–530 atm. pressure can be represented by the following equations, of which the first is for the fastest reaction:

$$\begin{aligned} P_4 + (3+n)H_2O &= P_2O_3,nH_2O + 2PH_3 \\ P_2O_3,nH_2O + 2H_2O &= P_2O_5,nH_2O + 2H_2 \\ 2PH_3 + (5+n)H_2O &= P_2O_5,nH_2O + 8H_2 \end{aligned}$$

On prolonged heating only phosphoric acid and hydrogen are formed according to the reaction:

$$P_4 + (10+2n)H_2O = 2P_2O_5,nH_2O + 10H_2$$

In the absence of catalysts oxidation of $P_2O_3$ occurs only at temperatures above 280°C. Compounds of cobalt, nickel, silver, copper and iron have catalytic action but inorganic acids, alkalis and salts have little influence. Nickel nitrate appears to be the most affective, enabling complete oxidation of phosphorus to phosphoric acid to occur in 20 min. at 200°C.[255]

The oxidation of red phosphorus under pressure has been shown to occur in two stages, in the first of which the phosphorus reacts according to the equations:

$$\begin{aligned} P_4 + 6H_2O &= 2H_3PO_3 + 2PH_3 \\ P_4 + 8H_2O &= 2H_3PO_4 + 2PH_3 + 2H_2 \\ P_4 + 12H_2O &= 4H_3PO_3 + 6H_2 \\ P_4 + 16H_2O &= 4H_3PO_4 + 10H_2 \end{aligned}$$

In the second stage the intermediate products are oxidized in the following way:

$$\begin{aligned} H_3PO_3+H_2O &= H_3PO_4+H_2 \\ 4H_3PO_3 &= 3H_3PO_4+PH_3 \\ PH_3+3H_2O &= H_3PO_3+3H_2 \\ PH_3+4H_2O &= H_3PO_4+4H_2 \end{aligned}$$

At 400°C. without a catalyst complete oxidation of the phosphorus occurs and at 280°C. in the presence of 1% NiO as catalyst the reaction is complete in four minutes. Only the first stage of the reaction is affected by the catalyst, maximum yields of phosphoric acid being obtained with a 3:1 ratio of water to phosphorus. At pressures between 100 and 350 atm. the partial pressure of hydrogen has no apparent effect on the reaction velocity.[256] Yellow phosphorus appears to be oxidized under the above conditions with the same velocity as red phosphorus. The phosphoric acid formed is purer, but the hydrogen is contaminated with phosphine.[257]

Under atmospheric pressure the reaction:

$$P_2+5H_2O = P_2O_5+5H_2$$

takes place slowly at 1000°C. in an atmosphere of nitrogen and in the absence of a catalyst. At 650°C. the reaction is rapidly catalyzed by $Fe_3(PO_4)_2$, the quantity of phosphine decreasing at higher temperatures.[258]

Steam oxidizes phosphorus vapour at 1000° to 1200°C. to form $PH_3$, $P_2O_4$, $P_2O_5$ and $H_2$, the main reactions being:

$$\begin{aligned} P_4+8H_2O &= 2P_2O_4+8H_2 \\ P_2O_4+H_2O &= P_2O_5+H_2 \end{aligned}$$

The formation of phosphine is nearly independent of temperature and decreases as the steam/phosphorus ratio is increased. Complete oxidation to $P_2O_5$ and elimination of $PH_3$ formation occurs in the presence of phosphate rock. The calculated equilibrium constant for the second of the above reactions is not in good agreement with experimental results. The latter seem to favour the formation of $P_4O_8$ and $P_4O_{10}$.[259]

Platinum and palladium supported on aluminium metaphosphate or zirconium pyrophosphate are stable and very active catalysts for the reaction[260]:

$$P_4+16H_2O = 4H_3PO_4+10H_2$$

Copper is an active, but less stable, catalyst. Using nitrogen as carrier gas the optimum conditions for over 99% oxidation of the phosphorus to phosphoric acid are 650° to 800°C., steam/phosphorus molar ratio of 16–30, and space velocities of 640–9500/hr. (The space velocity is the volume of $P_4$ gas, water vapour and carrier gas, per unit volume of catalyst.) Traces of phosphine and phosphorous acid are removed by heating the reaction products at 400°C. in a secondary catalyst chamber. At 700°C. with a steam/phosphorus ratio of 22 the percentage of phosphorus present as phosphorous acid in the product is given by the expression:

$$\%\ H_3PO_3 = 1{\cdot}1+6{\cdot}11\times 10^{-4}V$$

where $V$ is the space velocity. The phosphorous acid formed increases with the reaction temperature as shown in Fig. 5.

Some thermodynamic data for the reaction:

$$P_4(g)+16H_2O(g) = 4H_3PO_4(85\%)+10H_2(g)$$

are given in Table XXIII.

Operation of the reaction on a pilot plant scale has been described.[261–2]

Mixtures of carbon dioxide and phosphorus vapour containing more than 11% phosphorus quickly attain equilibrium at 800° to 1200°C. with the conversion of about 80% of the carbon dioxide to monoxide. For mixtures containing less than 11% of phosphorus all the latter is oxidized to phosphorus tetroxide and pentoxide. Calculation of the equilibrium constant from the experimental data suggests that the reactions involved are:

$$P_4+8CO_2 = 8CO+2P_2O_4$$
$$P_2O_4+CO_2 = CO+P_2O_5$$

In the presence of phosphate rock, phosphorus is oxidized completely to metaphosphate under the above conditions.[263]

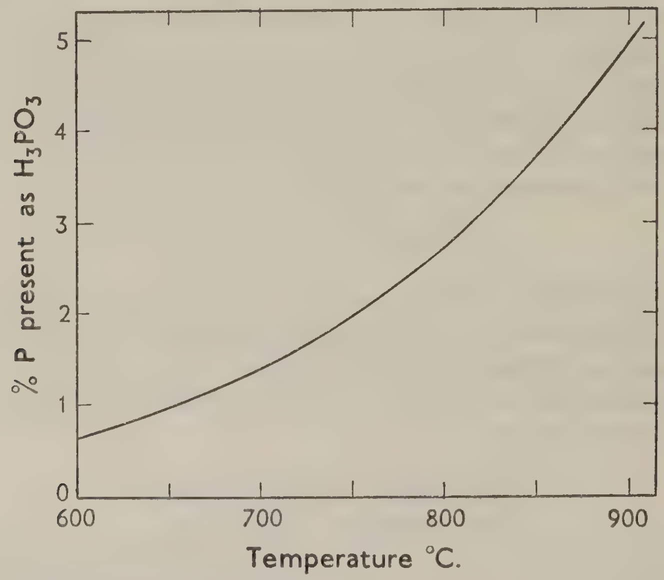

FIG. 5.—Effect of temperature on the amount of trivalent phosphorus in the oxidation of phosphorus vapour with steam

Under controlled conditions phosphorus vapour can be oxidized to phosphorus pentoxide in the presence of carbon monoxide. For mixtures containing 1% of phosphorus, 40% of carbon monoxide and 59% of nitrogen, and using 1·65 times the amount of air required to oxidize the phosphorus, a negligible amount of carbon monoxide is oxidized at 600°C. With higher concentrations of phosphorus (7% P, 85–92% CO) at 700°C. and using 25% excess of air, 22% of the carbon monoxide is oxidized. A greater excess of air and higher temperatures increase the amount of carbon monoxide oxidized and at 900°C. oxygen is consumed so fast in this reaction that the phosphorus oxidation is incomplete. Preferential oxidation of the phosphorus is increased by adding sufficient water vapour to the system to give metaphosphoric acid as the end product.[264]

*Table XXIII.—Thermodynamic Data for the Oxidation of Phosphorus Vapour with Steam*[260]

| Temp. °C. | $-\Delta H$ g.-cal./mole | $-\Delta G$ g.-cal./mole | $K$ (pressures in atm.) |
|---|---|---|---|
| 25 | 300,100 | 198,650 | $4{\cdot}98\times10^{145}$ |
| 100 | 292,400 | 174,000 | $9{\cdot}14\times10^{101}$ |
| 200 | 279,650 | 143,800 | $2{\cdot}75\times10^{66}$ |
| 300 | 263,900 | 117,500 | $2{\cdot}87\times10^{44}$ |
| 500 | 225,200 | 70,800 | $1{\cdot}08\times10^{20}$ |
| 700 | 175,900 | 36,600 | $1{\cdot}65\times10^{8}$ |
| 727 | 168,500 | 32,800 | $1{\cdot}50\times10^{7}$ |
| 827 | 139,500 | 20,640 | $1{\cdot}27\times10^{4}$ |
| 1000 | 83,600 | 6,000 | 10·8 |
| 1100 | 55,400 | 1,200 | 1·56 |

The air-oxidation at 20°C. and at atmospheric pressure of solid phosphorus deposited on ground quartzite is reported[265] to give the oxides $P_4O$, $P_4O_2$, $P_4O_6$ and $P_4O_{10}$. This reaction is complete in less than five minutes, but is preceded by an activation period which depends on the amount of phosphorus involved. The activation time is 30 min. when 1·3% of phosphorus is deposited on the quartz, and increases to 36 hr. when the amount of deposit is 0·85%. The $P_4O/P_4O_{10}$ ratio in the product is always 2:3. Ozone eliminates the induction period and the product then contains only $P_4O_6$ and $P_4O_{10}$.

The slow oxidation of moist yellow phosphorus in the presence of charcoal at room temperature gives a mixture of acids containing approximately 3% $H_3PO_2$, 0–14% $H_3PO_3$, 10–25% $H_4P_2O_6$ and 63–77% $H_3PO_4$.[266]

The heterogeneous catalysis of the reaction of phosphorus with water has been discussed.[267] If aqueous suspensions of phosphorus are exposed to light for up to a year, phosphorous acid, some phosphoric acid and traces of hypophosphorous acids are formed and a residue of red phosphorus remains. The transformation of yellow to red phosphorus seems to be the main reaction. The following reactions can then occur[268]:

$$\begin{aligned} 4P+6H_2O &= 3H_3PO_2+PH_3 \\ 2H_3PO_2 &= H_3PO_4+PH_3 \\ PH_3+O_2 &= HPO_2+H_2 \\ 4H_3PO_3 &= 3H_3PO_4+PH_3 \end{aligned}$$

The oxidation of phosphorus in liquid iron at 1500° to 1650°C. has been studied by adding phosphorus, in an atmosphere of water vapour and hydrogen, to molten iron containing 0·02% C, 0·01% Mn, 0·01% Ni, 0·007% Cr and 0·002% S.[269] With 1·2% or less of phosphorus in the system the reaction is:

$$2P(g)+3Fe(l)+8H_2O(g) = (FeO)_3P_2O_5(l)+8H_2(g)$$

for which the free energy and equilibrium constant are given by[270]:

$$\Delta G = 26{\cdot}6T-125{,}500$$

$$\log_{10} K = \frac{27{,}400}{T} - 58$$

At phosphorus contents of 1·2 to 3·0% the reaction is:

$$4P(g)+3Fe(l)+13H_2O(g) = (FeO)_3P_2O_5(l)+13H_2(g)+P_2O_5$$

and the free energy and equilibrium constant are given by:

$$\Delta G = 77{\cdot}95T-111{,}600$$

$$\log_{10} K = \frac{24{,}400}{T} - 17{\cdot}0$$

For the reaction:

$$4P(g)+13O(g)+3Fe(l) = (FeO)_3P_2O_5(l)+P_2O_5$$

the corresponding data are:

$$\Delta G = 226{\cdot}5T-531{,}000$$

$$\log_{10} K = \frac{118}{T} - 58{\cdot}2$$

The free energy of the reaction:

$$2P(g)+5H_2O(g) = P_2O_5(g)+5H_2(g)$$

is given by:

$$\Delta G = 13{,}900-51{\cdot}37T$$

Refs. p. 264

For phosphorus–oxygen equilibria in molten iron systems it has been shown that in the temperature range 1540° to 1580°C. the free energy of the reaction:

$$2[P]+5H_2O(g)+4CaO(s) = Ca_4P_2O_9(s)+5H_2(g)$$

as calculated from the expression:

$$\Delta G^\circ = 0{\cdot}0729T-187{\cdot}9 \text{ kcal.}$$

agrees closely with experimental data.[271]

The equilibrium constant,

$$K_p = \frac{(FeO)^5[\Sigma P]}{[Fe]^5(P_2O_5)}$$

where concentrations are in percentage by weight, for the reaction:

$$5FeO+2P = P_2O_5+5Fe$$

is 0·056 at 1450°C. and 0·091 at 1525°C. for the ternary Fe–P–O system containing 4–5% P. Magnesium and calcium oxides lower the value of $K_p$ but $SiO_2$ increases it.[272]

The oxidizing and combustion properties of white[273] and red[274] phosphorus have been used to produce chemical smokes,[275] incendiaries[276] and flame throwers.[277]

Red phosphorus is oxidized by ceric sulphate in the presence of phosphoric acid. The reaction is bimolecular and between 30° and 60°C. has a temperature coefficient of 1·46 for every 10°C. rise in temperature. At 32° to 42°C., 37° to 47°C. and 47° to 57°C. the activation energies are 7404, 7502 and 7765 g.-cal., respectively. The mechanism suggested for the reaction is[278]:

$$\begin{aligned} 2Ce(SO_4)_2+H_2O &= Ce_2(SO_4)_3+H_2SO_4+O \\ 2P+5O &= P_2O_5 \\ P_2O_5+3H_2O &= 2H_3PO_4 \end{aligned}$$

In acid solutions of potassium permanganate the reaction is[279]:

$$P+MnO_4^- = PO_4^{3-}+Mn^{2+}$$

Refluxing red phosphorus for 6–8 hr. in N sulphuric acid with 5–10 times its weight of potassium chlorate oxidizes 90% of the phosphorus:

$$6P+5KClO_3+9H_2O = 6H_3PO_4+5KCl$$

Small amounts of manganous sulphate catalyze the reaction to some extent.[280]

Red phosphorus is quantitatively oxidized by refluxing for 1 hr. with an acid (0·5N $H_2SO_4$) solution of potassium bromate[281]:

$$6P+6KBrO_3+3H_2SO_4+6H_2O = 6H_3PO_4+3Br_2+3K_2SO_4$$

At 30° to 55°C. the reaction is bimolecular with respect to bromate.[282] A second order reaction is reported for the oxidation of phosphorus with acid solutions containing one mole of bromine to five moles of bromate[283]:

$$5Br^-+BrO_3^-+6H^+ = 3Br_2+3H_2O$$

A similar but slower oxidation, requiring 3 hr. heating under reflux, occurs with potassium iodate[284]:

$$6P+6KIO_3+3H_2SO_4+6H_2O = 6H_3PO_4+3I_2+3K_2SO_4$$

This reaction is a composite one; the first stage:

$$5P+3IO_3^-+3H^++6H_2O = \tfrac{3}{2}I_2+5H_3PO_3$$

is slow and also produces some phosphate. This is followed by a rapid oxidation:

$$2P+3I_2+6H_2O = 6H^++6I^-+2H_3PO_3$$

The oxidation of the phosphite by iodate ion is very slow:

$$5H_3PO_3 + 2IO_3^- = I_2 + 3H^+ + 5H_2PO_4^- + H_2O$$

and the rate-determining step, which is catalyzed by hydrogen ions, is probably given by:

$$H_3PO_3 + I_2 + H_2O = 3H^+ + 2I^- + H_2PO_4^-$$

This reaction is somewhat faster than that involving iodate ions.[284]

The oxidation of red phosphorus by iodine in potassium iodide solution is bimolecular with a temperature coefficient of 4·101–3·198 at 20° to 35°C., the activation energy being 25,870–24,370 g.-cal.[285] Complete oxidation of the phosphorus takes place in 24–30 hr. at room temperature when the phosphorus to iodine molar ratio is 1:4. At 60°C. and a molar ratio of 1:3 the reaction is complete in 10 hr. The equation for the oxidation is inferred to be[286]:

$$2P + 3I_2 + 6H_2O = 2H_3PO_3 + 6HI$$

Oxidation with periodate according to the equation:

$$14P + 10KIO_4 + 5H_2SO_4 + 16H_2O = 14H_3PO_4 + 5K_2SO_4 + 5I_2$$

takes place quantitatively on heating under reflux for 4–5 hr. in 0·05–2·0N $H_2SO_4$ solution using a molar $KIO_4$:P ratio of 5:7.[287] In 0·5N $H_2SO_4$ this oxidation is of second order. The velocity constant $K$ was calculated from the equation:

$$K = tC_\alpha \log_e \frac{C_t(C_0 - C_\alpha)}{C_0(C_t - C_\alpha)}$$

where $t$ is the time in minutes, $C_0$ is the initial $KIO_4$ concentration, and $C_t$ and $C_\alpha$ are the concentrations at time $t$ and $\alpha$, respectively. Values of $K$ are given in Table XXIV when the initial concentration is N/15 $KIO_4$.[288]

*Table XXIV.—Oxidation of Red Phosphorus by Potassium Periodate*[288]

| Temperature °C. | Velocity constant $K \times 10^4$ mole/l./min. |
|---|---|
| 25 | 2·63 |
| 30 | 4·45 |
| 35 | 6·15 |
| 40 | 8·55 |

The oxidation of phosphorus by $XO_3^-$, $XO_4^-$, $X^-$–$XO_3^-$ mixtures and by $X^-$–$XO_4^-$ mixtures, where X is a halogen, has been summarized as follows.

The primary reaction with $XO_3^-$ or $XO_4^-$ in acid solution slowly forms $X_2$, phosphorous acid, and a small quantity of phosphate. A rapid secondary reaction of phosphorus with $X_2$ forms phosphorous acid initially and a further slow reaction then yields phosphoric acid and $X^-$. This last oxidation is the rate-determining step.

Mixtures of $X^-$–$XO_3^-$ and $X^-$–$XO_4^-$ liberate $X_2$ instantaneously and quantitatively in acid solution and the main oxidizing reaction is between $X_2$ and phosphorus. The rate of reaction of phosphorus increases with increasing concentration of oxidizing agent and with the temperature. Increase in temperature, however, causes volatilization of $X_2$. High concentrations of HCl and $NO_3^-$ interfere with the reaction. The most suitable acidity is 0·5–2·0N $H_2SO_4$.[289]

The reaction between phosphorus and iodine in carbon tetrachloride has been discussed on page 247. This has been modified and applied as a reduction process in organic chemistry. A number of organic compounds can be reduced at temperatures below 100°C., using phosphorus and potassium iodide with hydrochloric acid as diluent. For temperatures up to 150°C. phosphoric acid of sp. gr. 1·7 may be used,

Refs. p. 264

but sulphuric acid is unsuitable because it is reduced by the hydrogen iodide formed in the reaction.[290]

Molten iodine bromide reacts violently with phosphorus to form tri- and pentabromides.[291] A similar reaction occurs with iodine monochloride to form iodine and phosphorus pentachloride.[292]

The oxidation of elemental phosphorus with copper nitrate and similar reagents to form hypophosphoric acid is discussed in Section XXII. In the treatment of phosphorus burns with cupric salts the action of the latter is fastest at pH 10.[293]

Phosphorus heated in the dry state with alkaline-earth hydroxides and alkali metal nitrates forms ammonia, phosphine and hydrogen. When excess of nitrate is present in the mixture, nitric oxide, but no ammonia, results.[294] Magnesium, calcium or barium hydroxide forms phosphine free from diphosphine, $P_2H_4$.[295] Lithium hydroxide yields phosphine and $Li_3PO_4$.[296]

Red phosphorus reacts at room temperature with nitryl fluoride to form nitryl hexafluorophosphate. The reaction appears to proceed in the following stages[297]:

$$\begin{aligned} P+5NO_2F &= PF_5+5NO_2 \\ PF_5+NO_2F &= NO_2PF_6 \end{aligned}$$

White phosphorus and nitrososulphuryl fluoride react to give nitrosoyl hexafluorophosphate, $NOPF_6$.[298] Sulphuryl chloride converts phosphorus into phosphorus trichloride, red phosphorus being apparently more easily chlorinated than the white form.[299] The latter explodes with selenium monochloride,[300] reacts violently with selenium tetrafluoride and inflames in contact with selenium oxyfluoride.[301] Small amounts of white phosphorus dissolve in vanadium oxytrichloride without apparent reaction but in larger proportions an explosive reaction occurs at temperatures below 100°C.[302]

A slow reaction takes place, with formation of $P_2H_4$, when a concentrated aqueous solution of potassium hydroxide is added at room temperature to a solution of white phosphorus in glycerol. A yellow precipitate with the composition $P_5H_2$ is deposited on standing for several days.[303]

Red phosphorus with sulphur has been used in the polymerization of $\alpha$-olefins to form synthetic lubricants.[304] This has been applied to olefins containing 6 to 14 carbon atoms, at temperatures of 250° to 450°C. and pressures up to 280 atm.[305] Black phosphorus itself has also been suggested as a lubricant additive.[307]

An ether solution of white phosphorus forms colloidal gold when heated with chloroauric acid ($HAuCl_4$) in the presence of potassium hydroxide.[306]

An excellent review of the organic reactions of elemental phosphorus has appeared.[308] These reactions fall into three broad classes: the reactions of phosphorus with nucleophilic compounds such as organometallic derivatives; those with electrophilic compounds (e.g. alkyl halides); and those with alcohols or alkenes, which occur under oxidizing conditions. The products are often complex in nature, and good yields of individual compounds are seldom obtained.

### SECTION VI

# PHOSPHORUS HYDRIDES AND PHOSPHONIUM COMPOUNDS

### BY E. J. LOWE

## PREPARATION

Phosphine is reported to be a major product of the hydrolysis of phosphorus triiodide[1] and a minor product of the hydrolysis of phosphorus tribromide[1] and triphosphorus hexaoxydi-iodide.[161] A mixture of phosphine and hydrogen is obtained by the reaction of phosphorus with dry alkaline earth hydroxides[2] and lithium hydroxide.[3] Phosphine and sodium hypophosphite are obtained in higher yield and greater purity by reacting white phosphorus with sodium hydroxide in 70% v/v methanol/water mixtures instead of in water.[162] The reaction of phosphorus with steam, the main product of which is phosphoric acid, yields phosphine as a by-product,[4–7] the best yield being obtained from the reaction under pressure at the relatively low temperature of 300°C. and in the absence of any catalyst. All of the phosphorus present in the gases from a phosphorus blast furnace can be converted to phosphine by blowing steam through the furnace[8]; it is suggested that reaction occurs between the phosphorus and active hydrogen. Phosphine has also been produced by passing phosphorus vapour and steam through a bed of coke at 700–1000°C.,[9] and is evolved on heating white or red phosphorus under aqueous phosphoric acid, zinc chloride and calcium chloride solutions at atmospheric pressure and temperatures above 170°C.[9]

The thermal decomposition of sodium hypophosphite to give phosphine has been followed thermogravimetrically.[10] The other products are claimed to be sodium pyrophosphate and sodium metaphosphate, which at temperatures above 300°C. recombine giving sodium triphosphate[163]:

$$5NaH_2PO_2 \rightarrow Na_5P_3O_{10} + 2PH_3 + 2H_2$$

It is suggested[11] that phosphine is formed in the thermal decomposition of calcium phosphite by the reduction of phosphite or phosphate with hydrogen. Alkali metal phosphites or hypophosphites decompose in the presence of phosphoric acid at 190° to 400°C., giving phosphine and a phosphite-free glassy polyphosphate residue.[225] Phosphine is produced by the reduction of ammonium phosphates, orthophosphoric acid and metaphosphoric acid with hydrogen at temperatures above 600°C.[12–3] The reduction of metaphosphoric acid by natural methane at 1050°C., however, gave mostly phosphorus and only a minor amount of phosphine.[164]

Elemental phosphorus and hydrogen do not combine at normal temperatures and pressures to form phosphine,[14] but it can be prepared by rapidly cooling the reaction products of phosphorus with hydrogen energized by a high current arc.[15] Good yields of phosphine are obtained by causing phosphorus trichloride to react with lithium aluminium hydride in the presence of diethyl ether at temperatures below 0°C.,[16] but only a 0·25% yield is obtained at 75°C. in the absence of diethyl ether. However, lithium hydride is claimed to give commercially acceptable yields of phosphine under these conditions.[226] The reduction of phosphites or hypophosphites by sodium borohydride in acid solution also gave only traces of phosphine.[165]

Phosphine is liberated at the anode in the electrolysis of sodiophosphine and potassiophosphine in liquid ammonia,[17] the anode reaction being

$$6PH_2^- + 2NH_3 - 6e^- = 6PH_3 + N_2$$

It is evolved from the electrolysis of vanadium pentoxide in an acid sodium phosphate melt,[18] and it is claimed[19] that phosphine is liberated from a mercury cathode in the electrolysis of an aqueous solution containing sulphuric acid, potassium sulphate and an oxide of phosphorus, and it is also obtained in good yield from the electrolysis of an aqueous acid in the presence of white phosphorus.[20]

Some phosphine is formed by the acid hydrolysis of indium phosphide.[166] A safe laboratory procedure for the preparation of phosphine is the hydrolysis of aluminium phosphide in an inert liquid miscible with water.[167] The reaction of hydrochloric acid with a boiling alcoholic suspension of aluminium or zinc phosphide gives phosphine free from diphosphine or acetylene.[168] Excellent yields of phosphine of high purity can be obtained by reacting finely divided amorphous phosphorus, made by partial conversion of yellow phosphorus, with polyphosphoric acid and steam at temperatures above 250°.[227] Phosphine containing little hydrogen and free from diphosphine is obtained on heating an aqueous acid above zinc amalgam in the presence of white phosphorus.[9]

The formula, $P_2H_4$, for liquid diphosphine has been confirmed by careful determination of its molecular weight.[21] No evidence of higher homologues was obtained from the reaction between white phosphorus and aqueous potassium hydroxide.[21] A yellow precipitate of composition $P_5H_2$ was obtained from the reaction of white phosphorus in glycerol with concentrated aqueous potassium hydroxide.[22] At room temperature in an anhydrous sealed system diphosphine, $P_2H_4$, decomposes with evolution of phosphine to form a yellow solid of composition close to $P_9H_4$, but in the presence of moisture substances of composition close to $P_{12}H_6$ are formed.[23] When $P_2H_4$ is heated phosphine is evolved to yield non-stoicheiometric solid hydrides having H:P ratio less than 4:9.[23]

More recently a whole series of higher linear and cyclic phosphine hydrides (phosphanes) has been detected, as resulting from the pyrolysis of diphosphine (diphosphane), or the careful hydrolysis of calcium phosphide. They can be separated by fractional condensation or crystallization at $-30$ to $-78$°C.[219–21] or by gas-liquid chromatography on a kieselguhr/silicone oil column at 60°C.[220] and identified by mass spectrography. Only $P_3H_5$ is at present known in a reasonably pure state,[219] as a white solid stable at $-23$° but decomposing without melting when warmed, to give phosphine and a yellow solid, possibly $P_2H$. Higher homologues which have been obtained in the form of fairly highly enriched fractions are shown below, together with diphosphorus dihydride (diphosphane-2) so far only detected by a mass spectrum peak in the products of pyrolysis of $P_2H_4$ at 0·1 torr and 300–400°K.[222]

| | $P_nH_{n+2}$ | $P_nH_n$ | $P_nH_{n-2}$ | $P_nH_{n-4}$ | Others |
|---|---|---|---|---|---|
| Diphosphanes | $\mathit{P_2H_4}$ | $\mathrm{P_2H_2}$ | | | |
| Triphosphanes | $\mathit{P_3H_5}$ | $\mathit{P_3H_3}$ | | | |
| Tetraphosphanes | $\mathit{P_4H_6}$ | $\mathit{P_4H_4}$ | $\mathrm{P_4H_2}$ | | |
| Pentaphosphanes | $\mathrm{P_5H_7}$ | $\mathit{P_5H_5}$ | $\mathit{P_5H_3}$ | | |
| Hexaphosphanes | $\mathrm{P_6H_8}$ | $\mathrm{P_6H_6}$ | $\mathit{P_6H_4}$ | $\mathrm{P_6H_2}$ | |
| Heptaphosphanes | $[\mathrm{P_7H_9}]$ | $\mathrm{P_7H_7}$ | $\mathrm{P_7H_5}$ | $\mathit{P_7H_3}$ | |
| Octaphosphanes | | $\mathrm{P_8H_8}$ | $[\mathrm{P_8H_6}]$ | $\mathit{P_8H_4}$ | |
| Nonaphosphanes | | $\mathrm{P_9H_9}$ | | $\mathrm{P_9H_5}$ | $\mathit{P_9H_3}$ |
| Decaphosphanes | | $[\mathrm{P_{10}H_{10}}]$ | $[\mathrm{P_{10}H_8}]$ | | $\mathit{P_{10}H_4}$, $\mathrm{P_{10}H_2}$ |
| Undecaphosphanes | | | | | $\mathit{P_{11}H_6}$, $\mathrm{P_{11}H_3}$ |
| Dodecaphosphanes | | | | | $\mathrm{P_{12}H_4}$ |
| Tetradecaphosphanes | | | | | $[\mathrm{P_{14}H}]$ |

Italicized formulae are of compounds especially favoured at a particular value of $n$, while those in brackets are doubtful at present. There is a clear tendency for cyclic and condensed phosphanes of lower hydrogen content to be favoured over linear phosphanes, with increasing values of $n$. The higher phosphanes are volatile materials, decomposing slowly at 0°C. in the dark and rapidly at room temperature in daylight, to phosphine and solid yellow compounds of high P content.[221] A nomenclature similar to that of the boranes has been suggested: e.g. $P_3H_3$ = triphosphane-3, $P_9H_4$ = nonaphosphane-4.[220] From the shift of the appearance potential of the $P_2H_2^+$ peak between 300 and 430°K., the standard heat of formation of $P_2H_2$ has been calculated as $+26 \pm 5$ kcal./mole.[222]

In contact with boiling ammonia, diphosphine decomposes with evolution of phosphine to yield an ammonia-soluble black residue of variable composition in the P:H ratio range of 3·05–4·81:1 and $NH_3$:H range of 0·09–0·92:1.[24] With liquid ammonia the solid hydride $P_9H_2$ gives an amorphous product of composition $P_9H_{1\cdot38}(NH_3)_x$.[25] A solid phosphorus hydride was obtained from the reaction of a cobalt–tin–phosphorus alloy with concentrated hydrochloric acid.[26]

Phosphorane, $PH_5$, is not found among the hydrogenation products of phosphorus pentachloride with excess of lithium borohydride at $-80°$ or lithium aluminium hydride at $-100$°C.[188] In the latter case only phosphine and hydrogen are found. Similarly the only phosphorus-containing products from the reduction of phosphoryl bromide or chloride with lithium hydride, aluminium hydride or lithium aluminium hydride are phosphine and the solid polymeride $(PH)_n$. Although phosphine oxide was not isolated it may be an intermediate:

$$POCl_3 \rightarrow [PH_3O] \rightarrow [PH_2OH] \rightarrow (PH)_n$$

This suggestion is supported by the isolation of a white crystalline adduct, $PH_3OBH_3$, when lithium borohydride is used for the reduction. The adduct was stable at $-115°$, but decomposed at $-90°$, evolving hydrogen, and giving a viscous polymer $PH_2OBH_2$.[189] A kinetic study of the oxidation of phosphine by hypochlorite suggested that the formation of phosphine oxide was a rate determining step, but that its subsequent oxidation was very fast.[190]

By treatment of phosphine with bromine, phosphorus pentabromide and phosphorus pentachloride, the existence of such partially halogenated phosphines as $PH_4Br$, $PH_2Br$ and $PH_2Cl$ was indicated but not definitely established.[27] A laboratory preparation of phosphonium iodide, $PH_4I$, has been described.[28, 191] Phosphonium perchlorate has been prepared[159–60] by passing phosphine through cold aqueous perchloric acid. The salt is very explosive and could not be obtained dry, its composition being given as $PH_3,HClO_4$[159] and $2PH_3,3HClO_4$.[160] The analogous preparation of phosphonium perrhenate was unsuccessful.[160]

## PHYSICAL PROPERTIES OF PHOSPHINE

Transitions in solid phosphine have been reported at temperatures $30{\cdot}3_2°$, $88{\cdot}5_3°$ and $139{\cdot}6_6$°K. (melting point),[29, 30] at 30·29°, 49·43° and 88·10°K.[31] with heats of transition of 19·6, 185·7 and 115·8 g.-cal./mole, respectively, and at 139·35°K. (m.p.)[31] under the triple-point pressure of 27·33 mm. Hg with heat of fusion of 270·4 g.-cal./mole. A test of the third law of thermodynamics is made possible by evaluation of the entropy of two crystalline forms of this substance because of the slow conversion of the unstable to the stable form of solid phosphine at 49·43°K. The entropy of the stable and unstable forms at 49·43°K. is 8·14 and 8·13 g.-cal./degree/mole, respectively.[31] There is a region of abnormally high heat capacity in the supercooled solid between 30·29 and 35·66°K.[31] The change in volume on melting has been studied.[32] Calculation of the molar volume of liquid and solid phosphine gave 44·08 and 41·83 c.c., respectively, at the triple point 139·41 ± 0·05°K. The experimentally determined heat of vaporization at the b.p. (760 mm. Hg) is given as 3492 ± 4 g.-cal./mole at 185·7°K.,[30] 3489 ± 3 g.-cal./mole at 185·38°K.,[31] and 3493 ± 3 g.-cal./mole at 185·72°K.[33] Vapour pressure curves are given[31] for solid phosphine in the temperature range 128·67–139·35°K. as $\log_{10} P(\text{mm.}) = 7{\cdot}86434 - 895{\cdot}700/T$, and for liquid phosphine in the temperature range 139·35–185·56°K. as

$$\log_{10} P(\text{mm.}) = 10{\cdot}73075 - 1027{\cdot}300/T - 0{\cdot}0178530T + 0{\cdot}000029135T^2$$

which gives the heat of vaporization at the boiling point as 3472 g.-cal./mole. On the basis of the significant structure theory of liquids, the vapour pressure, molar heat capacity, molar volume and entropy of liquid phosphine have been calculated over the range 140–185°K. and show good agreement with observed values.[230] The surface tension of liquid phosphine calculated by the same authors also agreed well with previous data.[52] The entropy of vaporization of phosphine has been related to the internal order within the liquid.[34] The entropy of phosphine gas at the b.p. has been determined from experimental thermal data to be 46·39[30] and 46·39 ± 0·1[31] g.-cal./degree/mole, and calculated[30] from structural and spectroscopic data to be 46·43 g.-cal./degree/mole. The entropy at 298·1°K. is 50·35[31] g.-cal./degree/mole from thermal data and 50·5 ± 0·1,[35] 50·20,[36, 169] 50·22[170] and 50·23[37] g.-cal./degree/mole from spectroscopic data. Values of heat content $H^\circ$, free energy $G^\circ$ and heat capacity $C_p^\circ$ are also given for $PH_3$ and $PD_3$ over a range of temperatures.[169] Values of the heat capacity at constant pressure $C_p^\circ$, the entropy $S^\circ$, and the free energy function, $-(\phi^\circ - H_0^\circ)/T$, have been calculated for the molecules $PH_2D$, $PHD_2$, $PH_2T$, $PHT_2$, $PDT_2$ and PHDT over the temperature range 298·2 to 1000°K.[218] The entropy of the phosphonium ion, $PH_4{}^+$, is calculated from spectroscopic data to be 48·82 g.-cal./degree/mole at 298·16°K.[37]

## Thermodynamic Properties

Experimental determinations of the equilibrium $4P_{red} + 6H_2 \rightleftharpoons 4PH_3$ have been made[38] over the temperature range 627–771°K. and the data obtained have been analysed.[35–6, 216] For the gas phase reaction $P_4(g) + 6H_2(g) = 4PH_3(g)$

$$K_p = P^4_{PH_3}/P_{P_4} \times P^6_{H_2}$$

is $1 \times 10^{-11}$ atm.$^{-3}$ at 627°K. and $1{\cdot}9 \times 10^{-12}$ atm.$^{-3}$ at 771°K. Calculation for 298·1°K. gives the standard free energy change for the reaction

$$P_{(\text{solid, white})} + \tfrac{3}{2}H_2(g) = PH_3(g)$$

as $\Delta G^\circ_{298\cdot 1} = -3140$ g.-cal./mole, which indicates that thermodynamically there is a tendency for white phosphorus and hydrogen to combine to form phosphine although the rate of the reaction is not appreciable below about 300°C. For the reaction $P_4(g) + 6H_2(g) = 4PH_3(g)$, $\Delta H_0^\circ$ is estimated as $+1530$ g.-cal. Values of $(H^\circ - H_0^\circ)$ and $-(G^\circ - H_0^\circ)/T$ are tabulated for phosphine over the temperature range 298·1–1500°K.[36, 224] Tables of heat capacity, entropy, reduced isobaric-isothermal potential and reduced enthalpy have been calculated for phosphine over the temperature range 298–1000°K.[39] For phosphine gas, using the best thermodynamic data,[36] the constants in the empirical heat capacity equation $C_p = a + bT + cT^2$ are $a = +4{\cdot}496$, $b = +0{\cdot}014372$ and $c = -0{\cdot}000004072$.[40] This equation gives maximum deviation 0·29% and mean deviation 0·13% in the temperature range 298·1–1500°K. There is some uncertainty about the heat of formation of phosphine. The equilibrium data[38] give $\Delta H_f^\circ$ as $-2360$ g.-cal./mole, but this value is subject to a wide spread. Values of $-2300$[41] and $+2210$[42] g.-cal./mole are quoted. A direct determination[43] of the heat of formation of phosphine and diphosphine by examining the explosive decomposition of the hydrides in admixture with stibine, $SbH_3$, gave for phosphine, $PH_3$, $\Delta H_f^\circ = +1300 \pm 400$ g.-cal./mole, and for diphosphine, $P_2H_4$,

$$\Delta H_f^\circ = +5000 \pm 1000 \text{ g.-cal./mole}$$

From values of appearance potentials of various positive ion species in the mass spectra of phosphine and diphosphine, heats of formation have been calculated[171] for phosphine, $PH_3$, $\Delta H_f^\circ = 2300$ g.-cal./mole and for diphosphine, $P_2H_4$,

$$\Delta H_f^\circ = 9900 \text{ g.-cal./mole}$$

The thermochemistry of phosphine and phosphonium compounds has been discussed.[172, 224]

### Density, Critical Constants, Etc.

From a careful study of the density and compressibility of phosphine, the atomic weight of phosphorus was found to be 30·977.[44–5] The normal density of gaseous phosphine $L_0^{760}$ is 1·5307 g./l. and the factor for the compressibility between zero and 1 atm. pressure is $(1+\lambda)=1{\cdot}0091$.[45] The normal density of gaseous phosphine derived from the actual density measured between zero and 1 atm. satisfies an equation[46] of the form $L_p$ (g./l.) $=a+b_p$, where $a=1{\cdot}516817$ and $b=0{\cdot}013938$ for $p=1$ atm.

Certain relations between the critical constants of the inert gases and of gaseous hydrides, including phosphine, have been derived.[47] An isotope effect has been demonstrated by comparing the critical temperatures of phosphine, $PH_3$ (325·1°K.) and trideuterophosphine, $PD_3$ (323·6°K.).[173] Values of the critical constants for liquid phosphine calculated on the basis of the significant structure theory of liquids show reasonable agreement with observation.[230]

Data of state were determined for phosphine in the temperature range 190–300°K. and the experimental values of the secondary virial coefficient $B$ in the equation $PV_m=RT+BP$ were calculated.[48] $B$ can be expressed in terms of a power series in $1/T$ and ranges from $-452{\cdot}3$ c.c. at 189·9°K. to $-152{\cdot}6$ c.c. at 296·95°K. Good agreement is obtained with values of $B$ computed from critical data using Berthelot's equation, which shows that this equation can be used without serious error. The equation $p=[CT/(v+B)]-[A/(T(v+B)^2)]$ for the line of saturation of liquids and vapours has been derived and compared with van der Waals' equation, and the constants $A$ and $B$ have been determined from critical data for many compounds including phosphine.[49] The regular boiling-point relation between phosphine and the alkylphosphines indicates that phosphine is not associated.[50] Also comparison with the hydrides of neighbouring elements in the Periodic Table shows little or no evidence of hydrogen bonding,[51] although the physical properties of phosphine indicate that there may be some association in the liquid.[52] The degree of gas imperfection $\beta$ in the equation $PV/RT=1+\beta/V$ has been evaluated for several gases.[53] For phosphine $\beta=379$ at a b.p. of 185·35°K. or 143 at a b.p. of 185·72°K., giving $N_2/N_1=0{\cdot}038$ and 0·032, respectively, as the ratio of double to single molecules present in the gas at 1 atm. pressure.

Adsorption isotherms have been obtained for phosphine on both activated carbon and silica gel.[54–6] Adsorption of phosphine by cupric oxide-coated carbon[57] and by potassium benzenesulphonate[58] has also been studied. The dielectric constant for phosphine is 1·003373 at $-47$°C., 1·002381 at 16°C. and 1·001687 at 100°C.[59] The observed dipole moment (0·55 D.,[59] $0{\cdot}578\pm0{\cdot}010$ D.[182]) can only be explained by assuming the participation of the lone pair electrons on phosphorus in *sp* type hybridized orbitals.[174] The diamagnetic susceptibility of phosphine is $-26{\cdot}2\times10^{-6}$ c.g.s. units/mole.[175] Critical potentials have been determined for the ionization and dissociation of phosphine by electron bombardment, and the ions produced have been examined using a mass spectrometer.[60–1, 176]

The intense ultra-violet absorption of phosphine and deuterophosphine in the 1850–2500 A. region[177–8] shows a band structure which can be explained on the assumption that the upper state of $PH_3$ and $PD_3$ is pyramidal, with a barrier to inversion so low that all observed transitions are to levels well above the barrier.[179] The infra-red spectrum[180–1] and the microwave spectrum[182–3] of phosphine and deuterophosphine have also been recorded. The phosphorus nuclear magnetic resonance spectrum of liquid phosphine at $-90°$ shows the expected 1–3–3–1 quadruplet, of chemical shift $+238\pm1$ p.p.m. (relative to 85% $H_3PO_4$).[184] Calculated values of the vibration frequencies (cm.$^{-1}$) in the phosphine and trideuterophosphine molecules are in good agreement with observation, and force constants have been derived.[231]

## PROPERTIES OF DIPHOSPHINE AND PHOSPHONIUM HALIDES

Diphosphine melts at $-99$°C.[21] Vapour pressure data have been obtained for diphosphine[61, 21] which may be expressed[23] as $\log_{10} P(\text{mm.})=7{\cdot}330-1498/T$ in the temperature range 195–290°K.; tetradeuterodiphosphine, $P_2D_4$, has a vapour pressure which also satisfies this equation at least in the temperature range 195–240°K. The extrapolated boiling point of diphosphine is 63·5°C., Trouton's constant is 20·46, and the heat of vaporization is 6889 g.-cal./mole.[23]

The nuclear magnetic resonance spectrum of diphosphine is consistent with relatively rapid interconversion between two skew forms of the molecule. The similarity of the $J_{PH}$ coupling constants in $PH_3$ and $P_2H_4$ suggests that there is probably no great difference in bond hybridization and length between the two molecules.[185] The Raman spectrum of tetradeuterodiphosphine, $P_2D_4$, has been recorded.[186]

The specific heat of phosphonium iodide increases steadily in the temperature range $-180$ to $+10$°C. from 11·97 to 24·86 g.-cal./degree/mole.[62] Measurement of the low temperature density and coefficient of expansion has given the molar volume of phosphonium iodide as 55·9 c.c. at 0°K.[63] The magnetic susceptibilities of phosphonium bromide and phosphonium iodide are $-53{\cdot}0\times10^{-6}$ and $-71{\cdot}5\times10^{-6}$ c.g.s. units respectively at 15°C.[64] Measurement of the magnetic moment of solid phosphonium iodide has been used to demonstrate the variation of Overhauser effect with temperature.[65] The Raman spectrum of phosphonium iodide shows two intense lines consistent with its tetrahedral structure.[187]

## DISSOCIATION OF PHOSPHINE

An attempt[38] to synthesize phosphine by passing phosphorus vapour and hydrogen through a heated tube did not achieve the equilibrium previously reported for the decomposition of phosphine under similar conditions. This equilibrium was shown to be affected by the phosphine streaming rate. The decomposition of phosphine and deuterophosphine on hot wires has been studied.[66–7] The decomposition of phosphine on molybdenum at 500°C. is unimolecular at 0·01–0·1 mm. Hg pressure and tends to zero order at increased pressure up to 300 mm. Hg. At 500°C. the decomposition of phosphine on tungsten is practically independent of pressure. At 800–970°K. the decomposition of phosphine and deuterophosphine on tungsten is of first order at the lowest pressure of $1\times10^{-3}$ mm. Hg. The energy difference for $PH_3$ and $PD_3$ is 550 g.-cal. The equilibrium constants $K_I = p_{P_4}^{1/4}\cdot p_{H_2}^{3/2}/p_{PH_3}$ for the dissociation $PH_3 \rightarrow \frac{1}{4}P_{4(vap.)} + \frac{3}{2}H_2$, and $K_{II} = p_{H_2}^{3/2}/p_{PH_3}$ for the dissociation $PH_3 \rightarrow \frac{1}{4}P_{4(solid)} + \frac{3}{2}H_2$, are given by the equations[216]

$$\log K_{II} = 387/T + 0{\cdot}272 \log T + 1{\cdot}32\times10^{-3}T$$

and

$$\log K_I = -275/T + 2{\cdot}46 \log T - 4{\cdot}0\times10^{-4}T - 3{\cdot}74 \ (300\text{–}1300°)$$

The mercury-photosensitized exchange reaction between deuterium and gaseous phosphine has been investigated[68] in the temperature range 20–600°C. at pressures of 100–500 mm. Hg. The activation energy for the reaction $D + PH_3 \rightarrow PH_2D + H$ is 14·4 kcal. and for the reaction $H + PD_3 \rightarrow PD_2H + D$ is 15·0 kcal. The equilibrium constant for the reaction $PH_3 + HD \rightleftharpoons PH_2D + H_2$ calculated from spectroscopic data varies from 1·37 at 0°C. to 1·05 at 700°C. The photochemical decomposition of phosphine requires collision of a phosphine molecule with an excited metal atom to give H and probably $PH_2$ as the first step. Recombination of these products by a wall reaction is indicated.[69–71] The effect of added gases has been studied and is consistent with the above postulation. The $PH_2$ radical has been detected in the products of the photochemical dissociation of phosphine.[214] Flash photolysis of phosphine gives hydrogen and red phosphorus, probably by way of $PH_2$ and $P_2$ radicals.[192, 213] The photochemical dissociation of trideuterophosphine gives a slightly greater quantum yield than is obtained for phosphine,[72] the difference being attributed to differing secondary reaction efficiencies.

## ACID–BASE CHARACTER AND SOLUBILITY

Phosphine dissolves in water to yield a neutral solution.[73] The effect of acids and bases on this solubility is small and does not differ enough from the effect of dissolved neutral salts to be ascribed to acidic or basic properties of phosphine. The ratio of the concentration of solute in the solution phase to the concentration of solute in the gas phase has the mean value 0·201 ± 0·005 for a solution of phosphine in water at 297·5°K., Henry's law being obeyed below 1 atm. pressure. The variation with temperature of the solubility of phosphine in water is shown in Fig. 1, and the derived enthalpy of solution is $-2950 \pm 100$ g.-cal./mole. The solubility of phosphine in organic solvents is shown in Tables I and II and is much greater than in water.[9, 74, 193] The solubilities shown in Table I were obtained[9, 74] directly by allowing an excess of phosphine to come to equilibrium with the solvent in a closed system at substantially atmospheric pressure. Those shown in Table II were obtained[193] indirectly by gas–liquid distributive chromatography. The enthalpy of solution of phosphine in toluene

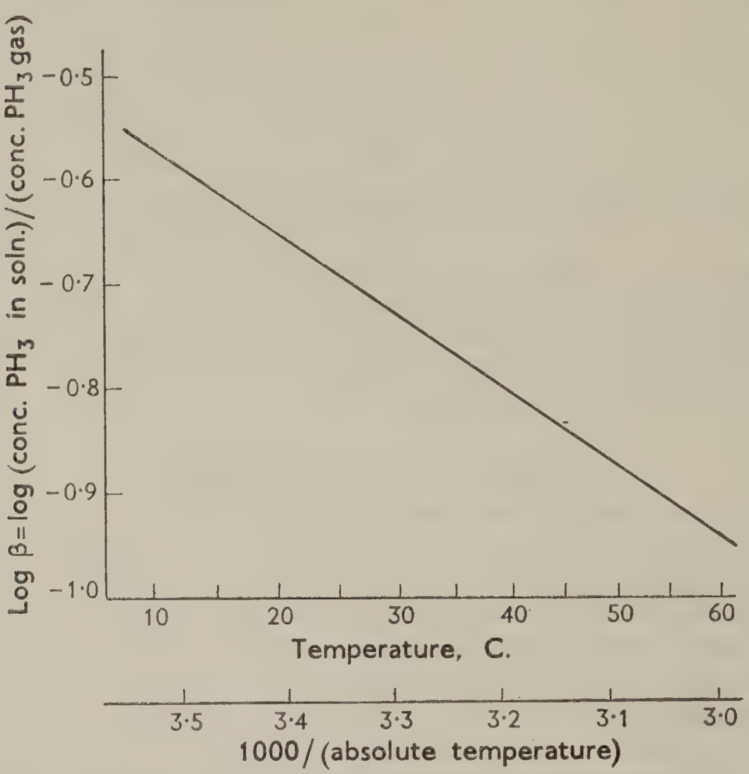

FIG. 1.—Solubility of phosphine in water, where β is the Ostwald solubility coefficient

*Table I.—Solubility of Phosphine in Organic Solvents*

| Solvent[9] | Temperature °C. | Solubility (ml. per ml. of solvent) |
|---|---|---|
| Acetone | 22·4 | 4·45 |
| Acetic acid | 20·0 | 3·19 |
| 1,2-Ethanediol | 19·2 | 1·45 |
| Propylene oxide | 22·8 | 3·06 |
| 1,2-Dichloroethane | 21·3 | 5·48 |
| 1-Nitropropane | 21·3 | 4·26 |
| Nitrobenzene | 22·5 | 3·06 |
| Aniline | 22·0 | 2·80 |
| Carbon disulphide | 21·0 | 10·25 |
| Carbon tetrachloride | 20·5 | 4·19 |
| *n*-Pentane | 21·5 | 4·33 |
| *n*-Decane | 20·9 | 5·73 |
| Benzene | 22·0 | 7·26 |
| Toluene | 22·0 | 7·15 |
| *cyclo*Hexane | 18·5 | 7·47 |
| Trifluoroacetic acid[74] | 26·0 | 15·9 |

is −3760 g.-cal./mole over the temperature range 20–40°C.,[9] and varies from −950 to −6000 g.-cal./mole over the temperature range 5–50°C. for other solvents.[193] The solubility is expressed as the volume of phosphine (measured at the temperature of the experiment and at 1 atm. pressure) dissolved in one volume of solvent under a phosphine partial pressure of 1 atm.

*Table II.—Solubility of Phosphine in Organic Solvents*

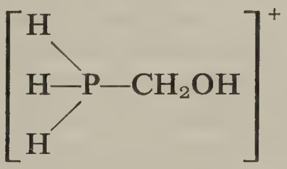
| Solvent | Distribution constant at 20°C. | Heat of solution over range 5–50°C. g.-cal./mole | Activity coefficient at −3·5°C. |
|---|---|---|---|
| Nitrobenzene | 8·59 | −1560 | 0·345 |
| Liquid paraffin | 15·9 | −3000 | 0·312 |
| Furfural | 11·8 | −3400 | 0·263 |
| 2′,2′-dichlorodiethyl ether | 20·0 | −2200 | 0·135 |
| Ethyl cellosolve | 9·4 | −950 | 0·205 |
| Didecyl phthalate | 23·5 | −4000 | 0·171 |
| Triethoxysilane | 12·2 | −5400 | 0·240 |
| Tetraethoxysilane | 12·45 | −5000 | 0·210 |
| Silicone 702-DF | 15·3 | −3600 | 0·807 |
| PFMS-4F | 16·5 | −2300 | 0·316 |
| VKZh-94B | 25·3 | —6000 | 0·208 |

The distribution constant is expressed as the volume of phosphine, measured at the partial pressure of the phosphine, dissolved in one volume of solvent.

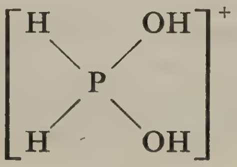
The equilibrium constant for the exchange $PH_2D(g) + H_2O(g) \rightleftharpoons PH_3(g) + HDO(g)$ using measured equilibrium data for the exchange

$$PH_2D(g) + H_2O(l) \rightleftharpoons PH_3(g) + HDO(l)^{75}$$

is calculated to be 1·52 at 25°C. No direct measurement of the acid–base strength of phosphine has been reported. The acidic and basic dissociation constants have been estimated[76] from kinetic data obtained by measuring the rate of approach to equilibrium in the hydrogen exchange between phosphine and water. Estimated values for the acid and base dissociation constants for phosphine in water are $1{\cdot}6 \times 10^{-29}$ and $4 \times 10^{-28}$, respectively. Despite the extremely small dissociation constants, proton transfers account very well for the chemical characteristics of the phosphorus–hydrogen bond.[77] It is suggested that the acid catalyzed reaction of phosphine with formaldehyde in aqueous solution proceeds via the quasi-phosphonium ion



This reaction is also reported to be subject to general metal catalysis.[78] Quasi-phosphonium ions have often been suggested as intermediates in reactions of phosphorus compounds; a sound basis for such proposals arises from a study of the tautomeric equilibrium in hypophosphorous acid[79] which proceeds via the cation



The proton affinities, or energies of the reaction $PH_4^+ \rightarrow PH_3 + H^+$ calculated from Born–Haber cycles, for phosphonium iodide, phosphonium bromide and phosphonium chloride are $-200 \pm 10$, $-209 \pm 21$ and $-217 \pm 22$ kcal., respectively.[80] A later determination gives molar lattice energies of 147·3 ± 5, and 141·2 kcal., respectively, for $PH_4Br$ and $PH_4I$, leading to a mean value of 194·5 ± 5 kcal./mole for the absolute proton affinity of phosphine.[229]

Phosphine dissolves in liquid hydrogen chloride giving phosphonium chloride which is sparingly soluble in the medium. The saturated solution has a moderate conductivity, and can be titrated with boron trichloride or boron trifluoride to give solid tetrahaloborates. Phosphonium tetrachloroborate, $PH_4BCl_4$, is similar to phosphonium iodide in stability, while the chlorotrifluoroborate, $PH_4BF_3Cl$, is somewhat less stable.[194] Phosphonium tetrabromoborate, $PH_4BBr_4$, can similarly be formed by treating a suspension of phosphonium bromide in liquid hydrogen bromide with boron tribromide.[195]

Measurements of the electrical conductivity of liquid ammonia solutions of phosphine and the solid phosphorus hydride, $P_{12}H_6$, indicate formation of salt-like compounds between ammonia and the hydrides.[81] On electrolysis of a solution of phosphine in liquid ammonia, phosphorus is deposited on the anode, apparently by discharge of the $P^{3-}$ ion.[17] The anode reaction $6PH_2^- + 2NH_3 = N_2 + 6PH_3 + 6e^-$ applies to the electrolysis of sodiophosphine and potassiophosphine in liquid ammonia,[17] but a more complicated series of reactions occurs in the similar electrolysis of tetrasodium diphosphide, protons liberated during solvent oxidation in the primary anode reaction becoming available to form the species $P_2H^{3-2-}$, $P_2H_2^{--}$ and $P_2H_3^-$ on reaction with the protophilic diphosphide ion. The ion $PH_2^-$ is proposed as an intermediate in the reaction of phosphine with methyl chloride in liquid ammonia to yield methylphosphines.[82]

The organic phosphines exhibit increasing basic properties with increasing degree of substitution. The relative basicities of phosphine and methylphosphines have been compared[83] and the basic strengths of many tertiary phosphines determined.[84] The rate of addition of alkyl halides to tertiary phosphines to give quaternary phosphonium halides is roughly correlated with the basicity of the phosphines in water.[84] Measurement of the dissociation constants of some tertiary phosphine oxides indicates that the oxides do not possess basic character.[85]

## ADDITION PRODUCTS

Phosphine forms addition compounds with a number of salts in which bonding presumably derives from donation of the unshared pair of electrons on the phosphorus atom. *X*-Ray measurements have shown that such sharing does occur in the case of the addition compound $(CH_3)_3P,AuBr_3$.[86] Diborane, $B_2H_6$, in the gas phase above −30°C., or preferably in the liquid phase above −110°C., reacts readily with phosphine to form diborane diphosphine, $B_2H_6,2PH_3$.[87] A kinetic study[88] of the homogeneous gas phase reaction of diborane with phosphine at 0°C. to yield the solid product $BH_3,PH_3$ gave observations consistent with the rate-controlling reaction $B_2H_6 + PH_3 \rightarrow BH_3,PH_3 + BH_3$ which has an activation energy of 11·4 kcal./mole. An inconclusive attempt has been made to verify this mechanism by comparison of $\Delta H$ for the reaction with postulated limits of $\Delta H$.[89] Diborane diphosphine is rapidly decomposed by water with the formation of hydrogen, phosphine and boric acid. A solution of diborane diphosphine in liquid ammonia evolves phosphine at −60°C. and yields a white solid of approximate composition $B_2H_6,PH_3,NH_3$. The compounds $B_2H_4Cl_2,2PH_3$, $B_2H_2Cl_4,2PH_3$ and $BCl_3,PH_3$, have been obtained by the reaction of diborane diphosphine with hydrogen chloride.[87] Boron trichloride phosphine is not completely dissociated in the gas phase at room temperature. It has a dipole moment of 5·2 ± 0·1 D. in benzene solution.[196] Diboron tetrachloride and phosphine at −78·5° form $B_2Cl_4,2PH_3$, a white solid which has a vapour pressure of 0·7 mm. at 25°C. and decomposes to give phosphonium chloride at 65°.[197]

Boron trifluoride and phosphine react at −130°C. to give the product $BF_3,PH_3$.[90] There is also evidence for the existence of the complex $2BF_3,PH_3$.[91]

Aluminium chloride and aluminium bromide react with phosphine at 70°C. and aluminium iodide reacts at 120–130°C. to form the white crystalline compounds $AlCl_3,PH_3$, m.p. 81–83°C., $AlBr_3,PH_3$, m.p. 114–118°C. and $AlI_3,PH_3$, m.p. 148–150°C., which can be readily fused and sublimed.[92] The chloride complex combines exothermically with alkyl halides to give primary alkyl phosphines.[198] Similar compounds with phosphine were not obtained in the case of beryllium halides.[92] The reaction of phosphine with other metal halides[93–4] yields $2SnCl_4,3PH_3$, $TiCl_4,2PH_3$, $TiCl_4,PH_3$, $TiBr_4,2PH_3$, $TiBr_4,PH_3$, $CuCl,2PH_3$, $CuCl,PH_3$, $CuBr,2PH_3$, $CuBr,PH_3$, $CuI,2PH_3$, $CuI,PH_3$, $AgI,PH_3$, $2AgI,PH_3$ and the very unstable product $AuI,PH_3$. The other silver and gold halides, tin tetraiodide, titanium tetraiodide and zirconium chloride do not react with phosphine. The heats of formation of some metal halide phosphines have been calculated from vapour pressure data[94] and measured calorimetrically[95]; these range from 8·6 to 16·0 kcal./mole of gaseous phosphine added to the solid metal halide. Copper halide phosphines have also been prepared by the reaction of phosphine and the copper halide in alcoholic solution.[96] The copper halide phosphines are soluble in ethanol, diethyl ether, acetone, chloroform, carbon tetrachloride and benzene.[96] Both carbon tetrachloride and silicon tetrachloride are soluble in liquid phosphine.[93]

Diphosphine reacts with boron trifluoride giving a product $P_2H_4,2BF_3$ which is fairly stable below −118°, but rapidly evolves phosphine at higher temperatures. Diborane and diphosphine yield a white solid, $P_2H_4,B_2H_6$, which is stable at −78°. It melts with little decomposition at −40°, but at room temperature evolves $B_2H_6$, $PH_3$ and $H_2$, leaving a non-stoicheiometric solid containing boron, phosphorus and hydrogen.[199]

It has been proposed[97, 25] that solid hydrogen phosphide, $P_{12}H_6$, is a sorption compound of phosphine and amorphous phosphorus. Theoretical consideration[98] of the structure of inert gas hydrates indicates that the formula of the solid phosphine hydrate should be $PH_3,5{\cdot}9H_2O$, the water occupying voids between the phosphine molecules.

The organic derivatives of phosphine form addition compounds which are similar to those formed by phosphine itself. Some of these compounds have proved of considerable interest. For example, mixtures of dimethylphosphine and trimethylaluminium react at temperatures above 215°C. to form methane and a solid trimeric product having formula $[(CH_3)_2P.Al(CH_3)_2]_3$ which probably has a six-membered ring structure of alternating phosphorus and aluminium atoms.[99] The extremely stable trimeric product having formula $[(CH_3)_2P.BH_2]_3$ is obtained when the addition compound formed between dimethylphosphine and borine is heated at 150°C.[100] This trimer also probably has a six-membered ring structure of alternating phosphorus and boron atoms. An extensive chemistry of organic compounds exhibiting phosphorus–boron bonding has been developed. Tertiary phosphines have been purified by distillation of carbon disulphide from their carbon disulphide adduct, for example $(CH_3)_3P,CS_2$.[101] Complex co-ordination compounds are formed between tertiary phosphines and platinum salts,[102–5] palladium salts,[105–6] nickel salts[107] and aqueous silver ions.[108] *Cis* and *trans* isomers have been obtained for the addition compounds based upon platinum.[102, 109] Compounds have been prepared in which tertiary phosphines partly replace the carbonyl group in iron,[110–11] ruthenium[112] and rhodium[112] carbonyl halides.

Unlike the phosphorus halides, phosphine does not form an addition compound with osmium tetroxide, $OsO_4$.[113]

## OXIDATION OF PHOSPHINE

The reaction of phosphine with oxygen has been widely studied and shown to involve a branching chain reaction. At ordinary temperatures a phosphine–oxygen mixture reacts explosively between two sharply defined pressure limits which depend on the composition of the mixture. The lower explosion limit is diminished by ultraviolet radiation owing to the formation of an active substance from the phosphine[114] or to a surface effect.[70–1] The lower explosion limit is also diminished by the presence of inert gases[115–7] which impede chain diffusion to the walls of the containing vessel. The inhibition is lost when the pressure of the inert gas reaches the same order of magnitude as that of the phosphine and oxygen. As the temperature is raised the lower explosion pressure limit falls and the upper limit rises.[118] At and above the upper limiting pressure oxygen is an inhibitor.[119–20] The upper limit of partial pressure of oxygen is proportional to the square root of the partial pressure of phosphine.[121] At high pressures the chain reaction is not affected by the walls of the containing vessel, but deactivation occurs when an activated species strikes both an oxygen molecule and a third body.[122] The upper and lower explosion limits of trideuterophosphine coincide with those of phosphine, the chain lengths are identical, and the individual steps in the oxidation of deuterophosphine and phosphine have similar rates.[72] At pressures below the lower explosion limit the reaction between phosphine and oxygen is immeasurably slow. Reaction at low pressure is induced by ignition in the presence of tungsten and molybdenum filaments and occurs almost wholly on the surface of the metal.[123] Mixtures of phosphine and oxygen ignite by dilatation[124] with instantaneous reaction if the gases are very dry. The ignition pressure rises sharply with increasing temperature and increases with increased phosphine partial pressure. The ignition pressure falls with increasing water content of the gases and falls very slightly in the presence of inert gases. Methylphosphine, $CH_3PH_2$, depresses the ignition pressure and does not itself ignite with oxygen on dilatation.[124] The rôle of the hydroxyl radical in the mechanism of combustion of phosphine and other hydrogen-containing compounds has been discussed.[125] Results of the flash photolysis of mixtures of phosphine and oxygen above the upper, and below the lower, explosion limits are consistent with a mechanism in which OH and $PH_2$ radicals carry on the straight chains, while O atoms are involved in branching only.[200]

The selective oxidation of phosphine in admixture with other oxidizable gases, for example gases obtained from the reaction of phosphorus with steam, has received some attention. Suitable oxidants include oxygen,[126] oxygen with nitric acid[127–8] and $NO+NO_2$ as catalyst,[129] aqueous phosphoric acid-containing ozone,[130] steam[131–2] in the presence of metal catalysts, sulphuric acid[133] with catalysts, sulphur dioxide[8] and anodic oxidation in phosphoric acid electrolyte.[134] A study has been made of the catalytic oxidation of phosphine adsorbed on active carbon[135–8] and of the phosphine-induced oxidation of carbon monoxide.[139–40]

Hypophosphorous acid is formed by the oxidation of phosphine in an aqueous suspension of iodine.[141]

## OTHER REACTIONS

Neutron bombardment of phosphine yields radiophosphine, hydrogen and phosphorus.[142] No evidence of higher hydride formation was detected in experiments in which phosphine was brought into contact with atomic hydrogen.[143–4] The main products of the reaction between phosphine and active nitrogen are molecular hydrogen and α-polyphosphorus nitride, $(PN)_n$.[145] Phosphine reacts with heated uranium,[146–7] uranium hydride,[148] thorium[149] and thorium hydride[150] to form the metal phosphide. It reacts with heated sulphur to give gaseous hydrogen sulphide and a residue comprising a mixture of phosphorus sulphides.[151] Phosphine reacts with hydrogen sulphide much more slowly than with sulphur, the reaction proceeding significantly only at temperatures above 320°C. to produce hydrogen and ill-defined phosphorus sulphides.[151] The reaction of phosphine with sulphur dichloride, $SCl_2$, gives a yellow viscous liquid of composition approximating to $H_2ClPS$. Trifluoromethylsulphenyl chloride, on the other hand, has yielded bis(trifluoromethyl)phosphine, $(CF_3S)_2PH$ (v.p. 149 mm. at 40°) and tris(trifluoromethyl)phosphine, $(CF_3S)_3P$. The latter is a colourless liquid, f.p. $-75°$, v.p. 30·5 mm. at 20°, and it decomposes above 50°.[201]

Pure sodiophosphine, $NaPH_2$, can be prepared by causing phosphine to react with a liquid ammonia solution of triphenylmethyl sodium.[152] Lithiophosphine, $LiPH_2$, is obtained almost quantitatively from the reaction of phosphine with phenyl lithium.[153] Both are colourless solids, which ammonolyze slowly in contact with liquid ammonia. Potassiophosphine, $KPH_2$, can, however, be prepared as a white, spontaneously inflammable solid, by direct interaction of phosphine with a solution of potassium in liquid ammonia, and shows little tendency to ammonolysis even during several days at $-33°$.[232–3] Phosphine reacts with ethyl magnesium bromide to give $PH_2MgBr$[152] or $PH(MgBr)_2$.[154] Trimethyl indium reacts with boiling liquid phosphine to give the complex $Me_3In,PH_3$. This decomposes at $-78°$ evolving $PH_3$ and $Me_3In$, and leaving a residue $(MeInPH)_x$, which further decomposes violently to methane and indium phosphide at 270° to 300°.[202] Gallium oxide is reduced by phosphine to gallium phosphide in high yield at 950°C.[203] Phosphine reacts with lithium aluminium hydride in diethyleneglycol dimethyl ether, yielding unstable $LiAl(PH_2)_4$. No reaction occurred in the absence of solvent.[204]

The partially substituted metal phosphine derivatives have found application as intermediates in organo-phosphorus chemistry.[205] The reaction of phosphine with solutions of nickel salts to give nickel phosphides and ill-defined alloys has been studied in various solvents.[155] The formation of $P(HgCl_2)_3$ by reaction between phosphine and aqueous mercuric chloride solution has been applied analytically.[156, 228] The pyrolysis of silane, $SiH_4$, with phosphine has been reviewed.[157] The complex mixture of silylphosphines and silanes includes monosilylphosphine, $PH_2SiH_3$, a colourless liquid b.p. 12·7°C.[206–7] decomposed by acid, alkali, ammonia or alcohol, with the formation of phosphine.[208] Trisilylphosphine, $P(SiH_3)_3$, is obtained by the reaction of silyl bromide and potassiophosphine:

$$3SiH_3Br + 3KPH_2 \rightarrow P(SiH_3)_3 + 2PH_3 + 3KBr$$

It is a colourless liquid, spontaneously inflammable in air, and has a vapour pressure given by $\log p = -(1901{\cdot}9/T + 7{\cdot}792)$ over the range $-30°$ to 11°C.[209]

With aliphatic aldehydes phosphine may form α-hydroxyalkylphosphines or phosphonium salts, 1,3-dioxa-5-phospha*cyclo*hexane derivatives, or spirophosphonium salts.[210] In strong acid media ketones give primary and secondary phosphine oxides.[211] Phosphine reduces aromatic nitrocompounds to azoxy derivatives in high yields, and converts sulphonyl chlorides, $RSO_2Cl$, to the corresponding mercaptans RSH, disulphides RSSR and phosphorotrithioates $(RS)_3PO$.[212]

That diphosphine is less reactive than phosphine is ascribed to a general observation that repetition of a function within a molecule causes lowered reactivity of the molecule.[158]

The acid hydrolysis of mixed phosphides, arsenides, nitrides and germanides of calcium and magnesium gives the following products, detected by mass spectroscopy[215]:

$Mg_3P_2/Mg_3As_2$: $P_3H_5$, $As_3H_5$ and $PH_2AsH_2$
$Mg_3P_2/Mg_3N_2$: $P_3H_5$, $PH_2NH_2$, $PH(NH_2)_2$, $P(NH_2)_3$ and $P_2H_3NH_2$
$CaGe/Ca_3P_2$: $P_3H_5$ and $GeH_3PH_2$

Trigermylphosphine, $(GeH_3)_3P$, prepared by treating trisilylphosphine with a small excess of germanyl bromide at room temperature, is a colourless liquid, m.p. $-83{\cdot}8°$, v.p. at 0° ~ 1 mm., which decomposes slowly at room temperature and rapidly at 55°. The infra-red and Raman spectra suggest strongly that the molecule is not planar.[217] The action of the electrodeless discharge on gaseous equimolecular mixtures of $PH_3 + H_2S$ or $PD_3 + H_2S$ at 0·1 torr, gives the compounds $H_2PSH$ or $D_2PSD$, identified by their mass spectra, and decomposing above $-130°$ to an amorphous involatile yellow residue. Their infra-red spectrum shows a sharp absorption at 477 cm.$^{-1}$, identified with the P–S single bond.[223]

## SECTION VII

# THE METAL PHOSPHIDES

### BY A. WILSON

The early literature is well reviewed by Mellor[1] and Gmelin.[2] In more recent work, methods of preparation, heats of formation, and methods of determination have been collected together for transition metal phosphides,[3] whilst melting points and a few thermochemical data have been included in a review dealing with phosphides as well as other classes of compounds.[4] Unit cell dimensions and magnetic susceptibilities have been given for a series of rare earth phosphides[547] whilst densities, oxidation resistances, decomposition temperatures, hardnesses and specific resistivities have been given for some transition-metal phosphides.[566] A valuable summary of crystal data, densities and thermal data for fifty-two metallic phosphides appeared in a report by the Tennessee Valley Authority,[5] but the most comprehensive collections of data on phosphides and their chemistry have been made by Hansen,[6] whose emphasis is on phase diagram work, by Samsonov and Vereikina,[7] by Aronsson, Lundström and Rundqvist[689] and by Van Wazer.[8]

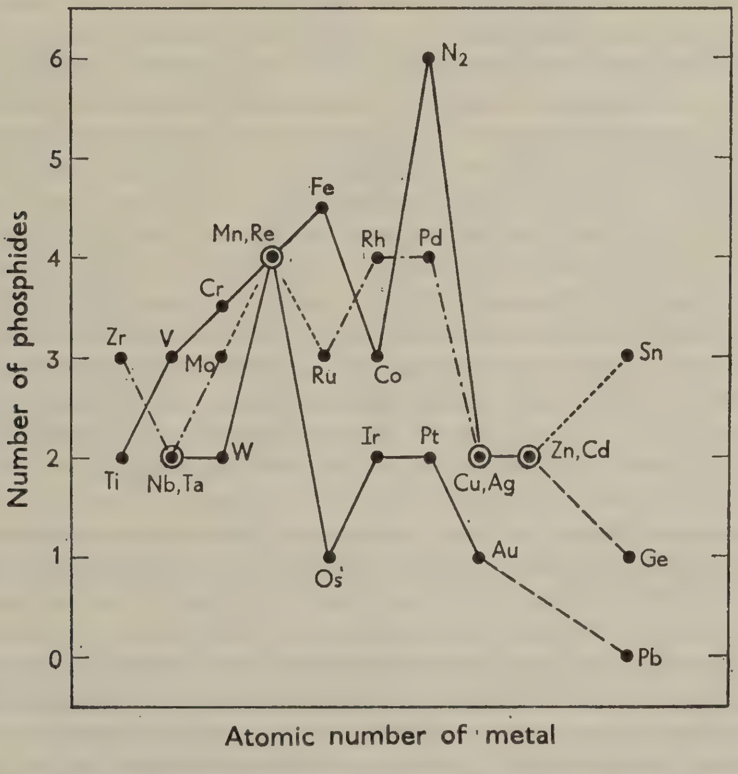

FIG. 1.—Periodic frequency of phosphides

Methods of preparation of phosphides will be discussed under the different metals concerned but two methods which have been used most successfully are the 'Faraday Method' and electrolysis of fused salts.[9–10] The 'Faraday Method' consists essentially of heating the metal with excess of red phosphorus at high temperatures in an inert atmosphere or in an evacuated sealed tube, whilst the fused-salts method consists in electrolyzing molten alkali-metal phosphates to which appropriate metal oxides or halogen salts have been added. Variations in current, voltage and bath composition give different phosphides. High melting binary phosphides, such as zinc or sodium phosphide, can be made below their melting points from the elements if the metal is reduced to particles small enough to react completely.[583]

A statistical study of the number of stable phosphides formed by different metals has been made, the results for which are summarized in Fig. 1.[11]

A survey of compounds of type XY and $X_2Y$ where Y can be phosphorus has confirmed the assumption that, in general, the densities of stable phosphides are arithmetic means of the densities of the separate components.[12]

Fuller structural information on phosphides is to be found in Section XXXIV, whilst relevant vapour pressure data are given in Section V. Where $\Delta H$ values are given a negative sign indicates a heat loss for the system.

## GROUP 1A

### Lithium

After unsuccessful attempts to prepare trilithium monophosphide by causing lithium to react with phosphorus in liquid ammonia, a material approaching the composition of trilithium monophosphide was eventually obtained by heating together the correct quantities of lithium and phosphorus in a closed vessel.[13] The compound has also been obtained by reacting lithium monophosphide with excess of lithium[14] and by the rather unusual method of treating phenyl lithium in ether with phosphine. The mixture was refluxed, filtered, and washed with ether to give as product trilithium monophosphide.[15] This is a grey compound, having *d* 1·4 g./c.c. and a crystal structure of the sodium arsenide type.[13] The estimated heat of formation is −44 kcal./mole.[16] Trilithium monophosphide is insoluble in dioxan, benzene, ether, tetrahydrofuran and light petroleum, and is sensitive to air and moisture.[15]

The reaction of lithium and phosphorus in liquid ammonia has been used by other workers[17] to obtain a compound with the empirical formula $Li_2P$. It is considered that under such conditions normal phosphides are not obtained and that the product is probably dimeric. In another investigation a residue corresponding closely to $Li_2P$ was obtained when $(PH)_x$ containing lithium hydride was heated slowly to 300°C.[18] Dilithium phosphide, or the product obtained from the synthesis in ammonia, is soluble in liquid ammonia forming a yellow–orange solution which conducts electricity.[17] It has been estimated that the heat of formation is zero.[16]

Lithium monophosphide has been prepared by three different routes although two of them are somewhat similar.[14] In one method lithium metal was added to molten white phosphorus and the excess of phosphorus distilled off under vacuum at 280°C. In the second method lithium was treated with phosphorus vapour below 400°C., whilst in the third method it was obtained by causing lithium hydride to react with red phosphorus at 500°C.[14] The heat of formation has been estimated to be 34 kcal./mole.[16] It is rather a reactive compound and is sensitive to air or moisture. With water a reaction proceeds readily which produces a yellow precipitate identified as $(PH)_x$. If it is heated in a vacuum, decomposition with the formation of phosphorus takes place at 600°C. Other phosphides such as the trilithium phosphide can be prepared from it and at temperatures about 900°C. it reacts with ammonia to form a compound $LiPN_2$.[14]

If phosphine is passed into a solution of lithium in liquid ammonia at −80°C., the blue solution turns yellow and a white crystalline powder, $PH_2Li,4NH_3$, can be recovered.[19] When heated this compound gives a substance with the empirical formula $Li_2PH$.[20] These compounds are probably not true phosphides since other workers have adapted the reaction to the preparation of monosodium phosphine.[21]

Several ternary compounds of lithium with another metal and phosphorus have been reported.[22–9] The compounds lithium magnesium phosphide and lithium zinc phosphide have been prepared by heating the elements together in a bomb in the absence of air.[28] Other ternary compounds, $Li_7VP_4$, $Li_5SiP_3$, $Li_5GeP_3$, $Li_5TiP_3$, $Li_3GaP_2$, $Li_3AlP_2$ and a series represented by the formula $Li_{8-x}Mn_xP_4$ have been made by heating finely ground mixtures of lithium phosphide, metal and phosphorus in bombs at temperatures varying between 500° and 1000°C. Variations of this method have also been successfully employed, ternary compounds being obtained by heating together lithium, metal and phosphorus, or by heating together trilithium phosphide and metal phosphide.[22] An attempt to produce $Li_9CrP_5$ was unsuccessful but by heating together trilithium phosphide, chromium, red phosphorus and sulphur at 800°C., it was possible to prepare mixed crystals of $Li_9CrP_5$ and $Li_2S$. *X*-Ray methods were used to differentiate between the products of these reactions and the reactants.[27] A ternary compound in which the third element was not a metal was prepared by causing trilithium phosphide to react with ammonia at 950°C. and more readily by heating lithium amide with phosphonitrilimide.[14] The last reaction is represented thus:

$$(1) \qquad LiNH_2 + HNPN \xrightarrow{600°C.} LiPN_2 + NH_3$$

In the series $Li_{8-x}Mn_xP_4$ the cubic compound $Li_7MnP_4$ forms a mixed crystal series extending as far as the composition $Li_{6 \cdot 67}Mn_{1 \cdot 33}P_4$. This composition is the beginning of a second mixed series which extends as far as $Li_{5 \cdot 5}Mn_{2 \cdot 5}P_4$.[29] Table I and Table II show some properties and preparation conditions of lithium phosphides.

*Table I.—Data on Some Mixed Phosphides containing Lithium*

| Compound | Colour | Molecular volume (c.c.) | Unit cell constants (kx units) | Ref. |
|---|---|---|---|---|
| LiMgP | brown | 32·6 | 6·01 | 28, 30 |
| LiZnP | brown | 28·8 | 5·77 | 28, 30 |
| $Li_3AlP_2$ | yellow-brown | 58·4 | $a = 11{\cdot}47$, $b = 11{\cdot}61$, $c = 11{\cdot}73$ | 24 |
| $Li_3GaP_2$ | medium brown | 58·0 | 11·74 | 24 |
| $Li_5SiP_3$ | brown | 90·0 | 5·84 | 24 |
| $Li_5GeP_3$ | brown | 91·7 | 5·88 | 24 |
| $Li_5TiP_3$ | brown | 95·4 | 5·96 | 24 |
| $Li_7VP_4$ | brown | | 5·98 | 27 |
| $Li_9CrP_5$ | | | 6·01* | 27 |

* An extrapolated value from data on $Li_9CrP_5$–$Li_2S$ mixed crystals.

Semiconductor properties have been predicted for lithium magnesium phosphide and lithium zinc phosphide.[31] Trilithium aluminium diphosphide has m.p. over 700°C. and a specific resistance greater than $10^8$ ohms cm. at room temperature.[22] It is thought that all of the phosphides listed in Table I have ionic character and they all react rapidly with water or acids to liberate phosphine.[22] This is also true of the grey to black phosphides which are listed in Table II. The water sensitivity of these decreases with increasing manganese content.[29] The compound lithium dinitrogen phosphide appears to be different from the other ternary phosphides. *X*-Ray analysis shows that its crystal structure is body centred tetragonal with lithium atoms lying in tetrahedral holes in a framework of $PN_4$ tetrahedra. The $[PN_{4/2}]'$ group is isoelectronic with $SiO_{4/2}$ which suggests that the compound may be similar to silicates. Other properties are not at variance with this suggestion since lithium dinitrogen phosphide is colourless, stable under vacuum to 1000°C., decomposes without melting at high temperatures, is stable to acids and bases and dissolves slowly in concentrated sulphuric acid.[14]

*Table II.—Lithium–Manganese–Phosphide Preparations with Conditions of Preparation and Unit Cell Constants*

| Preparation | $n$* | Preparation conditions | | Cell constants | | $c/a$ | Volume of the unit cell A.$^3$ |
|---|---|---|---|---|---|---|---|
| | | hr. | °C. | $a$ A. | $c$ A. | | |
| $Li_{7\cdot33}Mn_{0\cdot67}P_4$ | 7·00 | 4 | 850 | 5·977 | | | 213·5 |
| $Li_{7\cdot2}Mn_{0\cdot8}P_4$ | 6·00 | 4 | 850 | 5·977 | | | 213·5 |
| $Li_7MnP_4$ | 5·00 | 4 | 850 | 5·977 | | | 213·5 |
| $Li_{6\cdot8}Mn_{1\cdot2}P_4$ | 4·33 | 4 | 810 | 5·963 | | | 212·0 |
| $Li_{6\cdot67}Mn_{1\cdot33}P_4$ | 4·00 | 4 | 800 | 5·950 | | | 210·7 |
| $Li_{6\cdot6}Mn_{1\cdot4}P_4$ | 3·86 | 4 | 800 | 5·945 | | | 210·1 |
| $Li_{6\cdot5}Mn_{1\cdot5}P_4$ | 3·67 | 4 | 800 | 5·933 | 5·956 | 1·004 | 209·7 |

| $Li_4Mn_4P_4$ | 2·00 | 4 | 800 | 5·841 | 5·964 | 1·021 | 203·5 |

* Oxidation state of the manganese.

## Sodium

Sodium and phosphorus, when heated together in the correct proportions in an inert atmosphere, give the compound trisodium phosphide.[13, 32–3] It has been identified by means of *X*-ray photographs which show it to possess the sodium arsenide type of structure with $a = 4{\cdot}980$ and $c = 8{\cdot}797$ A.[13] Although the existence of this phosphide has been questioned,[8] it now seems to be established as the major product resulting from the reaction of white phosphorus with sodium dispersions in inert organic media.[584] The density, 1·74 g./c.c., has been calculated from the *X*-ray data.[13] From its heat of reaction with N-HCl, which is −149·8 kcal./mole, a heat of formation of −32·0 kcal./mole is calculated.[32] This figure compares with −40·0 kcal./mole, estimated using data for oxides as a guide[16] and a value of −28·3 kcal./mole determined by other workers.[33] This phosphide is easily hydrolyzed and the heat of reaction according to equation (2) is −93·0 kcal.[33]:

$$(2) \qquad Na_3P(s) + 3H_2O(l) \rightarrow 3NaOH(40\% \text{ aq. soln.}) + PH_3(g)$$

Trisodium phosphide has been used as a catalyst for olefin polymerization.[588]

Disodium pentaphosphide (Mellor, VIII, 835) is reported as being formed when monosodium phosphine is heated to 380°C.[20]

Reaction of sodium with phosphorus in liquid ammonia has been studied by two groups of investigators.[17, 34–7] Electrolysis of ammoniacal solutions of sodium was studied. One of the main processes taking place was explained by postulating the protonation of a diphosphide species $P_2^{4-}$.[36–7] Claims to have prepared tetrasodium diphosphide containing two molecules of ammonia of crystallization[17, 34] have been questioned by later workers[35] who state that the products of the reaction are disodium dihydrogen diphosphide and monosodium amide. Chemical analysis and *X*-ray powder photographs were used to identify these two compounds, respectively. The reaction of ammonium bromide with the ammoniacal solutions of sodium and phosphorus has been studied by both groups, one of which[34] puts forward equation (3) to represent the reaction and the other[35] equation (4):

$$(3) \qquad Na_4P_2 + 2Na + 4NH_4Br \xrightarrow[\text{ammonia}]{\text{liquid}} 2NaPH_2 + 4NaBr + 4NH_3$$

$$(4) \qquad Na_2H_2P_2 + 2NaNH_2 + 4NH_4Br + 2Na \xrightarrow[\text{ammonia}]{\text{liquid}} 2NaPH_2 + 4NaBr + 6NH_3$$

An estimate of 3 kcal./mole for the heat of formation of disodium phosphide has been made.[16]

For sodium monophosphide an estimated heat of formation is 34 kcal./mole.[16]

### Potassium

Tripotassium phosphide, formed from phosphorus vapour and potassium, has been shown to have the $Na_3As$ type of structure with $a = 5{\cdot}69$ and $c = 10{\cdot}05$ A.[38] It is green and has $d$ 1·74 g./c.c.[38] An estimated value of $-40$ kcal./mole has been reported for the heat of formation of tripotassium phosphide, while that of dipotassium phosphide is estimated as 3 kcal./mole.[16]

Potassium and phosphorus dissolve in liquid ammonia to form a compound the empirical formula of which is $K_3P_2$. It is probably dimeric and its solution in liquid ammonia conducts electricity. It reacts with lithium or sodium to form mixed phosphides.[17]

Monopotassium phosphide has an estimated heat of formation of 34 kcal./mole.[16]

A dipotassium pentaphosphide is said to be formed from $KPH_2$ when it is heated to 320°C.[20]

An *X*-ray study of $KPH_2$, which is really a substitution product of phosphine rather than a true phosphide, shows it to be monoclinic with $a = 7{\cdot}952$, $b = 4{\cdot}450$, $c = 5{\cdot}275$ A., $\beta = 120{\cdot}5°$, $\rho_{calc.} = 1{\cdot}488$ g./c.c.[39]

### Rubidium

$RbPH_2$, which is probably a substitution compound of phosphine, has been examined by *X*-ray methods and shown to be monoclinic with $a = 8{\cdot}419$, $b = 4{\cdot}746$, $c = 5{\cdot}513$ A., $\beta = 122{\cdot}0°$, $\rho_{calc.} = 2{\cdot}10$ g./c.c.[39]

### Cæsium

Alloys with phosphorus which were of unknown composition have been investigated as photoelectric materials, and found to have a sensitivity lower than fifteen microamperes per lumen.[40]

## GROUP 1B

### Copper

In copper sulphate solution white phosphorus becomes coated with a product the composition of which varies with changes in the concentration of the solution. In 0·1N. copper sulphate, for example, the material is reported as being black and having the composition $Cu_9P_{1{\cdot}6}$.[41]

Heating copper with red phosphorus in an evacuated flask for 20 hr. at 640°C. and then for a further 5 hr. at 1000°C. produces tricopper phosphide.[42] This is also produced when copper phosphates are reduced with hydrogen above 350°C.[43] Electrolytic methods, one involving the electrolysis of fused alkali metal phosphates containing copper compounds[44, 10] and the other the passage of a silent electrical discharge through compounds such as phosphorus trichloride and phosphorus tribromide using copper electrodes,[45] have also been shown to produce tricopper phosphide. A tensimetric analysis of the copper–phosphorus system, shown in Fig. 2, revealed the presence of this phosphide[46] and laboratory scale methods have been described for making copper–phosphorus alloys which contain it.[47] Tricopper phosphide is a dark grey material which melts at 1023°C.[48] and has hexagonal crystal structure, with $a = 7{\cdot}070$ and $c = 7{\cdot}135$ A.[49] Density determinations gave values of $d = 7{\cdot}147$ g./c.c.[42] and $d = 7{\cdot}09$ g./c.c.[44] The molecular volume is 31·0 c.c.[42] A heat of formation of $-32{\cdot}0$ kcal./mole was measured by combining red phosphorus and copper in a bomb at 630°C.,[50] and the free energy of formation of solid $Cu_3P$ from gaseous elements is given as $\Delta G = -47{,}400 + 11{\cdot}3T$ g.-cal./mole over the temperature range $T = 298$–1303°K.[548] Electrical measurements show that tricopper phosphide is almost a metallic conductor; its specific resistance at 0°C. is $1{\cdot}4 \times 10^{-4}$ ohms-cm. and the variation with temperature of this property is shown in Fig. 3. The magnetic

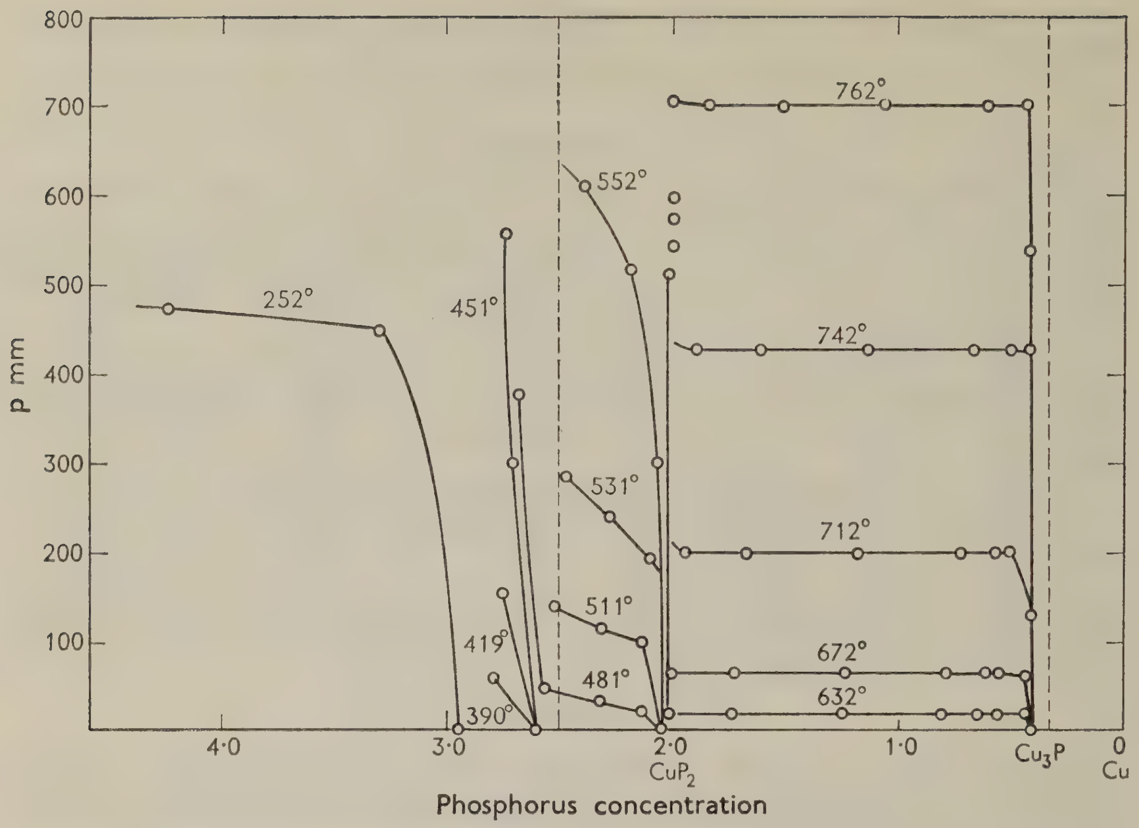

FIG. 2.—Vapour pressure–concentration diagram of the copper–phosphorus system

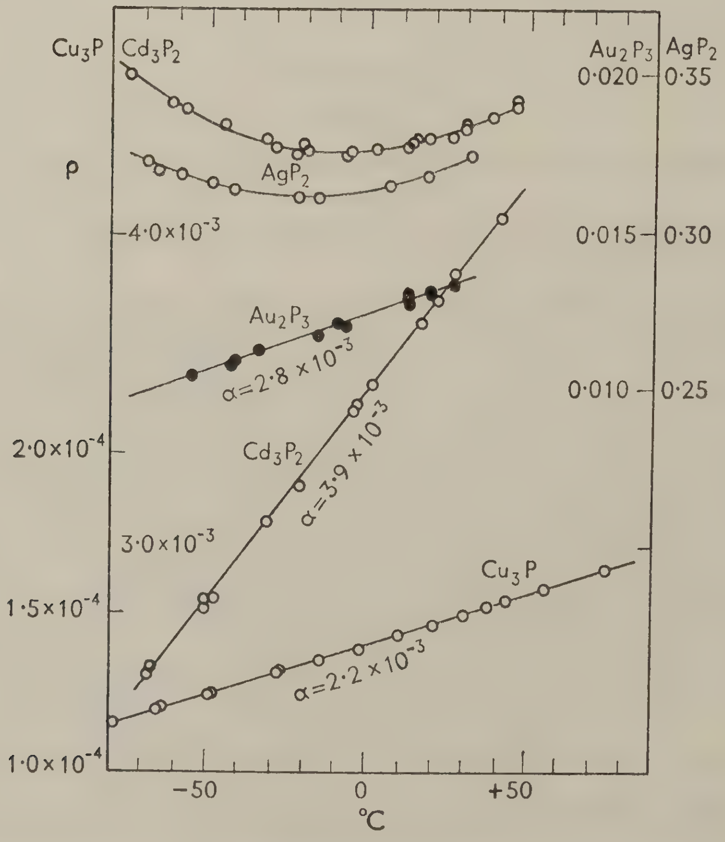

FIG. 3.—Specific resistance, $Q$, of $Cu_3P$, $Cd_3P_2$, $Au_2P_3$ and $AgP_2$ plotted against temperature. $\alpha$ is the temperature coefficient of the specific resistance

susceptibility measurements for this diamagnetic compound[51] are summarized in Table III.[42] It is oxidized by hot air and attacked by acids, feebly by dilute hydrochloric acid but more rapidly by nitric acid and hot sulphuric acid.[44]

*Table III.—Magnetic Susceptibilities of Tricopper Phosphide and Copper Diphosphide*

| | $-\chi_{gr}\cdot10^6$ | | | | | Mean | $-\chi_{mol}\cdot10^6$ | $-\chi_P\cdot10^6$ |
|---|---|---|---|---|---|---|---|---|
| $T$°C. | −183 | −78 | 20 | 168 | 388 | | | |
| $Cu_3P$ | 0·13 | 0·17 | 0·13 | 0·14 | 0·19 | 0·15 | 33 | 15 |
| $CuP_2$ | 0·25 | 0·32 | 0·29 | 0·25 | 0·30 | 0·30 | 35 | 15 |

In the above table $\chi_{gr}$, $\chi_{mol}$ and $\chi_P$ are the magnetic susceptibilities per gram of compound, per mol. of compound, and per atom of phosphorus, respectively.

The electrolysis of fused alkali-metal phosphates containing copper salts has also been used to produce dicopper phosphide,[44, 10] a dark brown compound, *d* 5·51 g./c.c.[44] It shows *p*-type semiconducting properties below 219°K.[51] and readily evolves phosphorus which ignites spontaneously.[44]

A patent has made reference to tricopper diphosphide. It is claimed that the phosphide can be prepared at 1100° to 1200°C. according to equation (5)[52]:

$$3Cu_2O+4H_3PO_4+7C \rightarrow 2Cu_3P_2+6H_2O+6CO_2+CO \qquad (5)$$

A magnetic test for superconductivity on copper monophosphide down to 1·28°K. gave negative results.[53]

In a tensimetric analysis of the copper–phosphorus system, copper diphosphide was identified.[46] It is formed at the same time as tricopper phosphide when copper phosphates are reduced by hydrogen at 350°C.[43] and can also be prepared from tricopper phosphide by heating it with the calculated quantity of phosphorus at 600°C. for 24 hr.[42] Its density is 4·20 g./c.c. and it has a molecular volume of 29·9 c.c.[42–6] Copper diphosphide has monoclinic symmetry, with $a=5{\cdot}802$, $b=4{\cdot}807$, $c=7{\cdot}525$ Å. and $\beta=112{\cdot}68°$. The space group is $P2_1/c$ with 4 copper atoms in one 4(*e*) position and 8 phosphorus atoms in two further sets of 4(*e*) positions. The melting point is approximately 900°C.[585] From dissociation pressures, the heat of dissociation, according to equation (6), is $\Delta H = +52\pm0{\cdot}8$ kcal./mole[46, 42] and the free energy of formation of solid $CuP_2$ from its gaseous elements is given by

$$\Delta G = -46{,}300+22{\cdot}5T \text{ g.-cal./mole } (T \text{ in °K.})^{548}$$

$$\tfrac{12}{5}CuP_2(s) \rightarrow \tfrac{4}{5}Cu_3P(s)+P_4(g) \qquad \bar{t} = 697°C. \qquad (6)$$

The vapour pressure variation with temperature can be represented by equation (7)[42]:

$$\log p_{(mm.)} = -11{\cdot}370\times10^3/T+13{\cdot}827 \qquad (7)$$

The specific resistance and its variation with temperature for copper diphosphide are shown in Fig. 4,[51] whilst its magnetic susceptibilities are shown in Table III.[42] The compound is similar to tricopper phosphide in its chemical properties, being oxidized by hot air and attacked by acids.[44]

Attempts to prepare copper triphosphide by heating together the calculated quantities of phosphorus and copper resulted only in the formation of a solid solution of copper in copper diphosphide.[46]

Some ternary compounds containing copper, phosphorus, and a third element have been prepared by direct combination of the elements in a silica tube heated for 2–3 days at 800°C. followed by 3–4 hr. at 1200°C.[55] Measurements on these compounds showed them to be cubic: CuPS has $a=9{\cdot}70$ Å., $d_{calc.}=5{\cdot}54$ g./c.c., $d_{obs.}=5{\cdot}30$ g./c.c. whilst CuPSe has $a=10{\cdot}15$ Å., $d_{calc.}=6{\cdot}61$ g./c.c., $d_{obs.}=6{\cdot}40$ g./c.c.[55] They are inert towards most mineral acids, though aqua regia attacks them slowly in the cold, and concentrated nitric acid attacks them on prolonged boiling. CuPSe is attacked by concentrated sulphuric acid. Warm alkali is without effect. In a sealed tube they do not melt below 1200°C. but heating under vacuum decomposes them.[55] The analogous compounds $CuPS_2$ (bright yellow powder $d_{obs.}$ 3·55, f.p. 910°C.) and $CuPSe_2$ (vitreous globules forming a black powder $d_{obs.}$ 5·01, f.p. 640°C.) have been made from the elements. Both have a wurtzite-type lattice. They are chemically inert, fairly stable in air or oxygen-free water, not attacked by mineral acids or concentrated alkalis, but dissolved by boiling concentrated nitric or sulphuric acids. They decompose on heating according to the equation

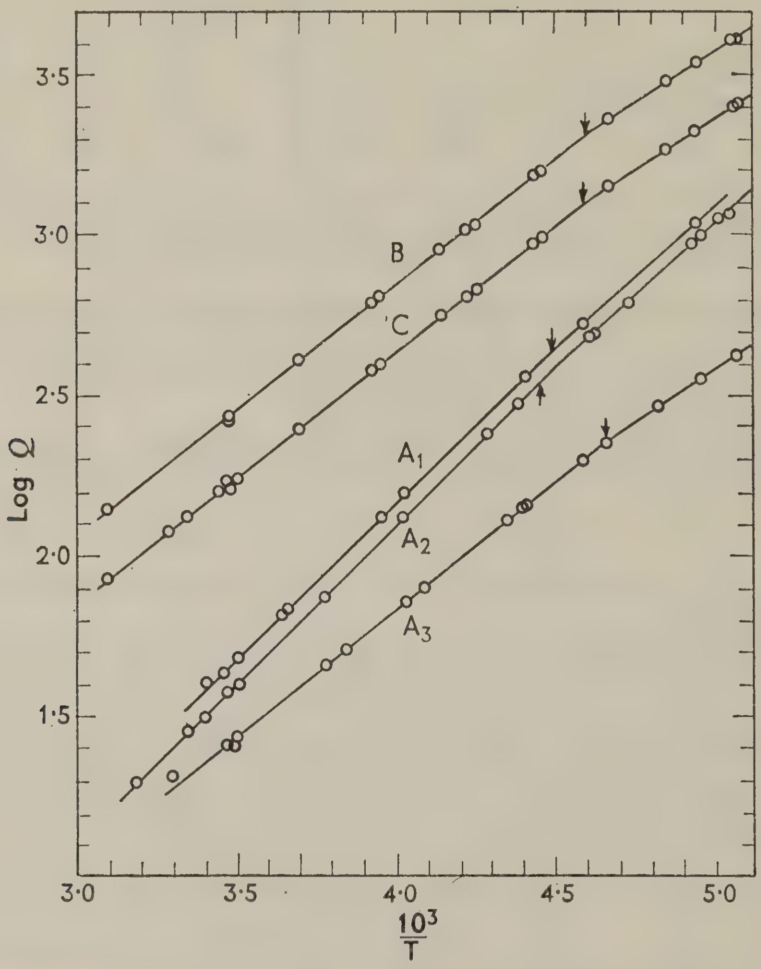

FIG. 4.—Logarithm of the specific resistance plotted against $10^3/T$ for $CuP_2$

$$4CuPX_2 \rightarrow Cu_2X + 2CuPX + P_2X_5{}^{586}$$

$CuSi_2P_3$ and $CuGe_2P_3$, which belong to a group of semiconductors of general formula $A^IB_2^{IV}C_3^V$, have disordered zinc blende structures with $a = 5{\cdot}25$ and $a = 5{\cdot}375$ A. respectively.[56] These and a series of analogues ($A^I$ = Cu, Ag; $B^{IV}$ = Si, Ge, Sn, Pb; $C^V$ = P, As, Sb, Bi) have been studied by *X*-ray and microstructure analysis.[587]

Alloys of copper with phosphorus are important industrially and several references are made in the literature to their commercial manufacture.[57–62] The copper–phosphorus system has been studied[63–4]; Fig. 5 shows the phase diagram up to 14% by weight of phosphorus. In the diagram the results of the investigators are compared with the previously determined diagram. The main investigations on copper–phosphorus alloys have dealt with thermal conductivity,[64] mechanical properties,[65–7] influence of phosphorus content on the crystallization of copper,[68] reaction diffusion[69] and the electrical properties.[65, 70] In their lubricating properties phosphorus–

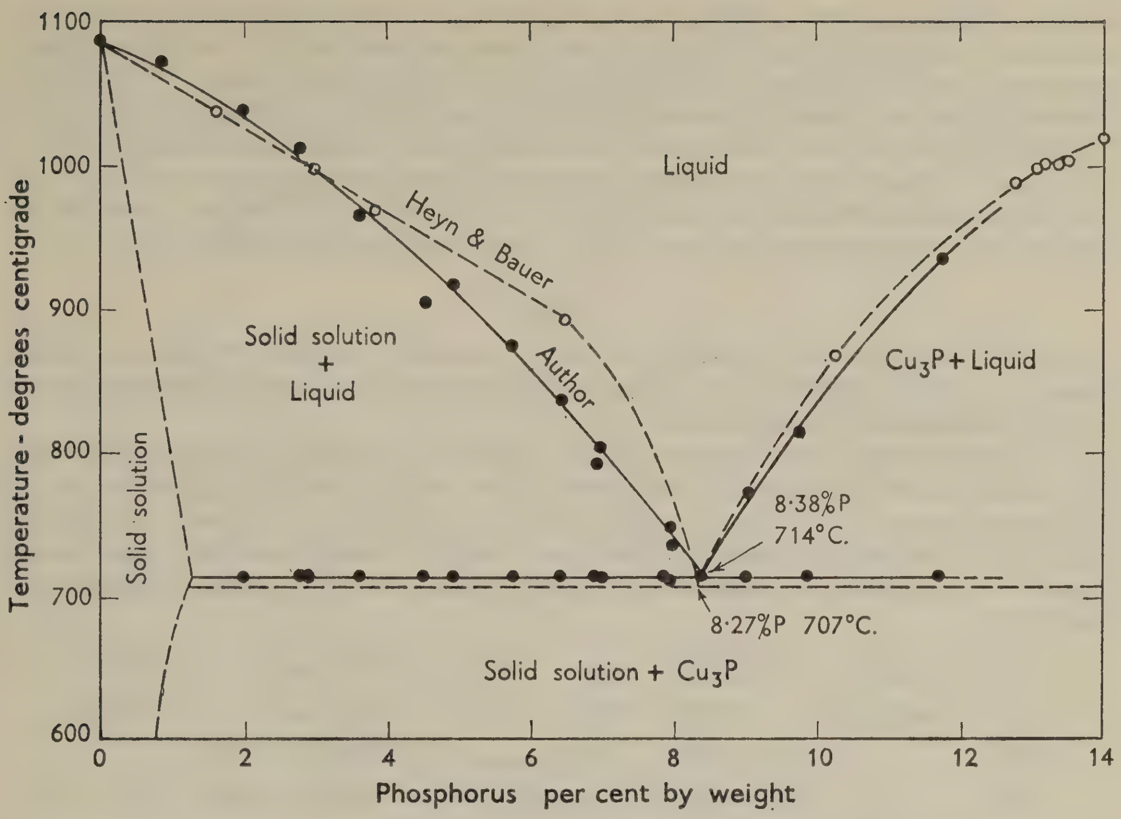

FIG. 5.—The equilibrium diagram of the copper–phosphorus system (0–14% P)

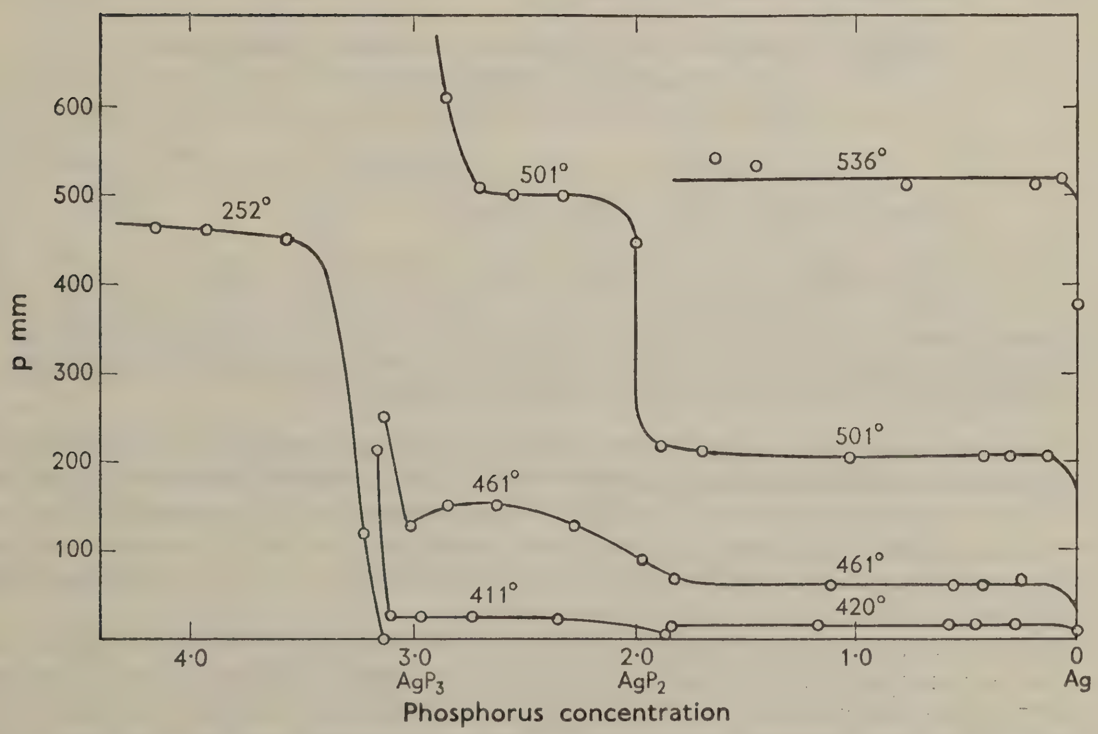

FIG. 6.—Vapour pressure–concentration diagram for the silver–phosphorus system

copper alloys have been shown to be as efficient as some sulphides but inferior to graphite.[71] Alloys or phosphides have found uses as deoxidants in metal smelting,[72] as a component of catalysts for the oxidation of phosphorus in steam,[73–4] as friction elements in brake linings or clutches[75] and as a hard solder or brazing material.[76–81] The effect of copper phosphides on the colour of copper red glass has been discussed.[82]

Ternary systems which have been investigated are copper–phosphorus–tin,[83–8, 63] copper–phosphorus–zinc,[63] copper–phosphorus–silver,[48, 89, 90] copper–phosphorus–chromium,[91] copper–phosphorus–nickel[91–3] and copper–phosphorus–iron.[94]

## Silver

Disilver phosphide is reported to have transistor properties[51] and a specific resistance at 0°C. of 0·30 to 0·33 ohms-cm.[51] This appears to be the sole reference to a silver phosphide of this formula.

Two phosphides, silver diphosphide and silver triphosphide, have been prepared by passing phosphorus vapour over heated silver and by heating together silver and red phosphorus.[48, 46, 54] V.p. measurements shown in Fig. 6[46] reveal that the two phosphides are miscible with one another. Heats of dissociation have been calculated[46, 54] according to equations (8) and (9) and the v.p. obeys equations (10) and (11)[54]:

$$(8)\quad 4AgP_3(s) \rightarrow 4AgP_2(s) + P_4(g) \qquad \Delta H = +35{\cdot}5 \text{ kcal.} \qquad \bar{t} = 456°\text{C.}$$

$$(9)\quad 2AgP_2(s) \rightarrow 2Ag(s) + P_4(g) \qquad \Delta H = +32{\cdot}9 \text{ kcal.} \qquad \bar{t} = 478°\text{C.}$$

$$(10)\quad \text{For } AgP_3 \qquad \log p_{(mm.)} = -7766/T + 12{\cdot}74$$

$$(11)\quad \text{For } AgP_2 \qquad \log p_{(mm.)} = -7186/T + 11{\cdot}60$$

The free energies of formation of solid $AgP_2$ and $AgP_3$ from the gaseous elements at $T$°K. are given by $\Delta G = -32{,}800 + 22{\cdot}5T$ g.-cal. and $-49{,}900 + 33{\cdot}8T$ g.-cal./mole, respectively.[548] Density determinations give for silver triphosphide $d = 3{\cdot}881$ g./c.c.[46] and for silver diphosphide $d = 4{\cdot}653$ g./c.c.[46] The two compounds are black and stable in the atmosphere.[54] Silver diphosphide is isostructural with copper diphosphide, the two compounds showing complete mutual solid solubility. The crystal lattice is monoclinic with $a = 6{\cdot}218$, $b = 5{\cdot}056$, $c = 7{\cdot}804$ A., $\beta = 113{\cdot}48°$.[585] Magnetic susceptibilities, measured from −183°C. to 388°C., are shown in Table IV.[42]

*Table IV.—Magnetic Susceptibilities for Silver Triphosphide and Silver Diphosphide*

| | $-\chi_g \cdot 10^6$ | | | | | Mean | $-\chi_{mol} \cdot 10^6$ | $-\chi_p \cdot 10^6$ |
|---|---|---|---|---|---|---|---|---|
| $T$°C. | −183 | −78 | 20 | 168 | 388 | | | |
| $AgP_3$ | 0·31 | 0·35 | 0·37 | 0·31 | 0·31 | 0·33 | 66 | 15 |
| $AgP_2$ | 0·28 | 0·35 | 0·35 | 0·32 | 0·32 | 0·32 | 54 | 16 |

In the above Table $\chi_g$ is the susceptibility per gram of compound, $\chi_{mol}$ is the susceptibility per molecule and $\chi_p$ is the susceptibility per atom of phosphorus.

A recent investigation of the silver–phosphorus phase system at low phosphorus concentrations shows that there is some solubility of phosphorus in silver as given in Fig. 7 and that this solution boils at 885°C.[95] In the figure $b_4f_2$ is the saturation curve of molten silver; this curve is extrapolated along $b_2f_2$ to cut the vertical axis at 885°C. which is the b.p. of silver saturated with phosphorus (1·7%). It is higher than the value obtained by Raub and co-workers.[48]

Ternary compounds AgPS and AgPSe have been prepared by direct combination of the elements, which were heated for 2–3 days at 800°C. and finally for 3–4 hr. at 1200°C. They are obtained as black vitreous masses which cannot be crystallized. They are inert to acids and warm alkali.[55] Ternary compounds of the type $AgM_2^{IV}P_3$ ($M^{IV}$ = Si, Ge, Sn, Pb) have been prepared from the elements and studied by $X$-ray and microstructure analysis.[587] The crystal lattice of $AgGe_2P_3$ is not cubic like that of the copper analogue, but distorted, with $a = 10{\cdot}3$, $b = 14{\cdot}6$, $c = 8{\cdot}9$ A.[589]

The system silver–phosphorus–copper has been investigated to determine the influence of phosphorus on silver–copper alloys.[90, 89]

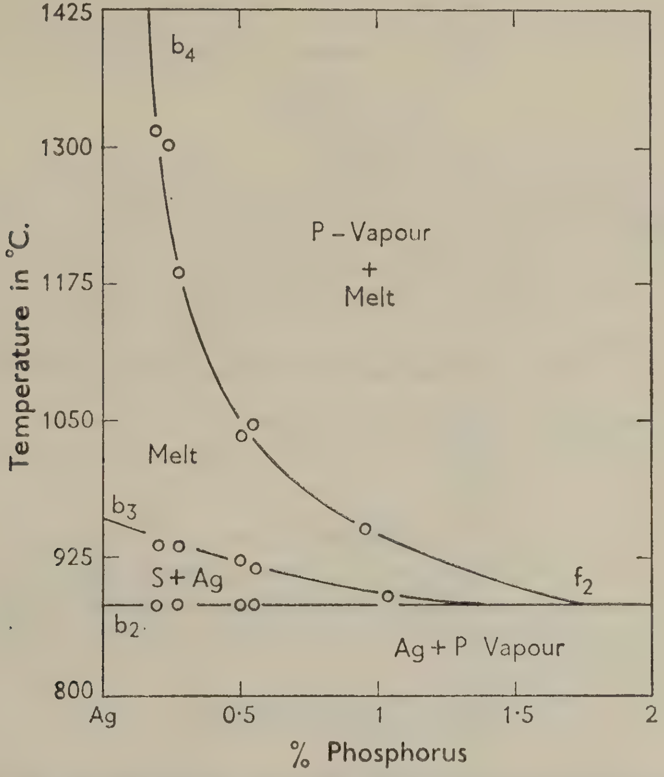

FIG. 7.—The second boiling point in the silver–phosphorus system

## Gold

By treating an auric compound in aqueous solution with phosphine it is claimed that gold monophosphide can be formed.[96] This compound is easily converted into gold under oxidizing conditions (equations (12) and (13))[96]:

$$(12) \qquad 4AuP + 5O_2 + 6H_2O \rightarrow 4Au + 4H_3PO_4$$

$$(13) \qquad 3AuP + 5AuCl_3 + 12H_2O \rightarrow 8Au + 3H_3PO_4 + 15HCl$$

Digold triphosphide is formed when gold is heated for prolonged periods at 500°C. in contact with phosphorus. It is a black compound having $d$ 8·123 g./c.c. and molecular volume 30·0 c.c.[46] The magnetic susceptibilities have been measured at temperatures ranging from −183° to 388°C.; mean values for these measurements are: $-\chi_g \times 10^6 = 0{\cdot}22$, $-\chi_{mol} \times 10^6 = 107{\cdot}0$, $-\chi_P \times 10^6 = 16$,[42] $\chi_P$ being the susceptibility per phosphorus atom. From v.p. measurements on the gold–phosphorus system, which are shown in Fig. 8,[46] the variation of v.p. of digold triphosphide with temperature was shown to obey equation (14):

$$(14) \qquad \log p_{(mm.)} = -9124/T + 12{\cdot}21$$

and the heat of disproportionation according to equation (15):

$$(15) \qquad \tfrac{4}{3}Au_2P_3(s) \rightarrow \tfrac{8}{3}Au(s) + P_4(g) \qquad \bar{t} = 630°C.$$

is $\Delta H = +41{\cdot}7 \pm 0{\cdot}2$ kcal./mole. The free energy of formation of solid $Au_2P_3$ from the gaseous elements at $T$°K. is given by $\Delta G = -57{,}500 + 33{\cdot}8T$ g.-cal./mole.[548] Results

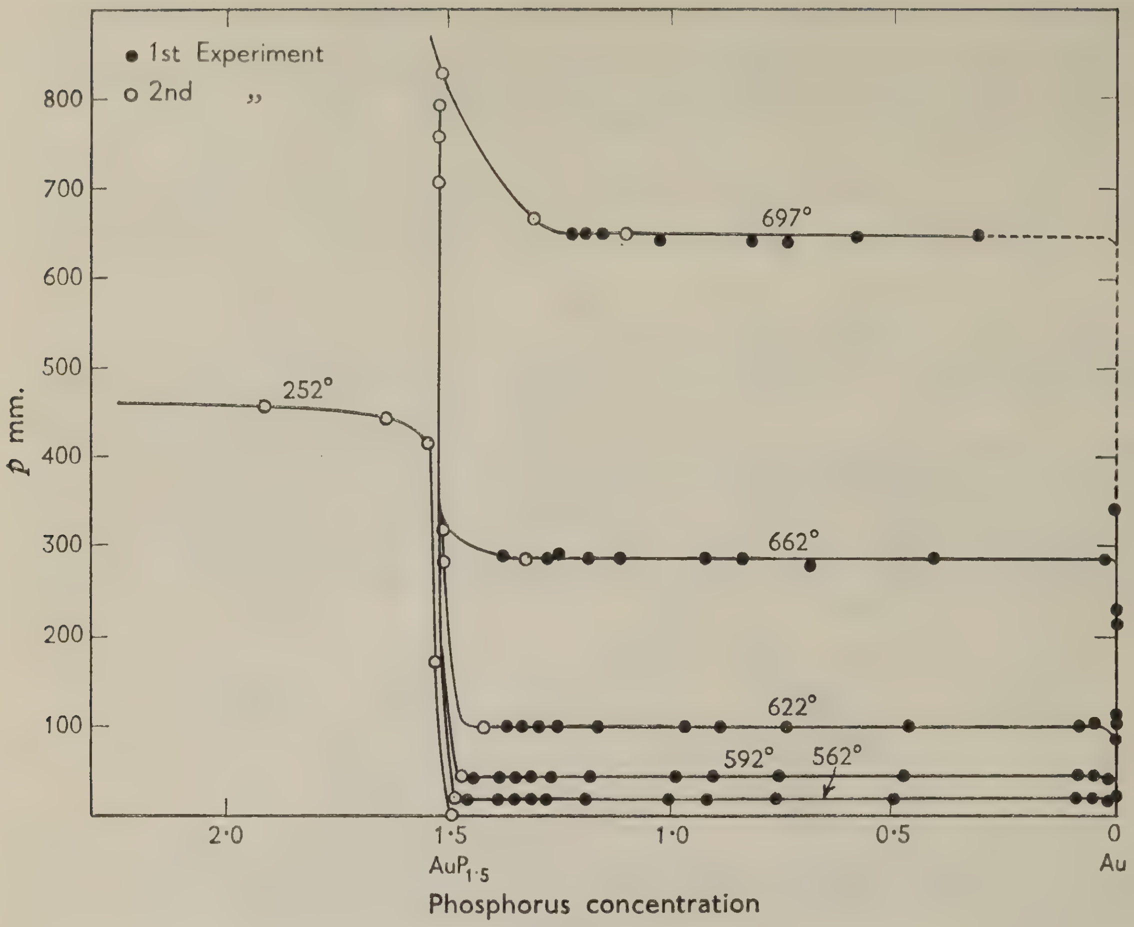

FIG. 8.—Vapour pressure–concentration diagram for the gold–phosphorus system

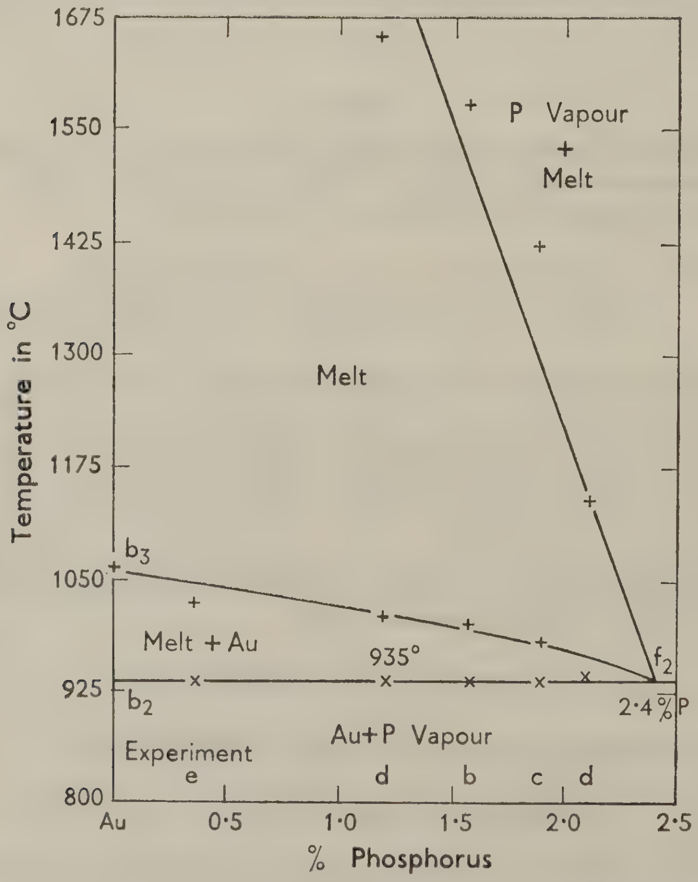

FIG. 9.—The second boiling point in the gold–phosphorus system

of specific resistance measurements are shown in Fig. 3, the value at 0°C. being $1{\cdot}24 \times 10^{-3}$ ohms-cm.[51]

Phase diagram studies on the gold–phosphorus system have been made at low phosphorus concentrations.[95] Fig. 9 shows that phosphorus is slightly soluble in liquid gold; the solubility is 2·4% at 935°C.[95]

The ternary diagram of gold, phosphorus and tin was investigated in connection with segregation phenomena.[97]

## GROUP 2A

### Beryllium

Little work has been done on the beryllium–phosphorus system but triberyllium diphosphide, which has been reported as having a cubic crystal structure with $a = 10{\cdot}17$ A., $d = 2{\cdot}25$ g./c.c. and molecular volume 39·6 c.c.[98] is thought to form an ionic lattice.[99] The anions form a close-packed lattice and the cations occupy the tetrahedral or octahedral holes.

A heat of formation of 48 kcal./mole has been estimated for beryllium monophosphide.[16]

In the system beryllium–phosphorus–iron a triangle represented by $Fe$–$Fe_2P$–$Be_2Fe$ has been investigated but no phosphides of beryllium were reported.[100]

### Magnesium

Trimagnesium diphosphide is probably the only phosphide of magnesium that exists. It has been prepared by heating the elements together in a sealed tube at 336° to 592°C.[101] and by causing magnesium to react with heavy metal phosphides[102] or even non-metallic phosphides.[582] From a high pressure study it was concluded that pressure alone would not form a phosphide from magnesium and red phosphorus[103]; in addition a shearing force was required but this may only be a device for raising the temperature. Reaction of the elements, i.e. passing phosphorus vapour in a stream of hydrogen over heated powdered magnesium was used as a method of preparing material for an *X*-ray study which showed the material to be cubic with $a = 12{\cdot}01$ A.[104] In another investigation the structure was said to be of the nickel arsenide type with $a = 5{\cdot}92$ A.[105] From these structural investigations densities 2·162 g./c.c.[105] and 2·058 g./c.c.[98] and molecular volume 65·6 c.c.[98] were determined. *K*-Emission line shift was investigated and found to be 0·15 e.v. From these investigations it was concluded that trimagnesium diphosphide possesses a strong ionic component.[106] The compound is easily hydrolyzed by water; the change of reaction velocity with time was found to be different for different specimens and this has been thought to indicate the presence of another phosphide, dimagnesium diphosphide, in the material.[101] Rough values of $-989 \pm 10$ g.-cal./g. and $-912 \pm 16$ g.-cal./g., both measured at 20°C., have been quoted for the heat of reaction with water.[107] Material obtained from magnesium turnings and phosphorus vapour gave a value $\Delta H_{20} = -989 \pm 10$ g.-cal./g., whilst a value of $\Delta H_{20} = -912 \pm 16$ g.-cal./g. was obtained for material prepared from magnesium powder and red phosphorus. The heat of formation is given as $\Delta H_f^\circ = -119 \pm 3$ kcal./mole,[108] and the free energy of formation of solid $Mg_3P_2$ from the gaseous elements is given by:

$$\Delta G = -150{,}800 + 22{\cdot}2T \text{ g.-cal./mole}$$

over the temperature range $T = 298$–$923$°K.[548] Trimagnesium diphosphide has been used as a grain disinfectant,[109–10] as a pesticide[111–3] and for removing small amounts of oxygen and other impurities from molten copper.[114]

A heat of formation of 50 kcal./mole has been estimated for magnesium monophosphide from data on oxides.[16]

A ternary composition exists; magnesium aluminium phosphide (containing the metals in the ratio by weight of 1 part of aluminium to 3 parts of magnesium) has a heat of reaction with water of approximately $-876 \pm 9$ g.-cal./g. at 20°C. It is used in sea flares.[107] $MgGeP_2$ has been shown to have the zinc blende type structure with $a = 5{\cdot}652$ A.[56]

### Calcium

Very little on the preparation of calcium phosphides has been reported in recent years. Three preparations of tricalcium diphosphide were incidental to the main studies. In the first case a study was made of the reactions of tricalcium phosphate with carbon.[115] One of the main processes which was shown to take place proceeds according to equation 16:

$$(16) \qquad Ca_3P_2O_8 + 8C \rightarrow Ca_3P_2 + 8CO$$

In the second instance a study was being made of the calcium–iron–phosphorus system and it was shown that calcium absorbs phosphorus from iron–phosphorus alloys containing more than 15% of phosphorus to form tricalcium diphosphide.[116] Finally, it was shown that calcium reacts with triphosphorus pentanitride at 200°C. to give as one of the products tricalcium diphosphide.[582] Patents dealing with its manufacture from tricalcium phosphate, carbon and water have been granted.[117] Preliminary studies indicate that the crystal structure is tetragonal with $a = b = 5{\cdot}44$ A. and $c = 6{\cdot}59$ A.[118] The compound is black–violet and has a heat of formation of $-120 \pm 2{\cdot}5$ kcal./mole[115]; a value of $-125$ kcal./mole was calculated from measurements of the heat of reaction with hydrochloric acid.[119] The free energy of formation of solid $Ca_3P_2$ from the gaseous elements is given by $\Delta G = -142{,}800 + 22{\cdot}5T$ g.-cal./mole over the temperature range $T = 298$–$1123$°K.[548] Observations on K-emission line shifts led the investigators to conclude that the compound has a strong ionic character.[106] The reaction with water is a diffusion controlled reaction which proceeds according to equation (17)[120]:

$$(17) \qquad Ca_3P_2 + 6H_2O \rightarrow 3Ca(OH)_2 + 2PH_3$$

It reacts with excess of phosphorus to give calcium monophosphide[118] and is decomposed at 250° to 300°C. by a mixture of carbon dioxide and sulphuryl chloride to give calcium chloride.[121] Several patents concerned with uses for tricalcium diphosphide have been granted, the main ones being for use in markers for torpedoes,[122] as a grain disinfectant,[123] for generation of phosphine, as an activator or collector modifier in froth flotation[124] and as a pesticide.[111–3, 125]

The next higher phosphide, calcium monophosphide, has been prepared by treating calcium dissolved in liquid ammonia with phosphine and decomposing the product thermally.[118, 549] $Ca(PH_2)_2,5NH_3$ is first formed and this is decomposed below 100°C. to give CaPH which yields calcium monophosphide at temperatures between 100° and 600°C. Previous work on this system has shown that $(PH_2)_2Ca,6NH_3$ could be formed which decomposed *in vacuo* at 0°C. to give $(PH_2)_2Ca,2NH_3$. Either of these compounds, if heated *in vacuo*, yields CaPH which in turn loses hydrogen at higher temperatures.[579] The Thénard process for the manufacture of calcium monophosphide has been improved by decomposing beforehand the calcium carbonate present in the lime used, by working in a current of nitrogen, and by allowing the phosphide formed from the calcium oxide and phosphorus to cool in a nitrogen atmosphere.[126] Other compounds such as calcium chloride, calcium carbide and calcium hydride, as well as metallic calcium, have also been shown to produce either a mixture of calcium monophosphide and tricalcium diphosphide or calcium monophosphide on reaction with red phosphorus.[118, 549] Preliminary results suggest that this brick-red compound has a tetragonal crystal structure with $a = b = 5{\cdot}93$ A. $c = 7{\cdot}94$ A.[118] Heating it above 600°C. converts it into tricalcium diphosphide,[118] whilst tricalcium phosphate is produced by reaction with carbon dioxide or a mixture of phosphorus vapour and carbon dioxide. Unlike tricalcium diphosphide, calcium monophosphide does not produce phosphine on treatment with water but reacts as shown in equation (18)[118]:

$$(18) \qquad 2CaP + 4H_2O \rightarrow 2Ca(OH)_2 + P_2H_4$$

Calcium diphosphide has been shown to form phosphates when heated with alkaline earth oxides in the presence of oxygen.[127]

### Strontium

The enthalpy of formation of tristrontium diphosphide was calculated as being $-160 \pm 2$ kcal./mole from measurements of the heat of reaction of the phosphide with dilute hydrochloric acid.[128]

### Barium

Barium, heated at 400° to 450°C. in phosphorus vapour, gives a dark grey product which is probably barium triphosphide.[129] Excess of phosphorus can be removed by heating *in vacuo*. At a temperature between 740° and 840°C. phosphorus is lost until the composition approaches that of barium diphosphide. Barium diphosphide is stable under these conditions and can be confirmed tensimetrically,[129] but at still higher temperatures it decomposes further to tribarium diphosphide (Mellor, VIII, 842).

## GROUP 2B

### Zinc

Trizinc diphosphide has been prepared by reducing trizinc phosphate with hydrogen at 600°C. in a closed system,[43] or by passing phosphorus vapour over zinc heated to 400°C.[130] Experiments indicate that it is also formed merely by rubbing together red phosphorus and zinc provided sufficient pressure is applied.[103] Pure trizinc diphosphide has been prepared from pure zinc and red phosphorus in a heated evacuated quartz ampoule, and further purified by sublimation, for measurements of its electrical resistivity and thermoelectric power.[590] Processes for its manufacture have been patented. In one method trizinc phosphate is reduced at elevated temperature with carbon[131]; in a second, phosphorus and zinc react in an externally heated ball-mill,[132] whilst in a third yellow phosphorus reacts with molten zinc.[133] *X*-Ray measurements show the crystal structure of trizinc diphosphide to be tetragonal with $a = 8{\cdot}097 \pm 0{\cdot}020$ A., $c = 11{\cdot}45 \pm 0{\cdot}030$ A.[130] The $^{31}P$ nuclear magnetic resonance spectrum is in accordance with this structure,[591] showing two peaks of equal intensity, with chemical shifts of +217 and +250 p.p.m. relative to 85% $H_3PO_4$. The density is 4·54 g./c.c. and it has molecular volume 56·9 c.c.[130] It is a dark grey metallic powder, but evaporated films appear bright in reflected light and dark red in transmitted light.[134] Trizinc diphosphide is decomposed by fusion with sodium hydroxide in air, according to the initial reaction

$$2M_xP_2 + 6NaOH + O_2 \rightarrow 2xM + 2PH_3 + 2Na_3PO_4 \tag{18a}$$

The zinc then undergoes further reactions with the formation of zincates.[593] In agreement with earlier work,[135] it is found that this phosphide sublimes at 1000°C. without decomposition.[136] A value of $-98 \pm 3$ kcal./mole was obtained for the heat of formation from the elements,[137] but this value differs from a previously determined value of $-55{\cdot}03 \pm 1{\cdot}5$ kcal./mole[138] and therefore the heat of hydrolysis was measured. From the hydrolysis measurements a figure of $-53{\cdot}37 \pm 0{\cdot}35$ kcal./mole was obtained[139] for the heat of formation of trizinc diphosphide. It has been shown that the phosphorescence of this compound is extinguished by infra-red radiation.[140] In studies on the electrical and optical properties it has been demonstrated that trizinc diphosphide can act as an *n*-type or *p*-type semiconductor material. The *n*-type material shows poor rectification characteristics.[134, 141–2, 51] Reports on the uses have been mainly connected with its toxicity,[143–58] although patents refer to its use as a catalyst in the preparation of aliphatic nitriles from aliphatic alcohols[159] and acetone from *iso*propyl alcohol.[160] Its heat transfer properties have also been investigated.[161] It has been reported that zinc phosphide is not completely destroyed in food cooking processes.[162]

Zinc diphosphide is prepared by heating zinc to approximately 700°C. and passing over it a stream of nitrogen containing phosphorus vapour.[130] The compound is yellowish-orange in colour and sublimes at 700°C. in phosphorus vapour, but decomposes to give trizinc diphosphide if heated to 700°C. *in vacuo*.[130] The crystal structure has been shown to possess tetragonal symmetry with $a = 5{\cdot}07$, $c = 18{\cdot}65$ A.[130] Densities by various methods agree quite well: 3·51 g./c.c. (*X*-ray), 3·56 g./c.c. (pyknometer), 3·53 g./c.c. (flotation).[130] It is practically insoluble in non-oxidizing acids,[130] but is decomposed by fusion with sodium hydroxide in air according to equation (18a) with further reaction of the zinc to zincates.[593]

If zinc is treated with phosphorus in a closed system, on the other hand, two forms of zinc diphosphide are formed, their ratio depending on the pressure of phosphorus vapour in the system. At 3 atm. and 700° to 850°C. the product contains 50% of the form described above (red tetragonal crystals, $a = 5{\cdot}08 \pm 0{\cdot}01$, $c = 18{\cdot}59 \pm 0{\cdot}05$ A., space group $P4_12_12$ or $P4_32_12$). The remainder is a new form of $ZnP_2$, which at 10 atm. is the sole product. It forms black monoclinic crystals, $a = 8{\cdot}85 \pm 0{\cdot}02$, $b = 7{\cdot}29 \pm 0{\cdot}02$, $c = 7{\cdot}56 \pm 0{\cdot}02$ A., $\beta = 102{\cdot}3 \pm 0{\cdot}2°$, density 3·47 g./c.c. *X*-Ray study of the product discloses no $Zn_3P_2$, and its structure resembles that of $ZnAs_2$. Optical absorption (red and black) photoluminescence (red) and photoconductivity (black) data are recorded.[550] A detailed crystal structure has been determined for the tetragonal modification. All the atoms are tetrahedrally co-ordinated, with each zinc atom bonded to four phosphorus atoms, and each phosphorus to two zinc and two phosphorus atoms.[592]

Ternary compounds which have been reported, zinc silicon diphosphide, zinc tin diphosphide and zinc germanium diphosphide, were prepared from phosphides of Group III elements.[163–4, 56, 594–5] They have the chalcopyrite structure with $a = 5{\cdot}398$ A. and $c/a = 1{\cdot}934$ for zinc silicon diphosphide and $a = 5{\cdot}46$ A., $c/a = 1{\cdot}97$ for zinc germanium diphosphide.[56, 163, 165, 594] Physical,[594] electric and photoelectric[166, 595–6] and optical[596] properties of these compounds have been discussed.

The phase diagram zinc–phosphorus–iron[167] and a small portion of the liquidus of the system zinc–phosphorus–copper[63] have been investigated.

### Cadmium

Tricadmium diphosphide is formed when cadmium diphosphide is heated *in vacuo* at 700°C. It is metallic grey,[130, 597] brittle and fairly hard. It melts peritectically at 739 ± 2° giving a mixture of cadmium and cadmium diphosphide,[597] and its heat of formation is −27·4 kcal./mole.[168] In a structural investigation the crystal structure was shown to be tetragonal with $a = 8{\cdot}746 \pm 0{\cdot}02$, $c = 12{\cdot}28 \pm 0{\cdot}03$ A.[130] Density $5{\cdot}60 \pm 0{\cdot}06$ g./c.c. and molecular volume 71·2 c.c. were calculated from the *X*-ray data.[130] Specific resistance measurements are shown in Fig. 3 (page 294).[51] Other values have been given for the specific resistance, as well as for the Hall effect,[597] thermoelectric power and semiconducting properties.[598] It is stable in water and non-oxidizing acids.[130]

Cadmium diphosphide has been prepared by heating the elements together in a sealed tube at approximately 600°C.[130, 599] and by subliming tricadmium diphosphide in a phosphorus-rich atmosphere.[130] The dark crystals distil at 640°.[599] The solid crystallizes with tetragonal symmetry having $a = 5{\cdot}28$ A., $c = 19{\cdot}70$ A. and $d$ 4·19 g./c.c.[130] The compound is similar to zinc diphosphide in being unaffected by water and only slightly affected by acids.[130] Transmittance measurements at room and liquid nitrogen temperatures show a strong infra-red absorption which, together with the very high optical activity of single $CdP_2$ crystals, points to a very large contribution by ionic bonding in the lattice.[599]

In experiments designed to give $CdPbP_{14}$ a black product was sometimes obtained which did not show the properties expected of a Group II-metal lead polyphosphide.[169] Further investigation showed it to be cadmium tetraphosphide. It was also prepared by heating purified white phosphorus with a cadmium–lead alloy at 565°C. for 2½–5 days,[170] or from the elements in a quartz double zone furnace held at 700° and

450°, respectively.[600] It has a monoclinic crystal structure, space group $P2_1/c$, with $a = 5{\cdot}26$, $b = 5{\cdot}18$, $c = 7{\cdot}64$ kx. units and $\beta = 80°\ 32'$. The electrical conductivity is 2 ohms$^{-1}$ cm.$^{-1}$ and the thermoelectric power 600 μv/°C.[600] This compound appears to be very inert to chemical attack, dissolving only slowly in hot aqua regia,[170] but when heated *in vacuo* it decomposes into its elements.[170]

The compound $CdPbP_{14}$ has been prepared by reaction of red phosphorus with an alloy of lead and cadmium at temperatures between 525° and 610°C. for 8–10 days.[169] It shows only slight chemical reactivity, dissolving slowly in concentrated sulphuric and nitric acids.[169] Other ternary phosphides are cadmium germanium diphosphide, cadmium silicon diphosphide, and cadmium tin diphosphide.[164] The first of these has the chalcopyrite structure and an energy gap of 1·8 e.v.[164] It has been discussed from the point of view of its use in semiconductor devices.[166] Cadmium tin diphosphide has an energy gap of 1·5 e.v.[164] Cadmium silicon diphosphide also crystallizes in the chalcopyrite structure ($a = 5{\cdot}678$, $c = 10{\cdot}431$ A.). Values of its melting point, microhardness, and energy gap have been recorded.[594]

Ternary cadmium phosphide halides of the general formula $Cd_4P_2X_3$ (X = Cl, Br, I) have been described. They all form deep orange cubic crystals and melt incongruently below 600°C. The bromide has a density of 5·29 g./c.c. and is unaffected by water or benzene at room temperature.[551]

### Mercury

A phosphide compound containing iodine has been reported.[171] White phosphorus is said to react with mercuric iodide suspended in carbon disulphide to give, upon evaporation of the solvent after fifteen days, a yellow dimercury di-iodine phosphide. A mixed lead mercury phosphide is mentioned under lead on page 313.

## GROUP 3

A great deal of attention has been given to Group III phosphides in recent years and in particular to indium phosphide and gallium phosphide. Most of the work has been done in connection with their semiconducting properties and, since the material belongs to the realm of physics rather than chemistry, information on such matters should be sought in more appropriate places.[172–4]

### Aluminium

In contradiction to previous reports (Mellor, VIII, 846), aluminium appears to form only the monophosphide, AlP. This has been prepared by reaction of phosphorus vapour with aluminium powder at 500°C.,[175] red phosphorus with aluminium at temperatures above 400°C.,[176–7] cadmium phosphide with aluminium[601] or aluminium chloride,[602] or by heating purified zinc phosphide with aluminium at 800° to 900°C. for 5 hr.[136, 552] In this last method almost quantitative yields were obtained. Patents have been granted for its manufacture from the elements,[178] from the elements plus carbon,[179] and also from zinc phosphide and aluminium.[180] The preparation of aluminium phosphide of semiconductor quality has been described.[553] Crystalline aluminium phosphide has a cubic zinc-blende type lattice with $a = 5{\cdot}42$ A.,[105] $a = 5{\cdot}451$ A.,[175–6, 136, 181] $5{\cdot}467 \pm 0{\cdot}002$ A.[552] Although it is very similar to zinc sulphide the solubility of aluminium phosphide in zinc sulphide is very limited, probably not in excess of 1 mol-%.[182] The colour of aluminium phosphide, which has $d$ $2{\cdot}40 \pm 0{\cdot}01$ g./c.c.[552] and a Mohs hardness of 5·5,[175] varies from dark grey to yellow for samples of the highest purity.[176] The melting point has been given as 1350°C. and the energy gap 3·1 e.v.,[608] though other workers[687] have claimed the melting point to be above 2000°C. A heat of formation of 66 kcal./mole has been estimated for the gaseous phosphide, using oxide data as a guide,[16] whilst from *K*-emission line shift observations it has been concluded that this compound has a strong ionic component.[106] An experimental determination gave a value of $-29 \pm 2$ kcal./mole for the heat of formation of AlP at 25°C.,[552] which is in reasonable agreement with the value $-39{\cdot}5 \pm 0{\cdot}5$ kcal./mole obtained by dissolution of the phosphide in hydrochloric acid at 22°C.[603] Other values of the heat capacity and enthalpy of aluminium phosphide have been recorded.[604] Phosphors with yellow emission can be prepared by diffusing aluminium phosphide into zinc sulphide at 900°C.[182] Several chemical properties have been investigated by different authors with conflicting results. The phosphide is said to be rapidly hydrolyzed by water, acids and alkalis.[183, 176] A typical reaction is given in equation (19):

$$2AlP + 3H_2SO_4 \rightarrow 2PH_3 + Al_2(SO_4)_3 \tag{19}$$

Dry hydrogen chloride decomposes it but it can be heated in hydrogen to 1000°C. without showing loss of weight.[176] This work is supported to some extent by others[136] who report that it has a low v.p. at 1000°C., has a faint smell of phosphine, reacts violently with concentrated or dilute hydrochloric acid and explodes with 1:1 aqua regia. It is reported though that after weeks in water it is still possible to detect the *X*-ray diffraction pattern of aluminium phosphide in the samples.[136] It may be that the formation of aluminium hydroxide gel tends to protect any unchanged phosphide or that the presence of aluminium or phosphorus in samples catalyzes their reaction. Investigators who question this work[177] report that aluminium phosphide is only slightly affected by boiling water, hot concentrated hydrochloric acid, nitric acid, and aqua regia. They also report that heating in air converts the phosphide to oxide, that hot 30% potassium hydroxide liberates phosphine and that an alkali fusion gives aluminium phosphate. Agents such as bromide, iodine in benzene, lead chromate or sodium carbonate, have little effect. Oxidizing agents are reduced. Other work has shown that if adequate precautions are not taken to provide an inert atmosphere the product may contain nitrogen or even carbon from carbon-containing atmospheres such as coal gas.[184] More recently it has been shown that good yields of pure aluminium nitride can be obtained by reaction of aluminium phosphide with nitrogen at 1375–1600°.[605] A further study of the oxidation shows that finely divided aluminium phosphide takes up oxygen interstitially at 650–700°. There is no appreciable change in lattice dimensions, but the compound changes colour from grey-green to orange-brown. Above 700° aluminium phosphide reacts with dry oxygen to give aluminium phosphate. Aluminium phosphide containing interstitial oxygen will evolve phosphorus when heated *in vacuo*, while unoxidized material is thermally stable under the same conditions.[606] There is no doubt that commercial preparations react with water since they have been used as a fumigant,[110, 185], and as a pesticide.[111–3, 186–8, 546] Aluminium phosphide has been incorporated into catalysts for the oxidation of phosphorus in steam,[74] or for the polymerization of olefins,[607] and patents have been granted for its use in high efficiency photo cells[189] and semiconductor devices.[190]

Ternary systems aluminium–phosphorus–germanium and aluminium–phosphorus–silicon have been investigated at low phosphorus concentrations.[191] Phosphorus in silicon–aluminium alloys is important since the phosphorus tends to form aluminium phosphide which then provides nuclei for crystallization of the alloys.[192–3]

### Gallium

Vacuum spark excitation of GaP has revealed the molecular species GaP, $Ga_2P$, and $GaP_2$, as their positive ions.[194]

Gallium monophosphide has sprung into prominence because of the importance attached to semiconducting materials[195] and several methods of preparation have been studied. The well-known method of heating the elements together in an evacuated sealed tube or one containing an inert atmosphere has been applied.[178, 196–7, 578] Other useful methods involve the decomposition of gallium chloride, gallium nitride, gallium oxide or gallium hydroxide in a stream of phosphine.[198–203] A stream of hydrogen containing phosphorus vapour can be used instead of phosphine[204, 175] and heating gallium with another phosphide such as zinc phosphide[136] or with phosphorus trichloride[199] has been used successfully. This last method is considered to be the most promising for the preparation of highly pure gallium phosphide.[199] Gallium phosphide can also be crystallized from a solution of gallium and phosphorus in bismuth metal, well below the melting point of GaP. The product is purified by treatment with concentrated nitric acid.[609] Finally, solid gallium phosphide has been shown to react with water vapour in a stream of hydrogen to give volatile species which redeposit gallium phosphide on cooling. The reaction can be represented as:

$$2GaP(s) + H_2O(g) \rightleftharpoons Ga_2O(g) + P_2(g) + H_2(g)$$ [610]

Many methods for the preparation of gallium phosphide have been patented,[200, 205–7, 180, 208–10, 554, 602, 611] whilst several investigators have reported on methods of growing large multicrystalline or single crystal specimens, mainly by vapour phase deposition techniques.[211–9] Vibrational mixing has been shown to decrease reaction times in the preparation of gallium phosphide,[220] whilst a study of reaction times for the reaction given in equation (20):

$$Ga_2O_3 + 2PH_3 \rightarrow 2GaP + 3H_2O \tag{20}$$

showed that at 750°C. the yield of phosphide increased linearly with time from 31·98% after 1 hr. to 58·33% after 5 hr. At 950°C. the yield of 98·66 to 100% was practically independent of time.[201] The preparation of semiconductor-grade gallium phosphide has been described.[555] Crystalline gallium phosphide has the cubic zinc-blende type of structure; reported values for the unit cell dimension vary from $a = 5{\cdot}436$ A. to $a = 5{\cdot}4506$ A.[175, 196, 221–2, 200–1, 181, 202] The density is given as 4·10 g./c.c.[609] Infra-red absorption measurements show an absorption at 14μ[233] which has been attributed to a lattice vibration. Evidence is also presented which supports the fact that the anharmonic mechanism is predominantly responsible for the infra-red absorption in the combination bands. The Raman spectrum of polycrystalline gallium phosphide has been recorded, excitation being by a 6328 A. He–Ne laser beam.[616] The refractive index of gallium phosphide for infra-red radiation varies from 3·4595 at 0·5μ to 3·0137 at 4·0μ.[617] For magnetic susceptibilities good agreement between theoretical and observed values has been reported.[224] Measurements between 60°K. and the m.p.[225–6] show that the diamagnetic susceptibility decreases with increasing temperature, the Van Vleck component (which arises because of deformation of electron clouds in the atoms) of gallium phosphide having a band width of 2·28 e.v. is $\chi_p = 27{\cdot}54 \times 10^{-6}$.[227] V.p. measurements have been made and the variation of v.p. with temperature is given by the following equations

(21)[228] $\log p_{(mm.)} = -10770/T + 9{\cdot}996$
(21a)[556, 614, 619] $\log p_{(mm.)} = -18870/T + 13{\cdot}60$ $(T = 781\text{–}1005°K.)$
(21b)[612, 614, 619] $\log p_{(mm.)} = -21570/T + 13{\cdot}021$ $(T = 1035\text{–}1380°)$

At the m.p. (1467 ± 3°C.[557]) the pressure of phosphorus above the material has been reported to be 13·45 atm.,[228] greater than 13·5 atm.[229] and 35 ± 10 atm.[557] From Schröder's equation $\log x = A/T + B$, where $x$ is the mol. % of GaP, an extrapolation to 100 mol. % gave for gallium phosphide a melting point of 1522°C. and an average latent heat of fusion for temperatures below 1270° of 30·7 ± 1·1 kcal./mole.[612] The heat of formation is variously reported as −29·1 ± 2·5,[613] −24·4 ± 1·25,[614] −42·75[610] and −49·51 ± 2·97[228] kcal./mole, the standard states of the elements taken accounting for some of the divergency of results. The standard entropy $S°$ is given as 14·4 g.-cal./degree/mole.[610] The following values of incremental heat content and entropy have been reported for $GaP_{0{\cdot}996}$[615] (see also reference 604).

| $T$(°K.) | $H_T - H_{298{\cdot}15}$ (g.-cal./mole) | $S_T - S_{298{\cdot}15}$ (g.-cal./°/mole) |
|---|---|---|
| 400 | 1,110 | 3·2 |
| 800 | 5,840 | 11·36 |
| 1200 | 10,790 | 16·37 |
| 1500 | 14,600 | 19·2 |

Hardness measurements, made by the Knoop method, show that gallium phosphide obeys the Goldschmidt Rule, $\log H = k - m \log r$ where $m$ is approximately 9, $r$ is the interatomic distance, $H$ is the scratch hardness expressed in Mohs numbers and $k$ is a constant.[230] The hardness, expressed in Mohs numbers, has been given as approximately 5·0.[175] An investigation into the bond character of phosphides showed that, like indium phosphide, gallium phosphide has a strong ionic component.[106] Other investigators showed that it differs from indium phosphide in not exhibiting a pressure-induced transition at up to 550 kilobars pressure.[231] Various etching techniques have been investigated.[232–3, 197] Gallium phosphide forms a continuous series of solid solutions with gallium arsenide[234–6] the cell dimensions of which follow a linear relationship[235] (see Vegard's Law[237]). Similarly it has been shown to form a continuous series of solid solutions with indium phosphide.[238] Gallium phosphide is a yellow compound, insoluble in water but soluble in inorganic acids and bases.[202] It reacts with solid sodium hydroxide in air, according to the equation

$$4GaP + 6NaOH + O_2 \rightarrow 4Ga + 2PH_3 + 2NaPO_3$$ [618]

Possible outlets for gallium phosphide as a semiconducting material have been discussed.[239–42, 190] Its Verdet constant,[243] which is larger than that of carbon disulphide or nickel tetracarbonyl in the visible region, makes it a possible material for use in Faraday cells.[244] Gallium phosphide diodes show avalanche breakdown in a similar manner to silicon diodes and they may show advantages over such devices as sources of very fast light pulses.[245] Patents have been granted on its use in photo cells.[189, 246] It has been considered as a heat transfer fluid in atomic energy work.[161] When an electric current is passed through $p$–$n$ junctions in Ga(AsP) semiconductors at 77°K., stimulated emission of coherent visible radiation ($\lambda = 7100$ A.) is observed.[558]

## Indium

Indium forms only a monophosphide. It was first prepared by heating together the calculated proportions of the two elements *in vacuo*.[247] The reaction was very slow and even after 400 hr. at 700°C. the yield was not 100%. Other investigators have used this method of preparation[248–9] as well as one involving the reaction of indium with zinc phosphide.[136, 180] The compound has also been produced by a continuous flow vapour phase reaction in the presence of an unreactive carrier gas, by direct reaction in the liquid phase, by the reaction of phosphine with indium chloride,[199] oxide[620] or hydroxide,[621] and by a replacement reaction starting with indium and phosphorus trichloride.[199] The last mentioned method may be worth investigating as a method for the production of very pure indium phosphide since zone melting is said to give only a small increase in purity.[250] On the other hand a patent specification claims the preparation of spectroscopically pure material from indium oxalate and phosphine at 300°C.[251] Hydrogen reduction of a mixture of indium chloride and phosphorus trichloride vapour also yields indium phosphide.[554] The preparation of semiconductor grade indium phosphide has been described.[559, 622] Reductions in reaction times in the preparation of indium phosphide by working at higher temperatures with pressure compensated vessels[252] and by employing vibrational mixing of components have been claimed.[220] A method of preparation based on a directional crystallization from a melt in a temperature gradient has been outlined.[253] Because of the great interest in this compound as a semiconductor material several patents for its manufacture have been obtained.[178, 250, 254–7, 207, 209–10, 602]

It is a dark grey material and has a metallic appearance.[247, 136] Its refractive index is given by the relations[629]:

$$n^2 = 7{\cdot}255 + 2{\cdot}316\lambda^2/(\lambda^2 - 0{\cdot}3922 \times 10^8) \quad \text{at } 298^\circ\text{K.}$$

and

$$n^2 = 7{\cdot}781 + 1{\cdot}661\lambda^2/(\lambda^2 - 0{\cdot}4397 \times 10^8) \quad \text{at } 77^\circ\text{K.}$$

Several *X*-ray measurements have been made on this cubic zinc-blende type material giving cell dimensions varying from

$$a = 5{\cdot}8688 \pm 0{\cdot}0001\ \text{A.} \quad \text{to} \quad a = 5{\cdot}8693 \pm 0{\cdot}0006\ \text{A.}^{258,\ 222,\ 181,\ 620}$$

Two different investigators have measured the intensities of *X*-ray diffraction powder lines and report agreement with calculated values, but unfortunately the two sets of

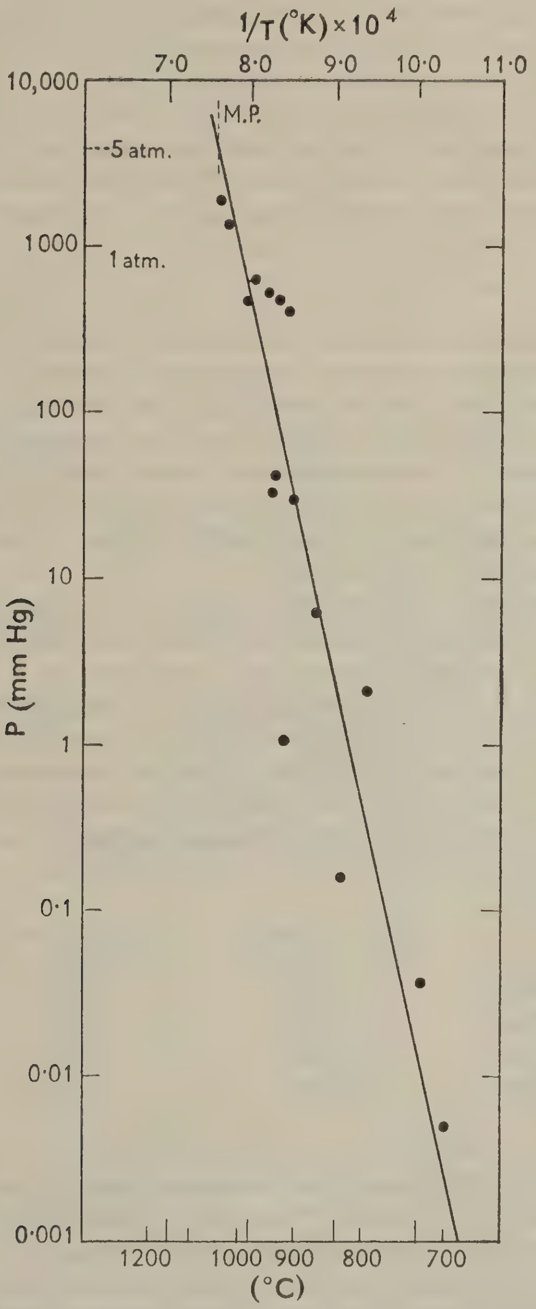

FIG. 10.—Dissociation pressure of InP from 700° to 1045°

experimental values do not agree very closely.[136, 247, 181] Deductions concerning the bonding in this compound have been made from calculations concerning the effective charge on the atoms,[259] from spectrographic measurements,[106] and from dissociation pressures and cohesion energies.[260] The cohesive energy for a purely ionic compound was calculated to be 84,000 g.-cal./mole whilst the dissociation energy of indium phosphide into liquid indium and phosphorus at a temperature below 900°C. was estimated to be 26,000 g.-cal./mole. V.p. measurements (shown in Fig. 10), together with a known heat of vaporization of indium and a known heat of dissociation of $P_4$ allowed a cohesion energy of 154,000 g.-cal./mole to be calculated. From these facts the investigators concluded that indium phosphide is mainly covalent[260] although in contrast other workers have claimed that it contains a strong ionic component.[106] The vapour pressure data presented in Fig. 10 fit equation (22)

$$\log p_{(\text{mm.})} = -23{,}000/T + 21\cdot0 \tag{22}$$

From the figure it can also be seen that the pressure of phosphorus over indium phosphide at the m.p. is 5 atm.[260] This is at variance with other values of 15·5 atm.,[229] 21 ± 5 atm.[557] and 60 atm.[261] (see also references 623, 624). M.p. data appear to be in good agreement with reported values of 1062 ± 7°C.,[261] 1062°C.,[262] 1070°C.,[260] 1050°C.,[248] 1058 ± 3°C.[557] and 1054 ± 5°C.[263] Piezo resistance measurements at 77°K. and 300°K. have been interpreted on the basis of a spherical conduction band with a minimum at the centre of the Brillouin zone,[264–5] but the investigators were unable to substantiate the existence of a second higher band.[264] Magnetic susceptibilities show good agreement with theoretical values; at 20°C.

$$-\chi_g \times 10^6 = 0\cdot313 \quad \text{and} \quad -\chi_{\text{mol}} \times 10^6 = 45\cdot6^{224-6}$$

It is thought that pressures of the order of 130 to 135 kilobars induce solid–solid type transitions to a conducting state which is apparently metallic.[231] A form of indium phosphide having a sodium chloride type lattice has been demonstrated at pressures of 22–130 kilobars.[560] The melting point of indium phosphide decreases by 2·9°C./kilobar up to 70 kilobars.[561] Measurements of conductivity at ordinary pressures and down to 1·5°K. have also been made but no evidence for superconductivity was found.[266] The thermal conductivity and Seebeck effect of indium phosphide have been measured between 300° and 800°K.[627]

Etching characteristics and formation of dislocation pits on {111} planes have been investigated[267]; etching methods have been developed to reveal the microstructure of polished specimens whose microhardness was being investigated. A value of 431 kg./mm.[2, 268] was obtained for the microhardness, which follows Goldschmidt's Rule.[230] From mass spectroscopy measurements on the composition of the gas phase above indium phosphide, it has been calculated that the free energy of formation at 1000°K. is −9200 g.-cal./mole and the entropy at this temperature is 25 e.u.[269] (see also reference 562). The following values of incremental heat content and entropy have been reported[615] (see also reference 604)

| $T$°K. | $H_T - H_{298\cdot15}$ (g.-cal./mole) | $S_T - S_{298\cdot15}$ (g.-cal./°/mole) |
|---|---|---|
| 400 | 1,150 | 3·31 |
| 800 | 5,920 | 11·57 |
| 1200 | 11,010 | 16·71 |
| 1300 | 12,400 | 17·82 |

For the standard heat of formation $\Delta H_f^\circ$ (298·15°) values of −11,[625] −21·5 ± 1·5[613] and −21·2 ± 1·0[626] kcal./mole have been recorded. Heats of fusion calculations have given a value of 15,200 g.-cal./mole[270] (see also reference 628). A series of experiments on sandblasting with various compounds (alumina, silica, steel powder, etc.) in a variety of gases (air, hydrogen, helium, etc.) showed that indium phosphide is triboluminescent.[271] Phase work has shown the indium–phosphorus system to be of the monotectic type; the various investigations are reproduced in Figs. 11,[261] 12,[262] 13[270] and in Table V data are reproduced for the system $InP/In_2Se_3$ in which mixed crystal formation starts at 33·3 mol.-% indium phosphide.[272] Alloys in this system which have compositions close to indium phosphide have a zinc-blende type lattice as have alloys $9InP$–$In_2Se_3$ and those extending from $4InP$–$In_2Se_3$ to $InP$–$In_2Se_3$. Decrease in lattice parameters with increase in $In_2Se_3$ content indicates solid solution effects in these alloys.[273] With indium arsenide[234, 274] or gallium phosphide,[238] indium phosphide forms continuous series of solid solutions, although the cell dimensions in the indium arsenide series do not obey Vegard's Rule.[274] Mainly because of the interest in indium phosphide an investigation was undertaken into the conditions under which it bonds to various metals and alloys.[275] Review articles on methods of preparation, properties and applications of intermetallic semiconductors include references to indium phosphide.[249, 240]

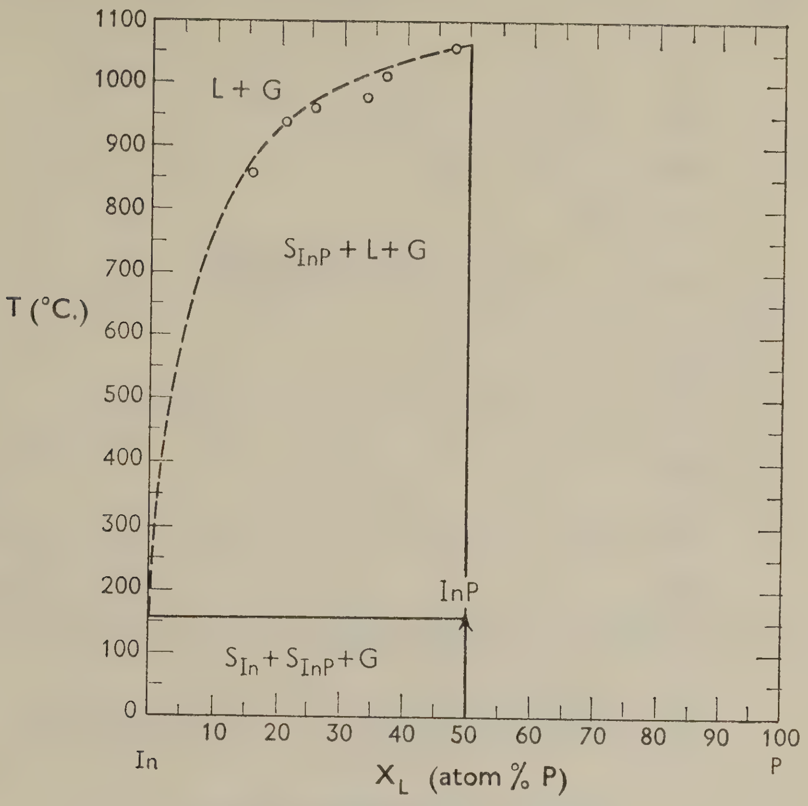

FIG. 11.—*T–x* projection of the system In–P

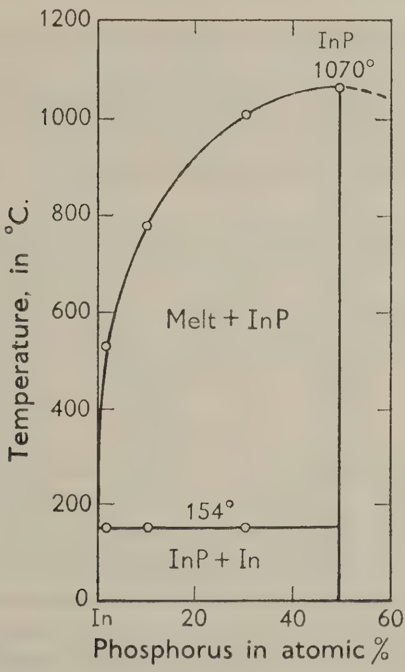

FIG. 12.—Indium–phosphorus phase diagram

The compound is stable to air oxidation and is not attacked by concentrated mineral acids,[247] acetic acid,[263] water or alkali.[276, 263] Hot solid sodium hydroxide decomposes the phosphide in air, with formation of indium, phosphine and sodium metaphosphate.[618] Dilute acids, hydrochloric, sulphuric or nitric readily form phosphine.[276, 263] Oxidation of indium phosphide crushed in a vacuum was studied by measuring the uptake of oxygen at 26°C. by the freshly prepared surfaces. The reaction does not appear to involve a distinct metastable complex before formation of the true oxide as has been observed with several Group III-Group V compounds.[277] Indium phosphide possesses useful rectification properties and shows a transistor effect[263, 278] although the evidence for the latter has been doubted.[279] Its possible use as a photovoltaic solar energy converter has been predicted[280] and a patent issued.[189] Measurements of the Faraday effect show that its Verdet constant is large enough to make it useful in Faraday cells[244] and the possible use of indium phosphide as a semiconductor operating at high temperatures has been discussed.[239, 281–3, 208, 190]

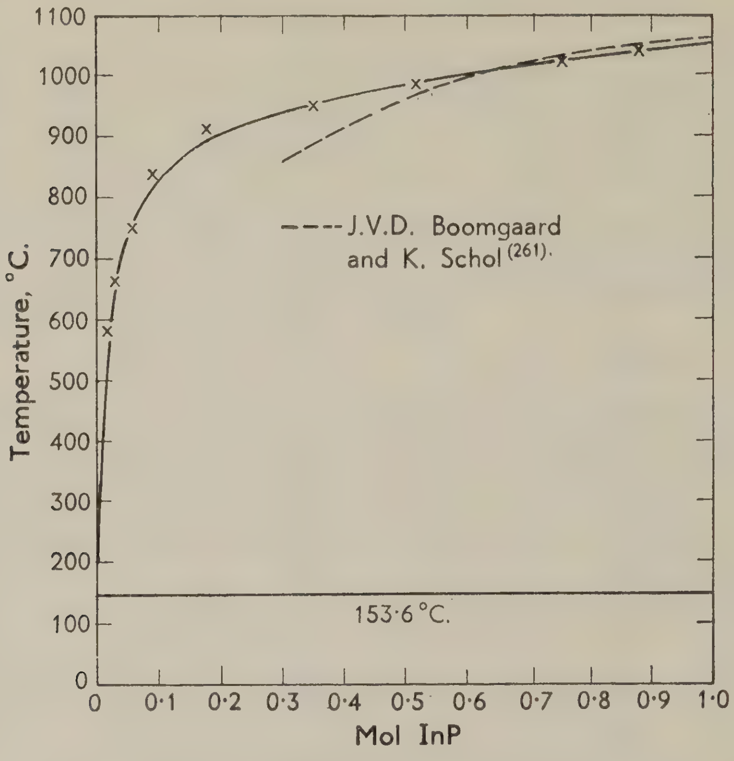

FIG. 13.—Phase diagram In–InP

An indium phosphide semiconducting cell has been used to determine the intensities of neutron sources.[284]

## Thallium

Claims have been made for the preparation of trithallium phosphide by heating together the correct proportions of thallium and white phosphorus in a sealed tube at 400°C.[285] It is a black compound which decomposes in moist air, ignites if heated in air and reduces potassium permanganate.[285]

In a thermal investigation of the thallium–phosphorus system an unidentified compound was found at 75 atomic-% of phosphorus. This corresponds to thallium triphosphide.[286]

The original phase diagram for the thallium–phosphorus system has been corrected and is shown in Fig. 14.[6]

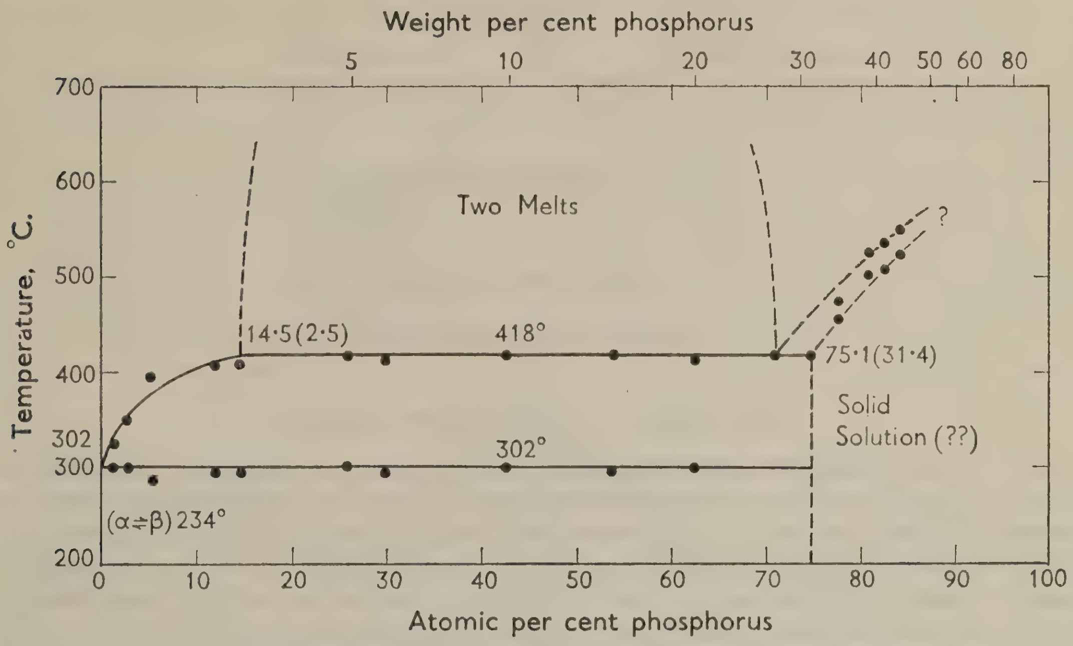

FIG. 14.—Phosphorus–thallium phase diagram

## GROUP 4

### Tin

Brief mention of tritin diphosphide has been made but only of its use as a catalyst in the production of high mol.-wt. polyesters.[287–8]

In an attempt to prepare tin triphosphide a mixture of tin and phosphorus in the ratio 1:3 was cooled slowly *in vacuo* from 700°C.[289] Chemical analysis showed that the product was tin monophosphide. Its crystal structure has hexagonal symmetry with $a = 8{\cdot}78$ A., $c = 5{\cdot}98$ A. The density, calculated from the *X*-ray data, agrees well with the measured density of 5·01 g./c.c. There is no reaction between tin monophosphide and concentrated nitric acid even at 300°C.[289]

Segregation phenomena have been studied in the system tin–phosphorus–gold[97] and the copper corner of the system tin–phosphorus–copper has received some attention, mainly on account of the phosphor bronzes.[84–5, 87–8]

### Lead

No lead phosphides have been prepared but several ternary compounds involving a second metal have been reported.[169, 290] $HgPbP_{14}$, $CdPbP_{14}$ and $ZnPbP_{14}$ were prepared by reaction of an alloy of lead and the appropriate second metal with red phosphorus. The temperature was maintained at 525° to 610°C. for a number of days and silvery coloured materials having high $d$ were obtained. *X*-Ray work showed that the compounds contain parallel zig-zag chains of phosphorus atoms.[290] They do not conduct electricity and are only slightly reactive chemically, being gradually attacked by atmospheric oxygen and not at all by boiling non-oxidizing acids.

## GROUP 5

### Antimony

The systems antimony–phosphorus–iron and antimony–phosphorus have been studied[291] but no phosphides of antimony have been reported. Fig. 15 summarizes the work on the antimony–phosphorus system.[291]

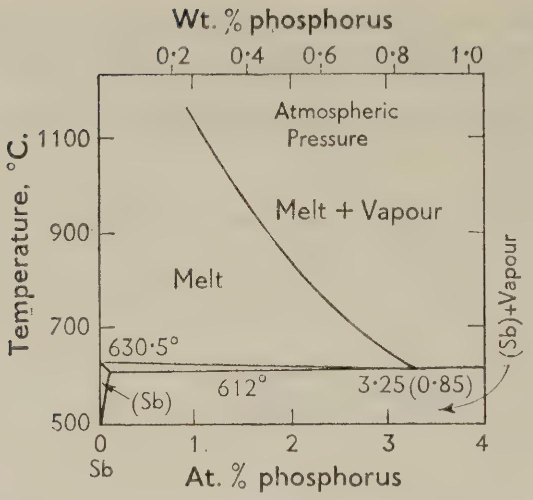

FIG. 15.—Phosphorus–antimony phase diagram

## THE FIRST TRANSITION SERIES

Some of the transition metal phosphides such as those of zirconium, titanium and vanadium are extremely inert, showing no signs of oxidation in air even at 1000°C.[292] Because of their inert nature, the definition of 'hard metals' has been broadened to include them with certain carbides, nitrides, borides and silicides.[293] The structures of many of these phosphides are similar to those of carbides and nitrides. Molybdenum monophosphide is isomorphous with tungsten carbide and as with the 'hard metals' the higher co-ordination number is retained, but the metal atom lattice shows an expansion of approximately 15% as against 5 to 10% for the nitrides and carbides.

*Table VI.—The Crystal Structures of Transition Metal Monophosphides*

| IIIA | IVA | VA | VIA | VIIA | VIIIA | |
|---|---|---|---|---|---|---|
| ScP<br>B1 | TiP<br>Bi | VP<br>B8 | CrP<br>B31 | MnP<br>B31 | FeP<br>B31 | CoP<br>B31 |
| YP<br>B1 | ZrP<br>B1 ← Bi | NbP<br>(Bh) ← NbAs | MoP<br>Bh | | RuP<br>B31 | |
| LaP<br>B1 | HfP<br>Bi | TaP<br>(Bh) ← NbAs | WP<br>B31 | ReP | | |

CeP, PrP, NdP, SmP, GdP, TbP, DyP, HoP, ErP, ThP, UP, PuP all have B1 structure.
Notation of structure types:
B1 = NaCl, B8 = NiAs, B31 = MnP, Bh = WC, Bi = TiP. Arrow points to the structure type which occurs with phosphorus deficiency.

The crystal structures of the transition metal monophosphides have been collated[563] (see Table VI). They are of six different types. The IIIA group, the lanthanide and the actinide monophosphides have an NaCl type lattice. Group IV phosphides have NaCl, TiP or NiAs lattices. Group V (2nd and 3rd period) have a NbAs lattice and a distorted variation tending towards the tungsten carbide type which is fully developed in MoP. The remaining phosphides have MnP or NiAs type lattices.

The monophosphides of Ti, Zr, Hf, Nb, Ta, Mo and W all vaporize by decomposition, yielding phosphorus and a solid phase of lower phosphorus content. In general the thermal stability of transition metal phosphides increases in the order Group VI < Group V < Group IV, and within any one group increases with increasing atomic number,[634] Mo and W being exceptions to the latter rule,[631] as shown by the figures in Table VII.

In the first transition series it is found that compounds of the type $M_3P$ are ferromagnetic if a highly unsaturated atomic shell is connected with a high ratio of lattice constant to atomic shell radius.[294]

*Table VII.—Partial molal free enthalpies of dissociation to* $P_2$[631]

| Compound | Temperature range studied °K. | $\Delta\bar{G}_T^\circ[P_2]$ kcal./mole $P_2$ | | |
|---|---|---|---|---|
| | | 1000°K. | 1500°K. | 2000°K. |
| $TiP_{0\cdot94}$ | 1295–1705 | 55·8 | 40·8 | 25·9 |
| $ZrP_{0\cdot92}$ | 1770–2120 | | 66·9 | 51·1 |
| $NbP_{0\cdot95}$ | 1200–1450 | 55·4 | 34·0 | |
| MoP | 1190–1450 | 54·3 | 28·3 | |
| WP | 950–1250 | 36·7 | 17·3 | |

### Scandium

Scandium monophosphide has been prepared by reaction of scandium filings with red phosphorus in an evacuated quartz tube at 1000°C. It has a cubic (NaCl type) structure with $a = 5{\cdot}312$ A.,[564] 5·302 kx.[630] The calculated density is 3·365 g./c.c. The compound is thermally stable on heating at $10^{-4}$ torr. No polymorphous transformations are found between 20–1500° and the compound does not melt below 2000°. It is oxidized by heating in air, with formation of scandium phosphate. Unaffected by water or bases, it is completely decomposed by dilute mineral acids.

### Titanium

The existence of trititanium monophosphide was indicated in experiments in which dry phosphine in a carrier stream of argon was passed over titanium powder.[295] In other experiments, designed to give dititanium phosphide, and in which titanium was heated with phosphorus, a phase was obtained which *X*-ray methods showed to be isomorphous with tri-iron phosphide,[296, 635] or trivanadium phosphide.[565] In the latter work, the tetragonal lattice was assigned the structure parameters $a = 9{\cdot}956$, $c = 4{\cdot}988$ A. A phase rule study of the titanium–phosphorus system confirmed the existence of trititanium monophosphide, having a tetragonal lattice $a = 9{\cdot}28$, $c = 4{\cdot}99$ A. and melting peritectically at 1760°.[636]

Dititanium phosphide has been prepared by reaction of dry phosphine with titanium at 800°C.[297, 295] If the temperature is allowed to rise above 800°C. there is a tendency for titanium monophosphide to form. Dititanium phosphide, m.p. 1920°, is claimed to be isomorphous with $Fe_2P$, having $a = 6{\cdot}71$, $c = 3{\cdot}46$ A.[636] Other work has shown evidence for a subphosphide which was thought to be dititanium monophosphide,[298, 635] but later investigations have shown that at least one of these compounds was trititanium monophosphide. However, more recently still clear evidence has been obtained for the existence of a new phase, approximating to pentatitanium triphosphide, $Ti_5P_3$ or $TiP_{\sim 0\cdot6}$. This phosphide is formed by the thermal decomposition of titanium monophosphide,[631] by the reaction of titanium tetrahydride with phosphine, or by the interaction of titanium with phosphorus or titanium phosphide.[635] An *X*-ray study of single crystals of $Ti_5P_3$ showed the lattice to be hexagonal, of $Mn_5Si_3$ type with space group $P6_3/mcm$,[632] $a = 7{\cdot}238$, $c = 5{\cdot}088$ A.[633] This phosphide seems to be distinct from trititanium diphosphide, $Ti_3P_2$ (tetragonal, $a = 7{\cdot}48$, $c = 10{\cdot}49$ A., congruent m.p. 2100°) and tetratitanium triphosphide (cubic, $a = 7{\cdot}425$, peritectic m.p. 2060°) observed in a phase rule study of the titanium–phosphorus system.[636] The latter phosphide may be identical with the phase of composition $TiP_{0\cdot7}$–$TiP_{0\cdot9}$ detected in another study.[635]

As indicated above, titanium monophosphide is formed when phosphine is passed over powdered titanium at a temperature higher than 800°, preferably 850°C.[295, 299] Other studies, in which phosphides were made by direct reaction of the elements, by reaction of tricalcium diphosphide with titanium metal,[566] or by reaction of phosphine with titanium tetrachloride, indicate that a homogeneous phase $TiP_{0\cdot94}$ exists.[298, 292] This is a grey-black metallic compound with *d* 3·95 g./c.c.[298] (4·08 g./c.c.[292]). It is very stable to heat, having no appreciable v.p. of phosphorus even at 1100°C.[298] The enthalpy of formation of titanium monophosphide, determined from heats of combustion, is −63·4 kcal./mole.[300] $TiP_{0\cdot94}$ is attacked only slightly by acids and water at room temperature[298, 292] whilst titanium monophosphide is highly resistant to oxidation.[299]

The diphosphide of titanium can be obtained by heating together titanium powder and red phosphorus or by heating the metal powder in a stream of phosphine and hydrogen.[292] It is orthorhombic, with $a=6{\cdot}181$, $b=8{\cdot}256$, $c=3{\cdot}346$ A.[637]

Crystal structure studies have been carried out on the ternary systems Ti(Cr, Mo or W)P,[638] TiCoP and TiFeP,[653] a compound which had been reported earlier.[462]

### Vanadium

By heating powdered vanadium with red phosphorus for several days at between 400°C. and 1000°C. a semimetallic grey black trivanadium phosphide with *d* 5·46 g./c.c. and molecular volume 11·33 c.c. is obtained which is attacked by concentrated sulphuric acid and warm nitric acid.[301] The compound forms tetragonal crystals isomorphous with $Ti_3P$, having $a=9{\cdot}387$, $c=4{\cdot}756$ A.[565]

Divanadium phosphide has been reported as being formed when a fused mixture consisting of $Li_3PO_4+\frac{1}{10}V_2O_5+2LiF$ is electrolyzed at 900°C. at 25 amp. and 5 volts.[302, 9] This compound is thought by others to be a mixture of monovanadium phosphide and divanadium trioxide.[301] An *X*-ray investigation lends a slight amount of support to this view because a phosphide lower than the monophosphide could not be confirmed.[292] However the compound crystallizes in metallic needles having *d* 4·5 g./c.c. It is readily attacked by boiling sulphuric acid, hot nitric acid, and boiling aqueous potassium persulphate but not concentrated hydrochloric acid. Solutions of alkali have no effect on it but fused alkali metal carbonate, nitrate or persulphate forms vanadates and phosphates.[302] Divanadium phosphide is an active catalyst for the decomposition of ammonia.[303]

Electrolysis of fused alkaline phosphate melts containing vanadium oxide[302, 9, 304] produces vanadium monophosphide, VP, as does heating powdered vanadium with red phosphorus for several days at elevated temperatures,[301] or causing tricalcium diphosphide to react with vanadium metal or chloride.[566] It is a grey-black compound, the density of which is variously reported as being 4·0 g./c.c.,[302] 4·69 g./c.c.[301] and 4·72 g./c.c.[292] The molecular volume is 17·7 c.c.[301] *X*-Ray powder photographs of vanadium monophosphide resemble those of molybdenum monophosphide but not those of the corresponding tantalum and niobium compounds.[301] As with other phosphides of vanadium, it is not attacked by water or dilute acid at room temperature, forms vanadates and phosphates with fused alkali, and reacts with warm nitric acid or concentrated sulphuric acid.[301–2, 292] Vanadium monophosphide reacts slowly with white phosphorus to form the diphosphide.[301]

The diphosphide is conveniently prepared from the powdered metal by heating it with red phosphorus[301, 292] or by passing a mixture of phosphine and hydrogen over it.[292] It is a black compound having *d* 4·5 g./c.c.[302] From the tensimetric analysis shown in Fig. 16,[301] a value of 57 kcal. was calculated for the heat of decomposition of vanadium diphosphide according to equation (23):

$$4VP_2(s) \rightarrow 4VP(s) + P_4(g) \tag{23}$$

The compound is probably isomorphous with the corresponding phosphides of tantalum and niobium since the *X*-ray diagrams are similar.[301] It is attacked by oxidizing acids.[301]

Phosphides of vanadium have been compared with those of tantalum and niobium[305] and a patent for their manufacture by heating finely divided metal with a large excess of phosphorus in a sealed container has been granted.[306]

The vanadium–phosphorus–iron system has been partly investigated.[307–8]

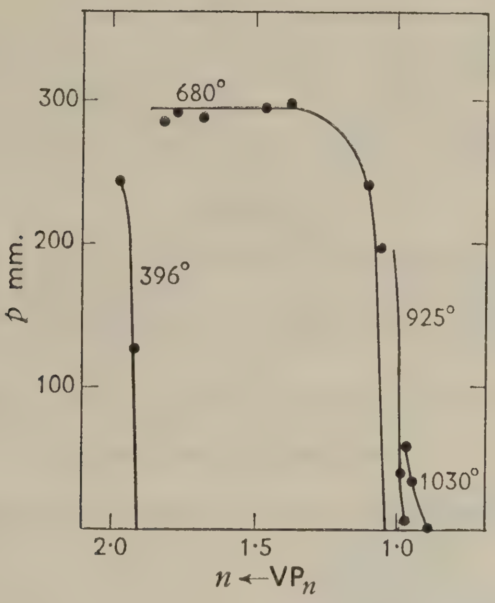

FIG. 16.—Vapour pressure analysis of the $VP_2$/VP system

## Chromium

Trichromium phosphide has been recognized in several phase studies[292, 309–10, 91] and has been obtained in mixtures by the electrolysis of fused salts.[311–2] It is isomorphous with the corresponding manganese, iron and nickel phosphides[309, 292] and forms continuous solid solutions with iron and nickel phosphides.[310, 91] The compound is a greyish black substance which melts incongruently. Its unit cell dimensions are $a = 9{\cdot}186$ A. and $c = 4{\cdot}558$ A.[308] and it has $d$ 6·25 g./c.c.[292] Water and dilute acids do not affect it at room temperature.[292]

Dichromium phosphide is formed together with monochromium phosphide when chromium phosphate is heated in hydrogen at 600°C. with continuous removal of the water vapour formed.[43] It has also been recognized in various phase studies.[91, 310] Dimanganese phosphide will only dissolve 50 molar-% of dichromium phosphide, whereas the iron and nickel compounds form continuous series of solid solutions.[91] Phase studies (see Fig. 17) showed the presence of this compound in the chromium–phosphorus system[310] but other investigators using $X$-ray methods were unable to identify it.[309]

Monochromium phosphide is prepared by electrolysis of fused alkali metal salts containing chromium salts[10] and, as indicated above, it is formed together with other phosphides when chromium phosphate is reduced with hydrogen.[43] When the diphosphide is heated with metal powder in a sealed silica tube it is converted into the monophosphide,[292] whilst the straightforward method of heating red phosphorus with chromium in a silica tube has been used successfully.[313] The reaction of tricalcium diphosphide with chromium metal or chloride is also said to yield chromium monophosphide.[566] Finally, phosphine passed over powdered chromium heated at 850°C. forms monochromium phosphide in 6 hr.[314, 299] The compound which is greyish black with a metallic lustre[292] and has $d$ 5·25 g./c.c.[292] crystallizes with the MnP type structure with $a = 5{\cdot}362$, $b = 3{\cdot}113$, $c = 6{\cdot}018$ A.[313] Isomorphism with the manganese, iron, and cobalt compounds has been established.[309, 292, 639] From measurements in a tensimetric analysis, shown in Fig. 18, the investigators were able

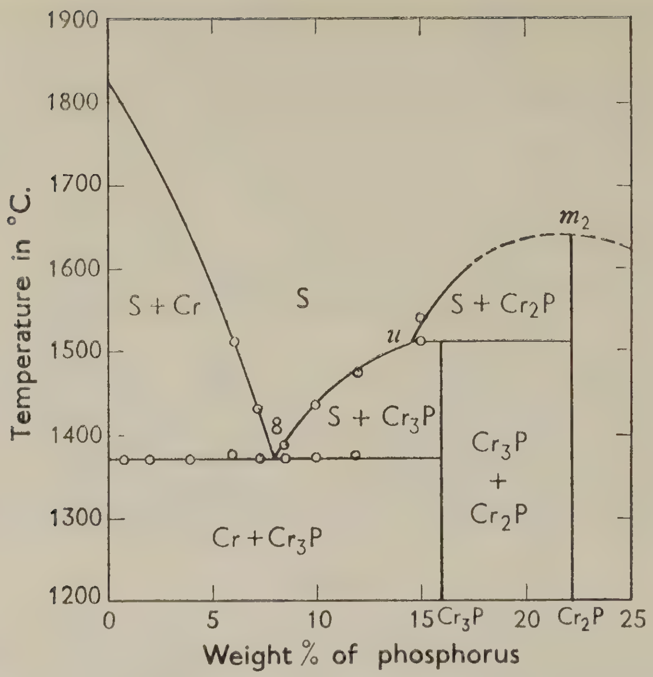

FIG. 17.—The phase diagram of chromium and phosphorus

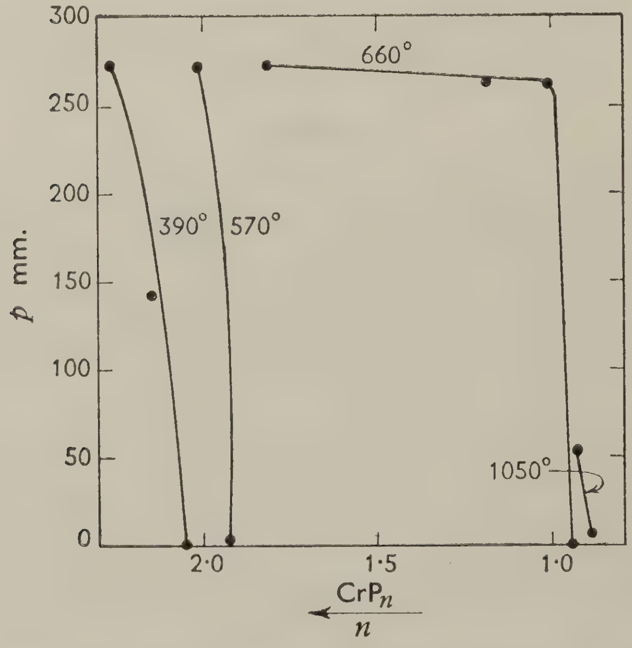

FIG. 18.—Vapour pressure analysis of the chromium–phosphorus system

to calculate a heat of reaction of monochromium phosphide with phosphorus according to equation (24)[315]:

$$(24) \qquad CrP(s) + P(white) \rightarrow CrP_2(s) \qquad \Delta H = -6{\cdot}5 \text{ kcal./mole}$$

Monochromium phosphide is highly resistant to oxidation,[299] and is not attacked by water or dilute acids at room temperature.[292, 314] It has been shown to be active as a catalyst for the decomposition of ammonia.[303]

If the metal powder is heated with red phosphorus or if a dry mixture of phosphine and hydrogen is passed over the metal powder heated to between 700° and 900°C. for between 2 and 10 hr., the diphosphide is obtained.[292] The data used to obtain the heat of reaction of monochromium phosphide can also give the heat of decomposition of chromium diphosphide according to equation (25)[315]:

$$(25) \qquad 4CrP_2(s) \rightarrow 4CrP(s) + P_4(g) \qquad \Delta H = +39 \pm 3 \text{ kcal.}$$

This phosphide has been used as a protective coating for metals which are readily oxidized.[316]

Ternary systems investigated include the chromium–phosphorus–manganese, chromium–phosphorus–nickel, chromium–phosphorus–copper, chromium–phosphorus–iron systems[91, 310] and the chromium–phosphorus–boron system.[344] The nickel-containing system is characterized by a ternary sigma phase.[308] In the boron system it was shown that the solid solubility of boron in $Cr_3P$ is appreciable.[344]

## Manganese

The manganese–phosphorus phase diagram was investigated up to 45 atomic-% of phosphorus. The results of this work are shown in Fig. 19 where it can be seen that a tetramanganese phosphide phase was claimed to exist.[317]

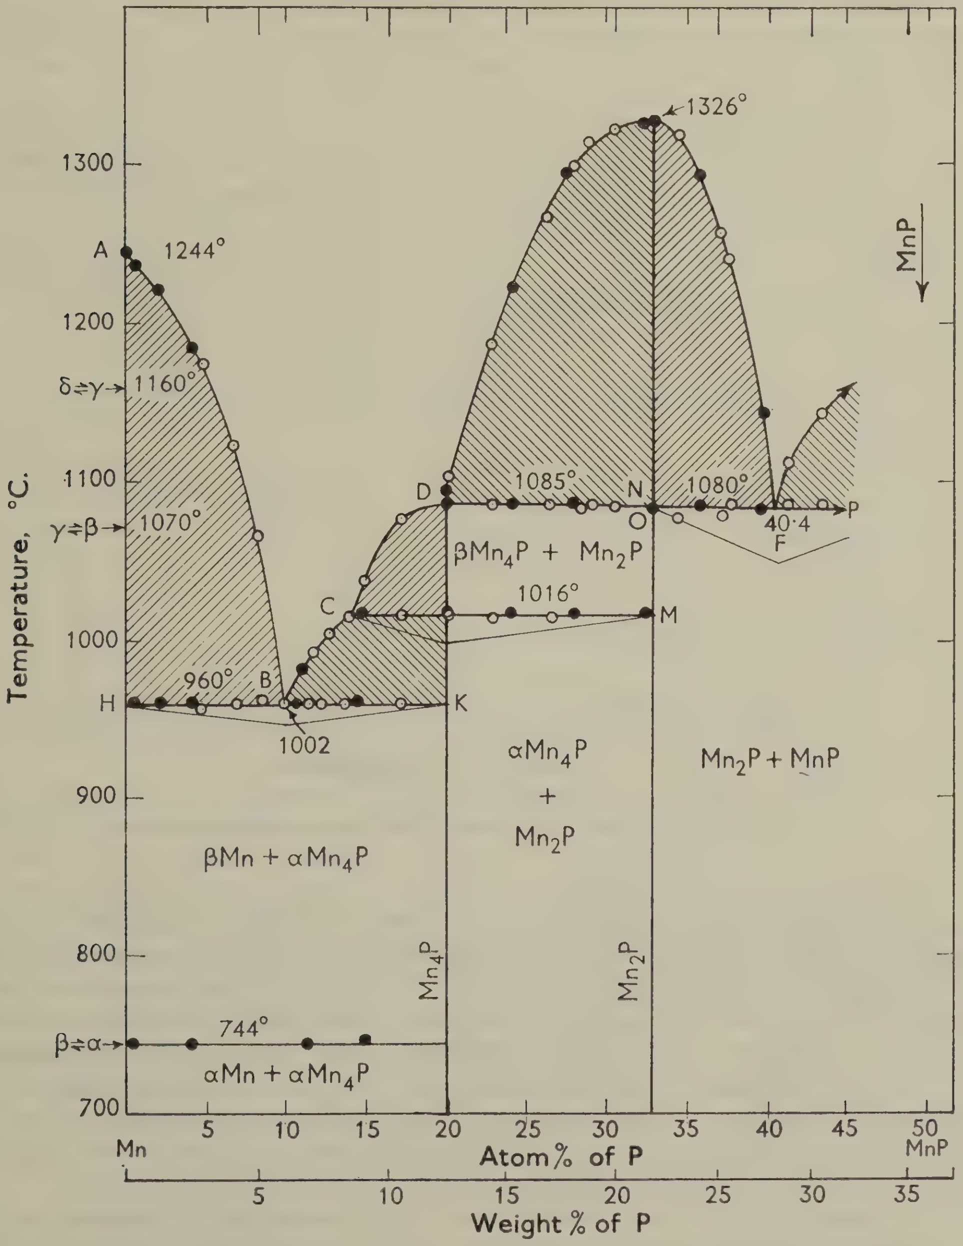

FIG. 19.—Phase diagram of the Mn–MnP system

Repetition of this work[318] (Fig. 20) suggests that the manganese-rich phase is trimanganese phosphide. This has been confirmed by $X$-ray work which disclosed a new phase, trimanganese phosphide but not tetramanganese phosphide.[319] The $X$-ray measurements give the space group as being probably $S_4^2$ because of isomorphism with tri-iron phosphide.[319] This has been confirmed[320] and the unit cell dimensions are variously given as $a=9{\cdot}160$, $c=4{\cdot}599$ A.,[319] $a=9{\cdot}00$, $c=4{\cdot}57$ A.[318] and $a=9{\cdot}181$, $c=4{\cdot}568$ A.[320] Although it is isomorphous with the corresponding iron compound, it forms a continuous series of solid solutions only with trichromium phosphide.[319]

Electrolysis of fused alkali metal phosphate melts containing manganese salts,[10, 9, 321, 311–2] and reduction of trimanganese phosphate with hydrogen[43] have both yielded dimanganese phosphide. The crystal structure has hexagonal symmetry, space group $P\bar{6}2m$, with $a=6{\cdot}08$, $c=3{\cdot}45$ A.[322] or $a=6{\cdot}081$, $c=3{\cdot}460$ A.[320] A Curie temperature of 20°C. for ferromagnetism in this compound has been reported,[294] but other work has shown that dimanganese phosphide is not ferromagnetic and that any ferromagnetism must be due to monomanganese phosphide.[323] There are indications from $X$-ray work that dimanganese phosphide may have a finite homogeneity range.[320] Galvanomagnetic measurements on material containing both monomanganese phosphide and dimanganese phosphide show that the Hall effect varies linearly with magnetization near the Curie point. The Hall constant decreases with decreasing temperature which indicates metallic type conduction.[324–5]

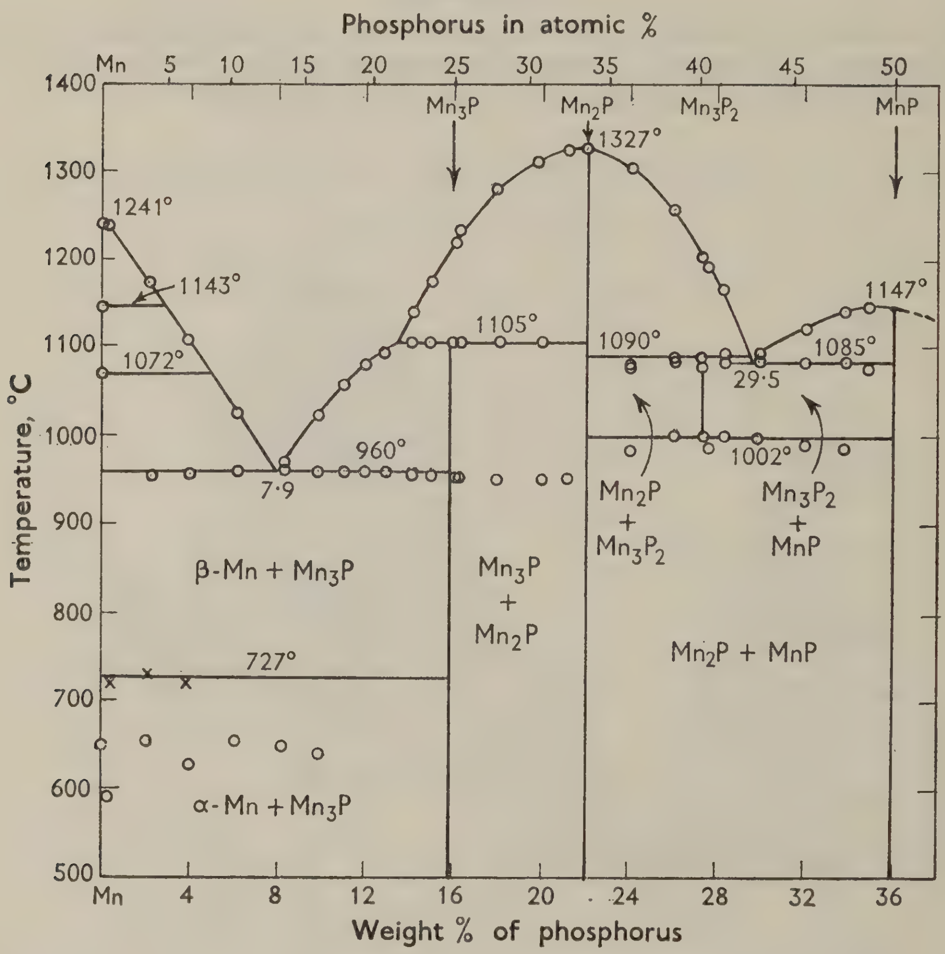

FIG. 20.—Part of the manganese–phosphorus phase diagram

Besides disagreeing as to the composition of the manganese-rich phase, the phase studies shown in Figs. 19 and 20 also disagree concerning the existence of the compound trimanganese diphosphide. It is reported as being ferromagnetic and to decompose at 1090°C. to give dimanganese phosphide and monomanganese phosphide.[318] *X*-Ray powder work on the manganese–phosphorus system throws doubt on the existence of this compound.[320]

The well-known method of electrolyzing fused phosphate melts containing salts of the metal has been used as a means of preparing monomanganese phosphide.[10, 9, 321, 311–2] In a study of the magneto-calorie effect,[326] monomanganese phosphide was prepared by reaction of a powdered mixture of red phosphorus and vacuum distilled electrolytic manganese at 650°C. for 50 hr. in a sealed evacuated quartz tube.[327–8] Variations of the technique have also been used.[313, 329] Finally, the reaction of tricalcium diphosphide with manganese metal or halide is said to give the monophosphide.[566] The monophosphide is magnetic, has $d$ 5·6 g./c.c.[321] and an orthorhombic crystal structure with $a=3{\cdot}167$, $b=5{\cdot}905$, $c=5{\cdot}249$ A.[322] or $a=5{\cdot}258$, $b=3{\cdot}172$, $c=5{\cdot}918$ A.,[313] or $a=5{\cdot}9$, $b=5{\cdot}25$, $c=3{\cdot}16$ A.[329] The orthorhombic B31 structure is distorted from a hexagonal nickel arsenide (B81) structure, due to metal–metal bonding in the hexagonal basal planes.[640] Manganese monophosphide is isomorphous with chromium, iron and cobalt monophosphides.[639]

Several investigations into its electrical and magnetic behaviour have been made. Magnetic moment measurements indicate a moment of 14·1 Weiss magnetons[330] and 1 Bohr magneton.[331] This last value has been explained by advancing the hypothesis that consecutive planes of manganese atoms in the structure are in states $3d^5$, $4s^2$ or $3d^7$. The assumption of an antiferromagnetism mechanism in this compound could not be confirmed.[332, 641] A value of $5{\cdot}98 \pm 0{\cdot}15$ Weiss magnetons, obtained from measurements of specific magnetization versus temperature and field strength,[333] agrees more with that of Guillard[331] than with that of Foex.[330] A large variation of Curie point was observed in these experiments but other workers have given the Curie point as 22°C.,[334, 327–8] 20°C.,[335] 25°C.,[333, 336] $18{\cdot}3 \pm 0{\cdot}2$°C.[641] and 40°C.[337] The value of 40°C. probably refers to the paramagnetic Curie temperature since a value of 39°C. has been reported.[336] Temperature versus resistance plots, which are very nearly linear above and below the Curie point, gave breaks at 22°C.[324, 338] The Curie temperature is independent of the intensity of the magnetic field.[325] Monomanganese phosphide is strongly paramagnetic above its critical temperature.[337] Measurements of volume change, magnetic transitions and density transitions[323] in going from the ferromagnetic to the paramagnetic state exhibit no hysteresis effects. This has been taken to indicate that the temperature at which spontaneous magnetization becomes zero is lower than the temperature of zero susceptibility.[339] Specific heat measurements in the neighbourhood of the critical temperature have been made[328, 340] and show a small increase of the order expected from the Weiss theory, but the accuracy of measurement was not high enough to decide whether the maximum in the specific heat corresponded to the maximum value of $I\partial I/\partial T$ or $\partial I/\partial T$ ($I$ is the saturation magnetic intensity).[340] The anomaly in the specific heat has a maximum value at 17°C. and then decreases up to 30°C.[328] Electric and galvanomagnetic measurements have been made[325, 324] and indicate that the conduction of monomanganese phosphide is governed by the overlap of the $d$ shells of the manganese atoms forming a narrow $d$ conduction band. The concentration of carriers is high and is comparable with that in metals.[325] The Hall effect near the Curie point varies linearly with magnetization and the Hall constant decreases with decreasing temperature.[324] Calculations on the filling of Brillouin zones and consideration of chemical binding between atoms has led to the prediction of semiconductor properties.[341]

Monomanganese phosphide is grey with a metallic lustre[342] and shows complete solid solubility in monocobalt phosphide.[313] The heat of combustion, −270 kcal./mole and heat of formation, −23 kcal./mole have been determined.[329] It is not attacked by cold water, cold dilute acids or cold concentrated nitric acid. It is attacked, however, by hot dilute nitric acid, molten alkali, alkali metal salts, disodium oxide and lead dioxide.[321] The compound is active as a catalyst for the decomposition of ammonia.[303]

The reaction of powdered manganese and red phosphorus in a heated sealed tube has been used as a method for preparing manganese triphosphide. V.p. measure-

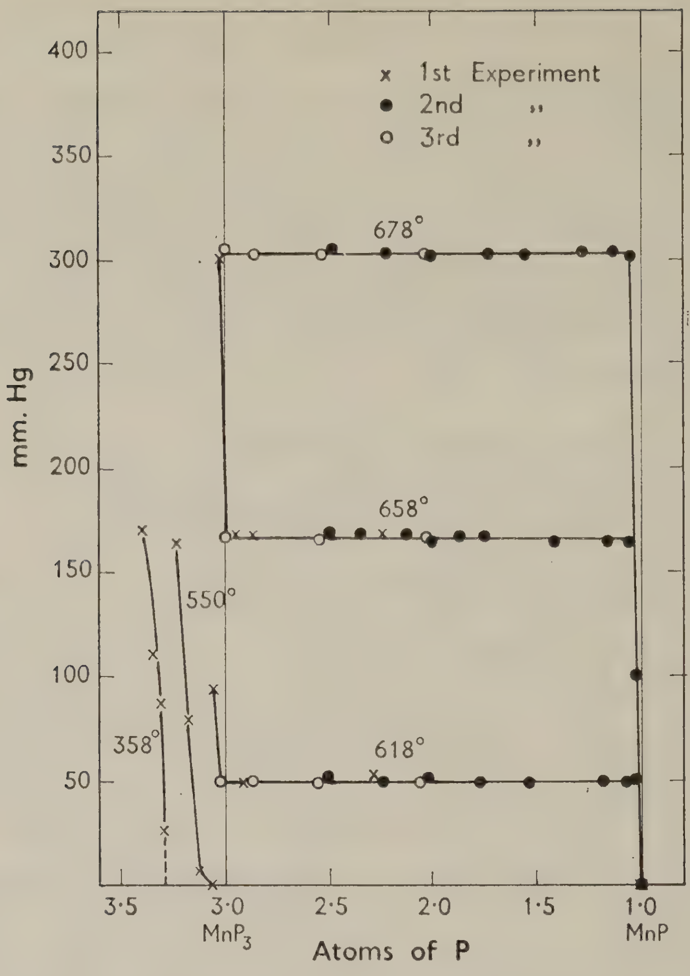

FIG. 21.—Vapour pressure analysis in the manganese–phosphorus system

ments on some preparations are shown in Fig. 21. From these results the dissociation pressure was shown to obey equation (26):

$$(26) \qquad \log p_{(\mathrm{mm.})} = -11856/T + 14{\cdot}948$$

and the heat of dissociation was calculated for equation (27):

$$(27) \qquad 2\mathrm{MnP_3(s)} \rightarrow 2\mathrm{MnP(s)} + \mathrm{P_4(g)} \qquad \Delta H = +54{\cdot}2 \text{ kcal.}$$

Manganese triphosphide takes up phosphorus into solid solution.[342]

Manganese forms a series of ternary phosphides of general formula $Li_{8-x}Mn_xP_4$. These can be obtained by heating trilithium phosphide, manganese and phosphorus at 800°C. in argon. They have been discussed under lithium and Table II (page 292) lists some of their properties.[29]

Ternary systems manganese–phosphorus–chromium,[91] manganese–phosphorus–iron,[91, 343] manganese–phosphorus–nickel[91] and manganese–phosphorus–boron[344] have been investigated. In the last system a ternary phase $Mn_5PB_2$ exists which is isostructural with $Fe_5PB_2$ and $Co_5PB_2$.[344]

## Iron

Andrieux's method, i.e. electrolysis of fused alkali metal phosphates containing a compound of the metal of which it is required to prepare the phosphide, has been applied to the synthesis of tri-iron phosphide.[345, 9] In this reaction the phosphide produced depends upon the molar ratio of ferric oxide to phosphorus pentoxide present in the melt and Fig. 22 shows the ratios at which various iron phosphides are produced. Thermal and tensimetric analysis served to identify the compounds formed.[9] Reaction of the elements in a heated sealed quartz tube produces tri-iron phosphide together with higher phosphides.[346, 50] For some magnetic measurements it has been produced by fusion of the elements,[347] whilst reduction of $Fe_2O_3$–$FePO_4$ preparations with hydrogen or carbon monoxide also produces tri-iron phosphide, though other phosphides may also be produced depending upon the ratio of iron to phosphorus in the original oxide–phosphate preparation.[348] *X*-Ray powder methods have been used to identify this phosphide in a study of the iron–phosphorus system,[349–51] and in an unknown spherulitic phase present in some tektites.[567] Other *X*-ray work has confirmed previous investigations and shown that the crystal structure is tetragonal with $a = 9{\cdot}090$, $c = 4{\cdot}446$ A.[352] Tri-iron phosphide has *d* 7·11 g./c.c.,[346] 7·13 g./c.c.[347] and its heat of formation (shown with those of other iron phosphides in Fig. 23) is −35·2 kcal./mole.[50] The free energy of formation of solid $Fe_3P$ from the gaseous elements has been estimated as $-50{,}600 + 11{\cdot}3T$ g.-cal./mole over the range $T = 298$–1439°K.[548] Magnetic measurements give for this compound a Curie temperature of 443°C. and a saturation moment of $1{\cdot}84\mu_B$ per atom of iron.[347] The maximum coercive field of 107 oersted was observed at 18°C.[347] Tri-iron phosphide can be separated from di-iron phosphide by magnetic means.[353] It has been recognized as a precipitation phase from solid solution of phosphorus in α-iron[354]

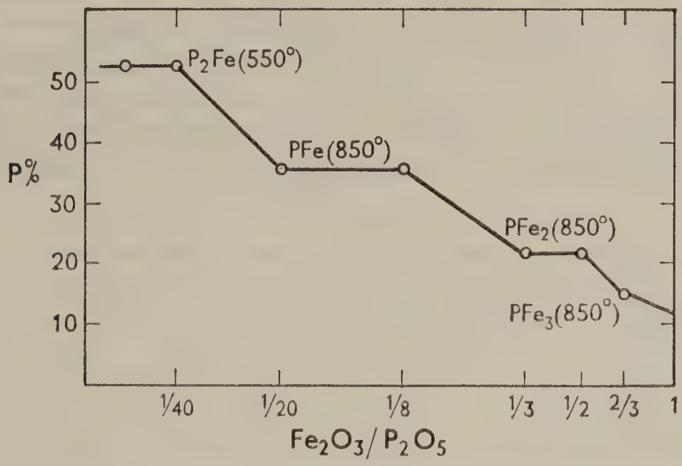

FIG. 22.—The iron phosphides formed at different $Fe_2O_3/P_2O_5$ ratios

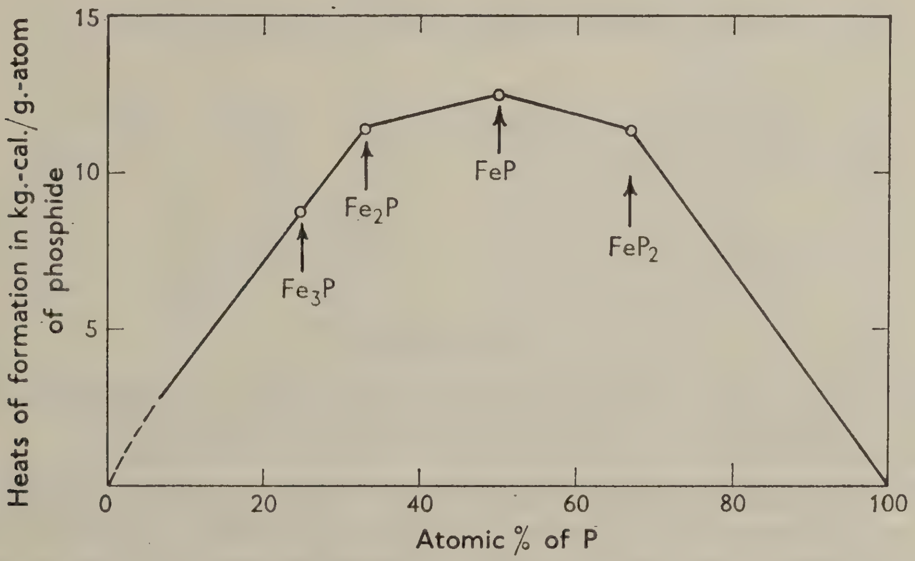

FIG. 23.—Heats of formation in the iron–phosphorus system

and the habit plane of this precipitated phase has been predicted using the theory of martensitic transformations.[355] This phosphide is not very resistant to chemical attack, being oxidized in the atmosphere and dissolved by acids.[345] Solid state reactions between lime, oxygen and tri-iron phosphide have been shown to proceed according to equation (28)[356]:

$$3CaO + 2Fe_3P + 7O_2 \rightarrow Ca_3(PO_4)_2 + 3Fe_2O_3 \quad (28)$$

Di-iron phosphide has been prepared by Andrieux's method,[9, 345, 10] by heating the elements together in a sealed evacuated quartz tube,[346] and by heating iron phosphates in an atmosphere of hydrogen or carbon monoxide above 950°C.[357, 348] A study of the iron–phosphorus system[349–50] as well as the iron–phosphorus–nickel system[358] showed the existence of di-iron phosphide. Further evidence is provided by the existence of discontinuities at above 22% P in the magnetic susceptibility,[642] density and surface tension[643] isotherms for the iron–phosphorus system. The manufacture has been accomplished by adding electrolytic iron to a molten copper–phosphorus alloy.[359] *X*-Ray work has shown that the crystal structure is hexagonal with $a=5{\cdot}87$, $c=3{\cdot}45$ A.,[359] $a=5{\cdot}852$, $c=3{\cdot}453$ A.,[360] $d=6{\cdot}89$ g./c.c.,[359] 6·77 g./c.c.[346] V.p. measurements are shown in Fig. 24.[346] The heat of formation has been variously given as −34·5 kcal./mole,[50] −35·2 ± 2 kcal./mole at 900°K. and −41·0 ± 4·1 kcal./mole.[361] At 1350°C. the heat of dissociation to $P_2$ vapour is 111·2 ± 2 kcal./mole.[568] The estimated free energy of formation of solid $Fe_2P$ from the gaseous elements over the temperature range 298–1638°K. is given by $\Delta G = -49{,}900 + 11{\cdot}3T$ g.-cal./mole.[548]

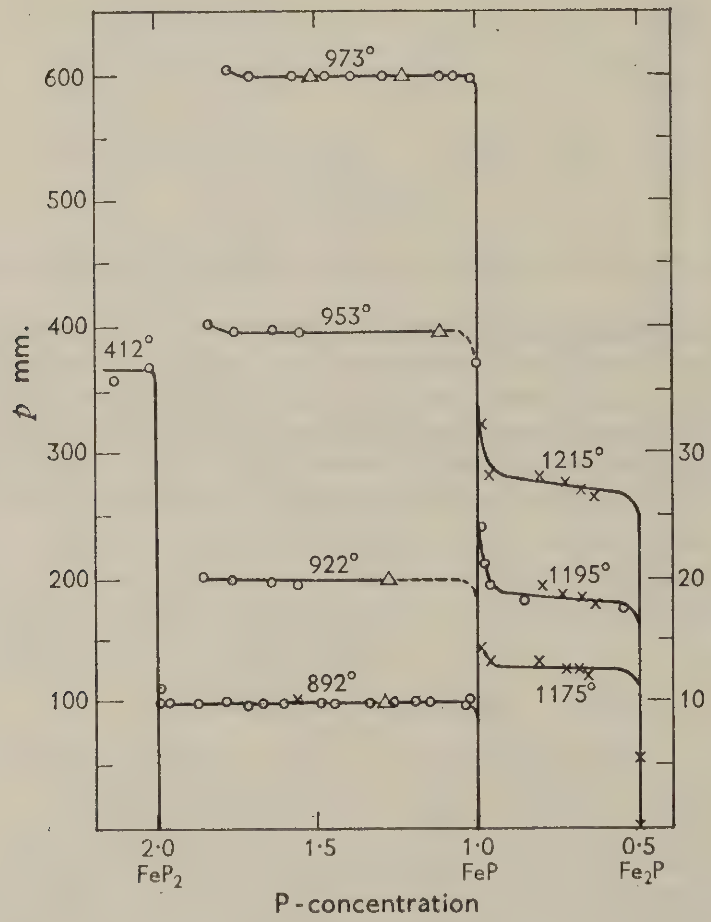

FIG. 24.—Vapour pressure analysis of iron phosphides. The right hand pressure scale corresponds to the determinations at 1175, 1195 and 1215°C.

Magnetic measurements have shown that di-iron phosphide, with the magnetization vector along the axis of symmetry of the hexagonal net, has a Curie point of

$-7$°C. and an absolute moment of 1·32 Bohr magnetons per atom of iron.[362] Samples containing a slight excess of phosphorus appeared to possess extreme magnetic hardness[362]; (magnetically hard materials retain a considerable portion of the magnetic moment they acquire on magnetization after the magnetizing field has been removed). Other workers have shown that the extrapolated saturation magnetization reaches a value at 0°C. of 66·3 gauss/g. of iron, a value which corresponds to a spin moment of $0{\cdot}85 \pm 0{\cdot}02$ Bohr magneton per iron atom.[363] It was also shown that the Curie–Weiss law[326] holds up to 900°K. and Curie points were observed at 306°K. (ferromagnetic) and 478°K. (paramagnetic).[363] A total magnetic moment of 14 Weiss magnetons corresponds with a neutral iron atom.[330]

Deposition studies have shown that this compound can be deposited electrolytically on a wire such that the [0001] axis is perpendicular to the surface of the wire.[364] It has been investigated as a material suitable for corrosion-resistant electrodes. Current–voltage curves were plotted in acids, alkalis and saturated potassium chloride solutions whilst rates of corrosion by hydrochloric acid, sulphuric acid, nitric acid and potassium hydroxide were determined at 25°C. and 80°C.[365] The same workers showed that this compound is a good conductor of electricity and has a negative coefficient of resistivity.[365] When used as an anode in normal sulphuric acid, normal potassium hydroxide, saturated potassium chloride and normal potassium acetate–normal acetic acid solution, di-iron phosphide is oxidized to ferric and orthophosphate ions.[365] Disproportionation of carbon monoxide on this phosphide has been shown to be due to ferric oxide impurity, the phosphide itself being inactive.[366] It was also shown to be inactive as a catalyst in the hydrogenation of *cyclo*hexene.[367] Reactions of di-iron phosphide with oxides FeO, $Fe_2O_3$, MnO, PbO, CaO + FeO, $CaO + Fe_2O_3$ have been examined thermally and heats of reaction shown to differ widely from values calculated using known heats of formation of compounds in each particular case. The differences may possibly be explained by assuming a specific heat effect, because the heats of reaction were studied at high temperatures whereas the calculated heats of reaction apply to normal temperatures.[368] With $Ni_2P$ di-iron phosphide forms single phase alloys.[311]

Monoiron phosphide is produced together with other phosphides when the metal reacts with red phosphorus at high temperatures in a sealed evacuated tube[346] or in an inert atmosphere of argon over the melt.[313] As shown in Fig. 22, it is also produced when sodium phosphate melts containing the correct molar ratio of ferric oxide to phosphorus pentoxide are electrolyzed.[10, 9, 345, 369–70] Iron pyrophosphate can be reduced by hydrogen at 620°C. to yield monoiron phosphide.[43] *X*-Ray investigation has shown that this steel-grey compound has a similar structure to the manganese and cobalt monophosphides. It is orthorhombic with $a = 5{\cdot}782$, $b = 5{\cdot}177$, $c = 3{\cdot}089$ Å.[322] or $a = 5{\cdot}191$, $b = 3{\cdot}099$, $c = 5{\cdot}792$ Å.[313] Two density determinations agree well giving $d = 6{\cdot}0$ g./c.c.[369–70] and $d = 6{\cdot}07$ g./c.c.[346] Its corrosion resistance when used as electrodes has been investigated: similar measurements were made to those given for di-iron phosphide,[365] and like that compound it was oxidized to ferric and orthophosphate ions.[365] The same workers report that it is a good conductor of electricity. Monoiron phosphide has a Curie point of $-58$°C., and an absolute moment of $0{\cdot}36\mu_B$ per atom of iron.[577] The paramagnetic susceptibilities of compositions in the FeP region have been determined.[644] Thermodynamic data are summarized in Fig. 23,[50] Fig. 24[346] and equation (29)[346]:

$$(29) \qquad 4FeP(s) \rightarrow 2Fe_2P(s) + P_2(g) \qquad \Delta H = +72 \text{ kcal.} \qquad t = 1200°\text{C.}$$

More recent values for the heat and entropy of dissociation/mole $P_2$ vapour at 1250°C. ($\Delta H^\circ_{1250} = 84{\cdot}8 \pm 2$ kcal., $\Delta S^\circ_{1250} = 50{\cdot}3 \pm 1$ g.-cal./mole/degree) lead to a value for the heat of formation of FeP (from solid Fe and red P at 900°K.) of $-28{\cdot}6 \pm 2$ kcal./mole.[568] The free energy of formation of solid FeP from the gaseous elements at $T$°K. is given by $\Delta G = -40{,}400 + 11{\cdot}3T$ g.-cal./mole.[548]

Like di-iron phosphide, this compound has been shown to be inactive as a catalyst for the hydrogenation of *cyclo*hexene[367] and for the disproportionation of carbon monoxide[366] but active for the decomposition of ammonia.[303]

It is more resistant to chemical attack than the lower phosphides since it is attacked only slowly by acids, alkalis and aqua regia. Sodium persulphate and boiling concentrated sulphuric acid attack it quite readily.[369] Silicon shows considerable solubility in monoiron phosphide, whilst monocobalt phosphide shows complete solid solubility.[313]

Iron diphosphide, which is the highest phosphide of iron so far prepared, has been obtained by reaction of the elements in a sealed evacuated tube[346, 371] and by Andrieux's method.[345, 10, 9] Results of vapour pressure measurements are shown in Fig. 24 and from these the heat of decomposition according to equation (30) was calculated to be +66 kcal.[346]

$$(30) \qquad 4FeP_2(s) \rightarrow 4FeP(s) + P_4(g) \qquad \Delta H = +66 \text{ kcal.} \qquad t = 930°\text{C.}$$

A more recent determination of the heat and entropy of dissociation/mole $P_2$ vapour at 1000°C. ($\Delta H^\circ_{1000} = 70{\cdot}6 \pm 2$ kcal., $\Delta S^\circ_{1000} = 52{\cdot}9 \pm 1$ g.-cal./mole/degree) leads to a value of $-43{\cdot}6 \pm 4$ kcal./mole for the heat of formation of $FeP_2$ from solid iron and red phosphorus at 900°K.[568] The free energy of formation of solid $FeP_2$ from the gaseous elements at $T$°K. is calculated to be $\Delta G = -64{,}800 + 22{\cdot}5T$ g.-cal./mole.[548]

Its crystal structure is of the marcasite type with $a = 2{\cdot}72(5)$, $b = 4{\cdot}97(5)$, $c = 5{\cdot}65(7)$ Å., $d = 5{\cdot}07$ g./c.c. and molecular volume 23·3 c.c.[346, 645] Iron diphosphide is rather more inert to chemical attack than the other iron phosphides.[345] It is antiferromagnetic.[577]

*X*-Ray studies failed to establish the existence of a phosphide $FeP_3$ which would correspond to $MnP_3$, $CoP_3$ or $NiP_3$.[371]

Individual iron phosphides are not manufactured for any specific purpose although a patent for their use in friction elements for brake linings and clutches has appeared,[75] but a mixture of the di-iron phosphide and the monoiron phosphide (containing approximately 25% of phosphorus) has received a great deal of attention. Ferrophosphorus, as this product is known, is sometimes manufactured for use in special steels and the patent literature on this substance is extensive.[372–82]

In phosphorus production where a phosphate rock is reduced by heating with carbon, some of the phosphorus is lost by combination with iron in the furnace charge to form ferrophosphorus. Efforts have been made to convert this into a useful source of phosphorus. These have included attempts to recover the phosphorus as such,[383–4] whilst other investigations have aimed at producing phosphates which would be useful as additions to animal feed or fertilizers.[385–92] Reaction with sodium sulphate and sodium carbonate at 700°C. gives trisodium phosphate.[393] In air oxidations the product varies according to the temperature of reaction. At 1250°C. the main product is $2Fe_3O_4, 1{\cdot}5P_2O_5$ and the heat of reaction for 1 mole or 142·7 g. of $Fe_2P$ is $-347$ kcal. whilst at lower temperatures the main product is $3Fe_2O_3, 1{\cdot}5P_2O_5$ and the heat of reaction for 1 mole is $-364$ kcal.[394] Oxidation with water vapour occurs starting at a temperature approximately 100°C. higher than air oxidations which produce the same products. For the reaction

$$3Fe_2P + 15{\cdot}5H_2O \rightarrow 2Fe_3O_4, 1{\cdot}5P_2O_5 + 15{\cdot}5H_2$$

the heat of reaction is $-37$ kcal./mole. A second decomposition with alkali metal sulphide or soda solution under pressure or with ammonia plus carbon dioxide can be carried out to give water-soluble phosphates.[394] Chlorine in the nascent state at 400° to 450°C. produced chlorides, the heat of reaction for 1 mole of $Fe_2P$ being $-231$ kcal. Chlorides are produced similarly with phosgene and here the heat of reaction is $-112$ kcal. per mole of $Fe_2P$.[394] In decompositions with nitric acid the best results are obtained with acid at a concentration of 30% which give as products ferric nitrate and phosphoric acid and a heat of reaction of $-573$ kcal./mole $Fe_2P$. This reaction cannot be considered as a means for obtaining phosphoric acid because of the difficulty of removing the iron.[394] However with concentrated sulphuric acid the iron is precipitated as anhydrous ferrous sulphate but even here it may be necessary to employ oleum to maintain anhydrous conditions.[394] Above 300°C.

aqueous alkali with or without the addition of oxygen reacts completely with ferrophosphorus. In reactions without the addition of oxygen hydrated FeO and $Fe_2O_3$ are obtained, whilst with added oxygen $Fe(OH)_3$ is the reaction product. Alkali metal carbonates react to a lesser extent than alkali metal hydroxides. Fusion at 1000°C. with sodium chloride produces trisodium phosphate.[394] With all of these reactions, except that with concentrated sulphuric acid, difficulty is experienced in separating the iron compounds from the phosphorus compounds and they cannot therefore be considered to have any economic possibilities.

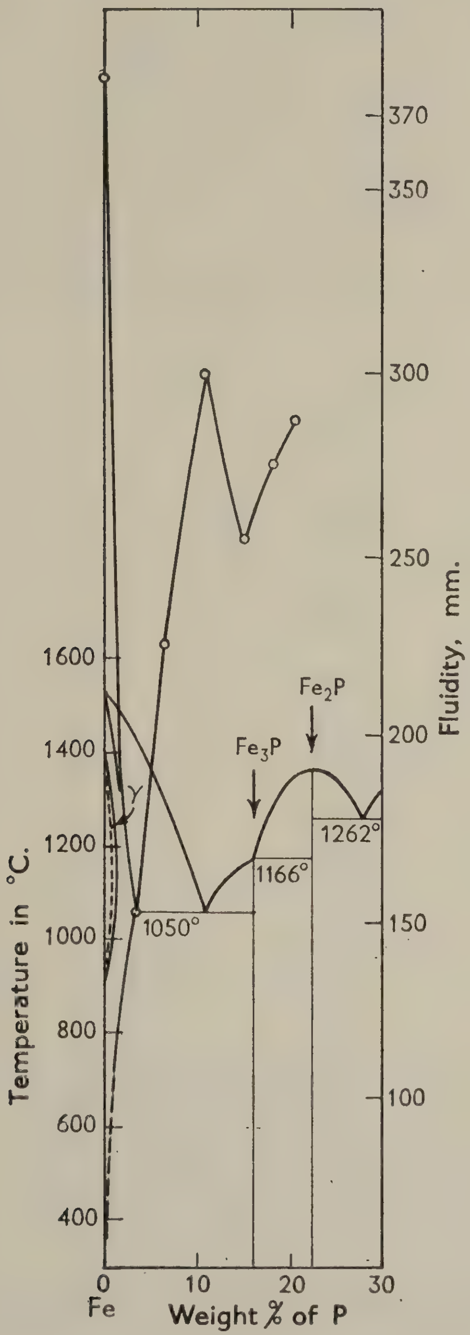

FIG. 25.—Structural and composition–fluidity diagrams for the iron–phosphorus system

Ferrophosphorus as such has been suggested as a heavy aggregate for dense concrete used in nuclear reactor shielding[395–403] and as an addition to green clay used in making refractory bricks. It is claimed that such addition eliminates the oxidation stage in the firing process (28 hr. at 500° to 980°C.).[404] A mixture of iron–phosphorus alloy and carbon is capable of reducing metal oxides to give pure metal or alloy[405] and a patent describes methods of obtaining alkali metals from a reaction between alkali metal carbonates and ferrophosphorus.[406] Phosphide-containing alloys have found some limited use because of their corrosion resistance,[407–9] and as brazing materials.[410] Physicochemical studies of the iron–phosphorus system have been made. Fluidities of molten alloys correlate well with the phase diagram shown in Fig. 25.[411–3] Experiments on undercooled alloys[414] show that phase differences exist between solid alloys formed from normal melts and those formed from undercooled melts. In these experiments it was found possible to establish the unstable iron–di-iron phosphide system.

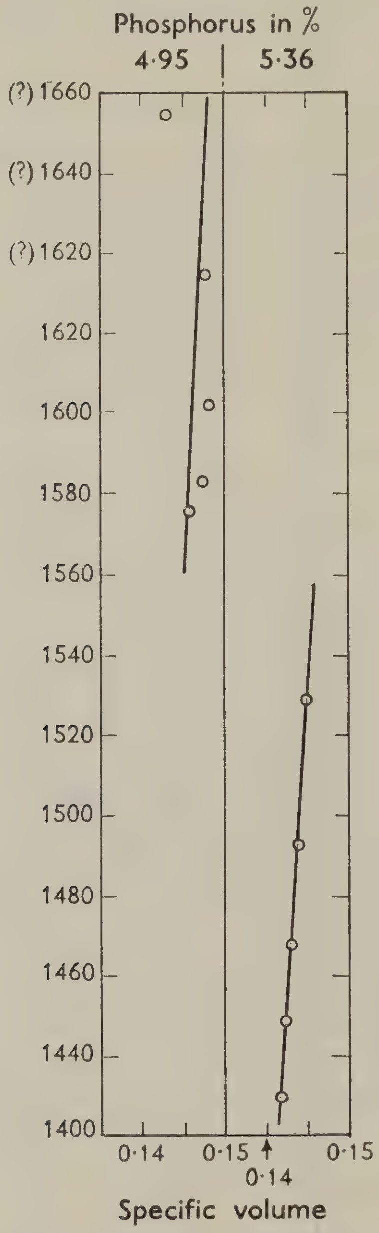

Fig. 26.—Specific volume of various iron alloys

In an effort to produce nickel-free alloys of high magnetic stability, the magnetic properties of iron–phosphorus alloys have been studied as a function of concentration and in relation to the precipitation phenomena.[415] Magnetostriction measurements show that the system is similar to the iron–tungsten system.[416] Alloys containing more than 1·5% of phosphorus are capable of precipitation hardening.[417] Hardness in annealed alloys shows an increase at 450°C., reaching a maximum at 550° to 600°C. Similarly electrical conductivity, coercivity and remanence show an increase and reach a maximum at 700° to 725°C.[417] Electromotive force measurements have been made on liquid alloys using the concentration cell:

$$\text{Fe, C}_{\text{satd.}}\text{, P} \mid \text{CaO, MgO, SiO}_2\text{, Ca}_3\text{P}_2\text{, Mg}_3\text{P}_2 \mid \text{Fe, C}_{\text{satd.}}\ \text{P}_{24\%}$$

With variation in phosphorus concentration of one electrode it was possible to show an inflexion at 22% of phosphorus and 1470°C. The composition corresponds to di-iron phosphide and the activity of the phosphorus indicated only slight dissociation for the compound.[418–9] Di-iron phosphide has also been noted as an inflexion at 22%P on magnetic susceptibility versus %P plots for the iron–phosphorus system.[420] Other magnetic susceptibility measurements have been made on dilute alloys (1·23 at.-% of phosphorus) but at temperatures around 1400°C.[421]

By studying the solubility of carbon in iron–phosphorus alloys at various temperatures, it was shown that phosphorus lowers the solubility of carbon in iron.[422] Activity coefficients of phosphorus[423] and specific volumes have also been measured.[424] The specific volumes of molten alloys are approximately proportional to the composition as shown in Fig. 26. Reaction diffusion was studied in the iron–phosphorus system: at 400° to 600°C. a unilateral diffusion of phosphorus was observed.[425]

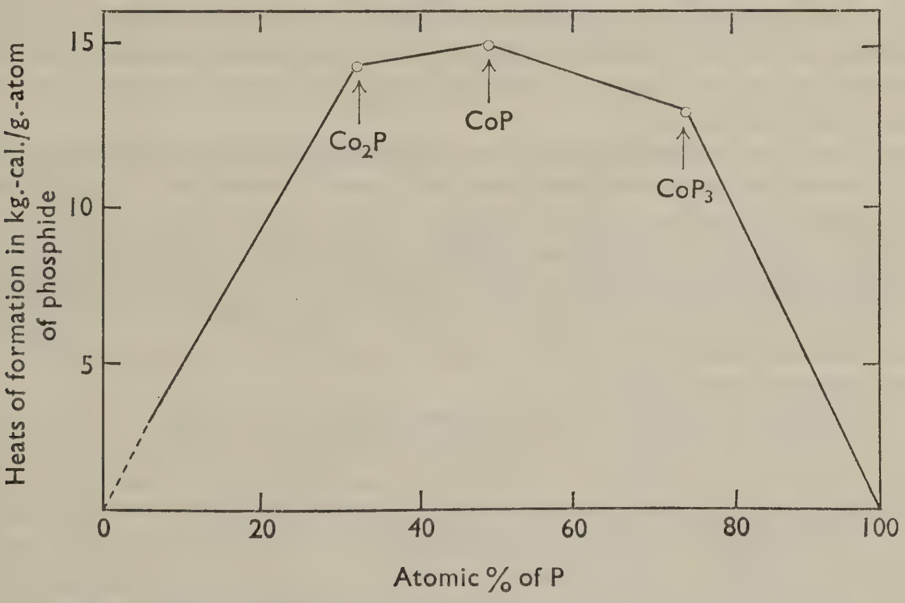

FIG. 27.—Heats of formation in the cobalt–phosphorus system

Investigations on ternary systems of iron and phosphorus with a third element are very numerous and in this class by far the most important, because of the relation to the iron and steel industries, are those dealing with the iron–phosphorus–carbon system.[426–41] In the iron–phosphorus–silicon system a new compound iron tetrasilicon tetraphosphide has been discovered.[442] Comparison of this system with analogous zirconium and titanium ones shows that the affinity for phosphorus is in the order $\text{Zr} > \text{Ti} > \text{Si}$.[442] The iron–phosphorus–niobium system was studied microscopically and by *X*-ray.[443] Three ternary compounds were found. FePNb melts congruently at 1820°C. and has *d* 4·99 g./c.c. $\text{FePNb}_2$ melts incongruently and so does $\text{FePNb}_4$. An investigation of the iron–phosphorus–boron system in the range $\text{Fe–FeP}_2\text{–BP–FeB–Fe}$ showed two ternary phases $\text{Fe}_5\text{PB}_2$ and $\text{Fe}_3\text{P}_{1-x}\text{B}_x$ which is homogeneous in the range $0{\cdot}48 < x < 1$ at 1000°C. $\text{Fe}_5\text{PB}_2$ is isostructural with $\text{Mn}_5\text{PB}_2$ and crystallizes with $a = 5{\cdot}482$, $c = 10{\cdot}332$ A., space group *I*4/*mcm*.[344]

Other investigations have been made of iron and phosphorus with silicon,[444–6, 442, 447] copper,[91, 94, 448] molybdenum,[449] nickel,[91, 450–2, 358] cobalt,[453–5] manganese,[91, 343, 455] chromium,[91, 310] tin,[455–6] vanadium,[455, 307–8] tungsten,[457] calcium,[116] beryllium,[100] aluminium,[458] sulphur,[459–60, 646–8] zinc,[167] oxygen[461] and titanium.[462] In this last mentioned system, thermal and structural investigations revealed a compound monoiron monotitanium monophosphide which has a congruent melting point of 1850°C. and a hardness of 980 kg./mm.$^2$ The iron–phosphorus–zirconium system is very similar to the iron–phosphorus–titanium system, and a compound monoiron monozirconium monophosphide having hardness 1150 kg./mm.$^2$ has been shown to exist.[463] Another compound, tetrairon monozirconium diphosphide, with hardness 1080 kg./mm.$^2$ has also been discovered, but no corresponding titanium compound has been reported.[463] Crystallographic data have been presented for the isostructural systems (Ti, Zr, Nb, Ta)FeP.[653]

Quaternary systems of iron and phosphorus with carbon and chromium,[430] carbon and manganese,[430] carbon and silicon,[440] silicon and oxygen,[464] carbon and molybdenum,[465] copper and platinum[466] have been studied, as well as the effect of phosphorus on the iron–manganese–silicon–oxygen system.[467]

### Cobalt

Tricobalt phosphide is thought to be one of the products when cobalt salts react with sodium hypophosphite, but the reaction tends to give intermetallic compounds rather than true phosphides.[468–9] In an examination of the Fe–$Fe_2P$–$Co_2P$–Co portion of the cobalt–phosphorus–iron system, tricobalt phosphide could not be established although there is a solid solution $(Co,Fe)_3P$.[453–4] Treatment with dilute hydrochloric acid of the products obtained from the above hypophosphite reaction converts them mainly to cobalt monophosphide, but a small amount of dicobalt triphosphide is formed as well.[468]

The reaction of a heated mixture of cobalt powder and red phosphorus has been used to produce dicobalt monophosphide for vapour pressure and *X*-ray studies.[470, 50] Andrieux's method, under the correct conditions of melt composition, voltage and current, also produces dicobalt phosphide.[10, 9, 311–2] The reduction of cobalt phosphates with hydrogen can also produce variable results. Dicobalt phosphide and monocobalt phosphide are produced if cobalt orthophosphate is reduced at 550°C., while a mixture of dicobalt phosphide and phosphorus is produced if cobalt metaphosphate is reduced at 675°C.[43]

Fig. 27 shows the heats of formation of some cobalt phosphides.[50] The free energy of formation of solid $Co_2P$ from the gaseous elements at $T$°K. is given by $\Delta G = -58{,}400 + 11{\cdot}3T$ g.-cal./mole.[548] *X*-Ray measurements have shown dicobalt phosphide to possess a crystal structure of the lead chloride type[471, 364] with $a = 6{\cdot}63(8)$–$6{\cdot}68(2)$ A., $b = 5{\cdot}67(0)$–$5{\cdot}75(1)$ A., $c = 3{\cdot}52(0)$–$3{\cdot}53(5)$ A.,[471] or $a = 5{\cdot}646$–$5{\cdot}638$ A., $b = 3{\cdot}513$–$3{\cdot}507$ A., $c = 6{\cdot}608$–$6{\cdot}603$ A.[472] The variations in lattice parameters are due to the fact that the compound has an extended homogeneity range, the P-rich limit at 1000°C. corresponding to $Co_{1{\cdot}94}P$.[471–2] The molecular volume from *X*-ray data is 10·3 c.c.[470]

If the compound is deposited electrolytically on flat surfaces or wires there is a preferred orientation and the crystals deposit with [001] axes perpendicular to the surface.[364] The results of vapour pressure measurements for this phosphide and others are summarized in Fig. 28.[470]

Dicobalt phosphide is attacked by oxidizing acids such as nitric acid and aqua regia.[470] Alloys with $Ni_2P$ are single phase,[311] while alloys with $Fe_2P$ are suitable for the manufacture of permanent magnets.[649]

Tricobalt diphosphide is formed as a finely divided, air sensitive precipitate when cobalt chloride in tetrahydrofuran reacts with $[(CH_3)_3Si]_3P$. The reaction goes according to equation 31[473]:

$$(31) \qquad 2[(CH_3)_3Si]_3P + 3CoCl_2 \rightarrow Co_3P_2 + 6Si(CH_3)_3Cl$$

Monocobalt phosphide has been obtained by the same methods as dicobalt phosphide. In the method using sodium hypophosphite it has not been obtained in a pure state.[468] Heating cobalt orthophosphate at 550°C. in an atmosphere of hydrogen gives a mixture of mono- and di-cobalt phosphides[43] but cobalt pyrophosphate is converted only into monocobalt phosphide.[43] The electrolysis of phosphate melts containing cobalt salts[10, 9, 311–2] and heating together red phosphorus and cobalt have also been used as methods of preparation. In this latter preparation, vapour pressure measurements, *X*-ray photographs, and thermal measurements confirmed the presence of monocobalt phosphide.[470–1] It has the MnP type of structure,[313, 322, 471] with $a=5{\cdot}077$, $b=3{\cdot}281$, $c=5{\cdot}587$ A.,[313] or $a=5{\cdot}588$, $b=5{\cdot}066$, $c=3{\cdot}274$ A.[322] It is

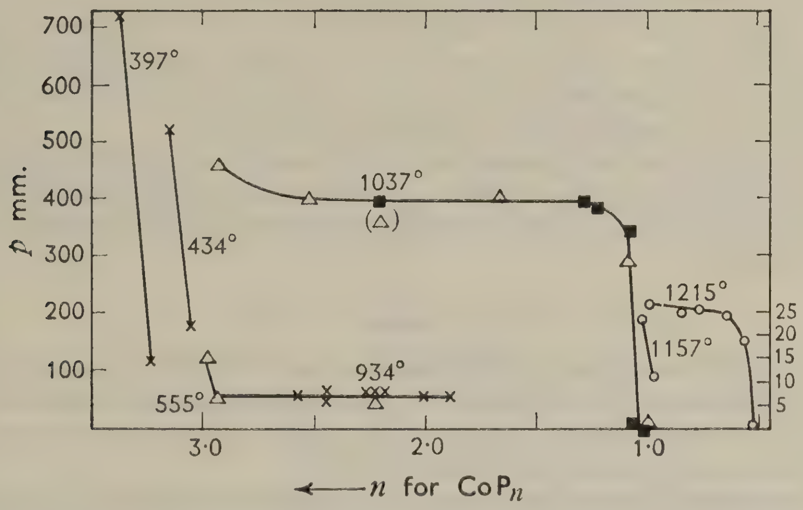

FIG. 28.—Vapour pressure analysis in the cobalt–phosphorus system

capable of forming solid solutions with FeP, MnP and CrP. Boron dissolves to some extent and silicon shows considerable solubility.[313] The heat of formation is shown in Fig. 27,[50] whilst equations (32) and (33) were established by means of v.p. measurements.

$$\text{(32)} \qquad \tfrac{1}{2}\mathrm{CoP(s)} + \mathrm{P(rhomb.)} \rightarrow \tfrac{1}{2}\mathrm{CoP_3(s)} \qquad \Delta H = -15 \text{ kcal.}$$

$$\text{(33)} \qquad 4\mathrm{CoP(s)} \rightarrow 2\mathrm{Co_2P(s)} + \mathrm{P_2(g)} \qquad \Delta H = +69 \text{ kcal.}$$

Assumptions were made concerning the temperature dependence of the dissociation of monocobalt phosphide.[470] The free energy of formation of solid CoP from the gaseous elements at $T$°K. is given by the expression $\Delta G = -49{,}400 + 11{\cdot}3T$ g.-cal./mole.[548] In an investigation into the use of monocobalt phosphide in corrosion resistant anodes its rates of corrosion in hydrochloric acid, sulphuric acid, nitric acid and potassium hydroxide were determined at 25°C. and 80°C.[365] Current–voltage curves were also plotted for various liquids.[365] Monocobalt phosphide is attacked by nitric acid and aqua regia[470] and it is oxidized to cobaltous and orthophosphate ions when used as anode material in acid, alkaline or acetate solutions.[365]

Andrieux's method of electrolyzing alkaline phosphate melts has been shown to produce cobalt diphosphide.[10, 9]

A rather unusual reaction between cobalthexammine nitrate and monopotassium phosphine in liquid ammonia gives a dark brown pyrophoric powder, $\mathrm{Co(PH_2)_3}$, which decomposes spontaneously to give $\mathrm{Co(PH)_3}$. If this is then heated to 560°C. a crystalline substance with the composition $\mathrm{CoP_{2{\cdot}37}}$ is formed.[474]

Cobalt triphosphide, required for an *X*-ray, vapour pressure, and thermal study,[470] was prepared by reaction of the elements. From the *X*-ray measurements a molecular volume of 35·7 c.c. was calculated. The v.p. measurements (which are shown in Fig. 28) were used to establish equation (34):

$$\text{(34)} \quad 2\mathrm{CoP_3(s)} \rightarrow 2\mathrm{CoP(s)} + \mathrm{P_4(g)} \qquad \Delta H = +72 \text{ kcal.} \qquad t \sim 900\text{–}1050°\text{C.}$$

The free energy of formation of solid $\mathrm{CoP_3}$ from the gaseous elements at $T$°K. is calculated to be $\Delta G = -103{,}200 + 33{\cdot}8T$ g.-cal./mole.[548]

Electrodeposition of cobalt containing up to 15% of phosphorus has been achieved from acid solutions, but it was not possible to establish the existence of a phosphide.[475] In the cobalt–phosphorus system, the effect of phosphorus on the $\alpha \rightleftharpoons \beta$ transformation of cobalt has been studied[476] and the mechanism of reaction-type diffusion was investigated.[425] At 400° to 600°C. a unilateral diffusion of phosphorus was observed.[425] Cobalt phosphides have been used for protecting alloys prone to air oxidation[316] and for joining metals with high melting points.[477]

In the ternary system cobalt–phosphorus–boron, three ternary phases were found[344]: $Co_3P_{1-x}B_x$ is homogeneous in a narrow range near $x=0{\cdot}7$, $Co_3P_{1-y}B_y$ is homogeneous in a range near $y=0{\cdot}5$ and is isostructural with $Fe_3P$ and finally $Co_5PB_2$ which is isostructural with $Fe_5PB_2$ and $Mn_5PB_2$.

A semiconducting ternary compound CoPS has been described having a cubic cobaltite (CoAsS) lattice with $a=5{\cdot}422$ A.[569] A ternary compound $CoPS_3$ has been described.[648] Crystallographic data have been presented for the isostructural phases (Ti, Zr, Nb, Ta)CoP.[653]

## Nickel

Although not all the nickel phosphides reported in the literature have been confirmed, it is still probably true to say that nickel forms more phosphides than any other element with the possible exception of cobalt. A tentative phase diagram has been presented which includes ten binary phases.[651]

Trinickel phosphide is the lowest one which has been reported. Several methods have been used for its preparation and of these two are the familiar Andrieux's method[10, 9, 311–2] and reaction of the elements in a sealed tube.[50] The reaction of sodium dihydrogen hypophosphite with nickel sulphate solution gives compositions in the range $Ni_{3{\cdot}18}P$ to $Ni_{3{\cdot}48}P$. These preparations are not homogeneous, however, and contain nickel metal.[478] Nickel–tin alloys heated with red phosphorus at 550° to 700°C. for 5 to 56 hr. produce a mixture of phosphides one of which has been shown to be trinickel phosphide by *X*-ray, thermal, and tensimetric analysis.[479] *X*-Ray studies have also identified this phosphide in heat treated chemically deposited nickel coatings containing 7 to 10·5% of phosphorus,[480] and in precipitates of chemically reduced nickel.[481–2] The crystal structure of trinickel phosphide is tetragonal with space group $I\bar{4}$ and unit cell dimensions $a=8{\cdot}923$, $c=4{\cdot}40$ A.[481]; $a=8{\cdot}954$, $c=4{\cdot}386$ A.[483–4]; $a=8{\cdot}91(6)$, $c=4{\cdot}38(9)$ A.[485] Density 7·9 g./c.c. was determined from *X*-ray measurements.[485] The heat of formation from the elements is −48·4 kcal./mole and is shown in Fig. 29, together with heats of formation of other nickel phos-

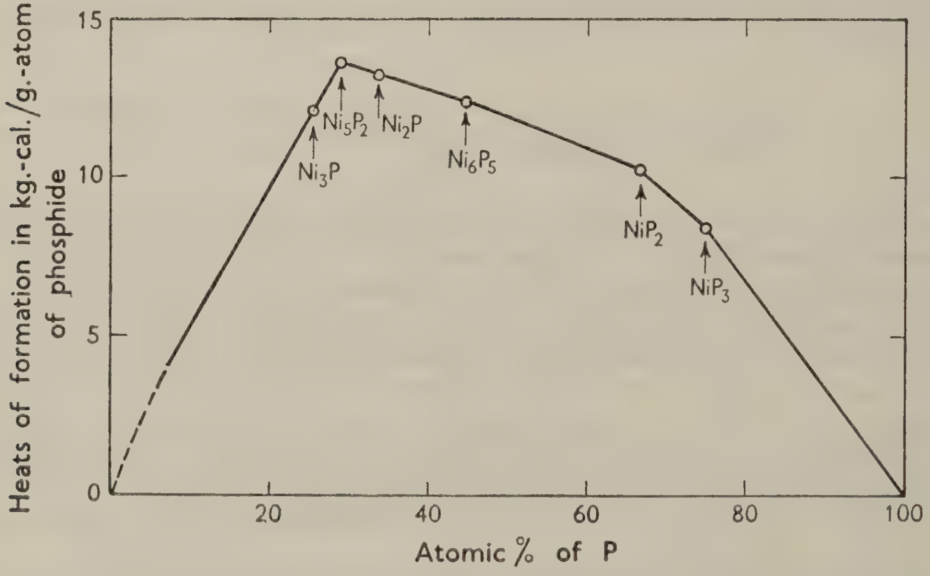

FIG. 29.—Heats of formation of nickel phosphides

phides.[50] Trinickel phosphide is insoluble in hot concentrated hydrochloric acid but is easily soluble in warm nitric acid.[479] It has been shown to be isomorphous with the corresponding iron and manganese compounds[485, 91] but forms a continuous series of mixed crystals only with tri-iron phosphide. Trichromium phosphide is only slightly miscible although 50% of the non-isotype tricopper phosphide can be dissolved.[91] An alloy consisting of trinickel phosphide and nickel, produced from spent nickel plating baths, has been used for bonding metal surfaces and for flame spraying on to various surfaces.[486–7]

Pentanickel diphosphide has been produced by reaction of the elements[50] and by Andrieux's method.[10, 9] Under carefully controlled conditions it can be obtained by the action of phosphine on nickel salt solutions.[488] In ammonia solution, for example, trinickel diphosphide is produced, some of which reacts with excess of nickel salt to give nickel and this in turn reacts with more trinickel diphosphide to give pentanickel diphosphide.[488] The reactions involved may proceed according to equations (35), (36), (37) and (38):

$$3NiX_2+2PH_3 \rightarrow Ni_3P_2+6HX \tag{35}$$

$$Ni_3P_2+5NiX_2+8H_2O \rightarrow 8Ni+2H_3PO_4+10HX \tag{36}$$

$$Ni_3P_2+3NiX_2+6H_2O \rightarrow 6Ni+2H_3PO_3+6HX \tag{37}$$

$$Ni_3P_2+2Ni \rightarrow Ni_5P_2 \tag{38}$$

The action of sodium hypophosphite on various nickel salts has been investigated and although the products were not considered as being true phosphides, material corresponding to pentanickel diphosphide has been obtained by reaction with acetic acid.[489, 468] The structure of pentanickel diphosphide is in debate, the compound having either an hexagonal lattice with $a=13{\cdot}220$, $c=24{\cdot}632$ A.[650] or a trigonal cell with $a=6{\cdot}608$, $c=24{\cdot}634$ A.[651] A high temperature $\beta$-form of $Ni_5P_2$ is obtained by quenching $Ni_{2\cdot60}P$ from 1050°.[651] This phosphide is a black non-magnetic compound[488] with a heat of formation from the elements of $-95{\cdot}9$ kcal./mole[50] (see Fig. 29), and a free energy of formation (from the gaseous elements at $T$°K.) given by $\Delta G=-126{,}300+22{\cdot}5T$ g.-cal./mole.[548] It is homogeneous at 28·2 at.-% P, but a composition with the theoretical 28·6 at.-% P contains some $Ni_{12}P_5$.[651] It can be converted into dinickel phosphide by ignition in hydrogen at 800°C.[488] or by treatment with hydrochloric acid.[489] Dilute hydrochloric acid reacts to give nickel chloride according to equation (39)[488–9]:

$$Ni_5P_2+10HCl+6H_2O \rightarrow 5NiCl_2+2H_3PO_3+8H_2 \tag{39}$$

In an investigation of the nickel–phosphorus system it was shown that crystallization of undercooled alloys could produce an unstable system nickel–pentanickel diphosphide.[414]

In an *X*-ray study of the nickel–phosphorus system a compound heptanickel triphosphide was shown to be cubic with $a=8{\cdot}63(0)$ A.[485] Additional weak lines indicated possible lower symmetry and, if the compound $Ni_{2\cdot4}P$ reported in a later *X*-ray investigation is the same compound, then the crystal system is not cubic but tetragonal with cell dimensions $a=8{\cdot}646$, $c=5{\cdot}070$ A.[484] and the compound should be $Ni_{12}P_5$ and not $Ni_7P_3$.[651] It has been prepared by Andrieux's method.[311–2]

Reduction of nickel phosphates with hydrogen at 450° to 600°C. and with continual removal of the water vapour formed produces dinickel phosphide[43] as does Andrieux's method[10, 9, 311–2] or heating a tin–nickel alloy with red phosphorus.[479] In the action of an alkali metal hypophosphite on a nickel salt, intermetallic compounds are produced which yield a product $Ni_2P$ or $Ni_4P_2$ when treated with dilute hydrochloric acid.[489, 478] *X*-Ray measurements indicate that dinickel phosphide is hexagonal with $a=5{\cdot}85(0)$, $c=3{\cdot}365$ A.[485] or $a=5{\cdot}859$, $c=3{\cdot}382$ A.[484, 320]; $d$ 7·2 g./c.c.[485] Electrodeposition experiments show that dinickel phosphide orients itself with its [1120] axis parallel to the surface upon which it is being deposited.[364] It is isomorphous with di-iron phosphide and dimanganese phosphide[485] and forms a series of mixed crystals with these, as well as with dichromium phosphide.[91] Like dimanganese phosphide, it exhibits an appreciable homogeneity range.[320] The reaction in equation (40):

$$(40)\qquad \tfrac{3}{2}Ni_2P(s) + P(white) \rightarrow \tfrac{1}{2}Ni_6P_5(s) \qquad \Delta H = -12 \text{ kcal.}$$

has been established from tensimetric measurements.[479] The free energy of formation of solid dinickel phosphide from the gaseous elements at $T$°K. is said to follow the expression $\Delta G = -55{,}400 + 11{\cdot}3T$ g.-cal./mole over the range 298–1383°K.[548] There is no reaction with hot concentrated hydrochloric acid,[479] but it reacts easily with dilute hydrochloric acid according to equation (41).[489]

$$(41)\qquad Ni_2P + 4HCl + 3H_2O \rightarrow 2NiCl_2 + H_3PO_3 + \tfrac{7}{2}H_2$$

Dinickel phosphide has been studied as a catalyst for the conversion of nitrobenzene into aniline[490] and for the polymerization of $\alpha$-olefins.[491]

It has been reported that a trinickel diphosphide can be obtained by reaction of phosphine with ammoniacal nickel salt solutions. It is easily decomposed by water and dilute acids.[488] Alloys in the range $Ni_2P$–$Ni_{1\cdot25}P$ quenched from temperatures below 850° give a mixture of dinickel phosphide and pentanickel tetraphosphide (hexagonal, $a = 6{\cdot}789$, $c = 10{\cdot}986$ A.). Above this temperature $Ni_2P$ and NiP are the stable phases.[651–2]

Andrieux's method,[10, 9] or heating a nickel–tin alloy with red phosphorus at 550° to 700°C.,[479] produces hexanickel pentaphosphide. It has been identified by $X$-ray, thermal, and tensimetric means. Its heat of formation is shown in Fig. 29 and from vapour pressure measurements equations (42), (43) and (44) were established[479]

$$(42)\qquad 2Ni_6P_5(s) \rightarrow 6Ni_2P(s) + P_4(g) \qquad \Delta H = +63 \text{ kcal.}$$

$$(43)\qquad \tfrac{1}{7}Ni_6P_5(s) + P(white) \rightarrow \tfrac{6}{7}NiP_2 \qquad \Delta H = -11 \text{ kcal.}$$

$$(44)\qquad \log p_{(mm.)} = -13{,}740/T + 14{\cdot}951$$

A reaction which appears to have been tried only in the case of nickel phosphides is that of nickel tetracarbonyl with phosphorus or phosphine at 50°C.[492] Mononickel phosphide is deposited as black, non-magnetic crystals which are converted into nickel orthophosphate when heated in air.[492] The lattice is orthorhombic with $a = 6{\cdot}050$, $b = 4{\cdot}881$, $c = 6{\cdot}890$ A.[651] It is scarcely attacked by dilute hydrochloric acid, but is easily soluble in nitric acid and aqua regia.[492] The free energy of formation of solid mononickel phosphide from the gaseous elements at $T$°K. is given by the expression $\Delta G = -63{,}800 + 11{\cdot}3T$ g.-cal./mole over the range 298–1243°K.[548]

The reaction of red phosphorus with a nickel–tin alloy at 550° to 700°C. produces several phosphides, one of which is nickel diphosphide.[479] It has also been synthesized by heating mixtures of metal powder and red phosphorus in evacuated sealed silica tubes at 800° to 1100°C.[493] $X$-Ray investigations have shown it to be monoclinic with $a = 6{\cdot}365(9)$, $b = 5{\cdot}615(2)$, $c = 6{\cdot}071(5)$ A., $\beta = 126{\cdot}22(4)°$ and space group probably $C2/c$ or $Cc$.[493, 651] Vapour pressure measurements enabled investigators to establish equations (45) and (46)[479]:

$$(45)\qquad \tfrac{24}{7}NiP_2(s) \rightarrow \tfrac{4}{7}Ni_6P_5(s) + P_4(g) \qquad \Delta H = +57 \text{ kcal.}$$

$$(46)\qquad \log p_{(mm.)} = -12430/T + 14{\cdot}135$$

The free energy of formation of solid nickel diphosphide from the gaseous elements at $T$°K. is $\Delta G = -62{,}800 + 22{\cdot}5T$ g.-cal./mole.[548]

The reaction discussed for nickel diphosphide was also shown to produce nickel triphosphide. $X$-Ray, thermal and tensimetric analyses were used to prove its existence.[479] The variation of vapour pressure with temperature obeys equation (47):

$$(47)\qquad \log p_{(mm.)} = -9340/T + 12{\cdot}865$$

and thermochemical calculations using the vapour pressure data enabled equation (48) to be established[479]:

$$(48)\qquad 4NiP_3(s) \rightarrow 4NiP_2(s) + P_4(g) \qquad \Delta H = +43 \text{ kcal.}$$

The heat of formation is shown in Fig. 29, and the free energy of formation of the solid phosphide from the gaseous elements at $T$°K. is given by $\Delta G = -82{,}200+33{\cdot}8T$ g.-cal./mole.[548] Electrical properties of the compound have been reported.[660] Nickel triphosphide is soluble in warm nitric acid but not in hot concentrated hydrochloric acid.[479]

By bubbling nickel tetracarbonyl through liquid phosphorus at 60°C. or through a solution of phosphorus in turpentine, a black precipitate was obtained which was thought to be nickel tetraphosphide.[492] It is a rather unstable powder and evolves phosphorus when heated in air. Fuming nitric acid makes it inflame whilst aqueous potassium hydroxide and aqueous ammonia produce phosphine and hydrogen.[492]

An electrically conducting ternary sulphide, NiPS, having a cubic cobaltite (CoAsS) lattice with $a=5{\cdot}544$ A., has been reported.[569]

Electrodeposition of nickel–phosphorus alloys from solutions containing $Ni^{++}$ and $PO_4^{3-}$ ions has been attributed to direct absorption of phosphorus from the electrolyte at the electrode.[494] Partial investigations in the ternary systems nickel–phosphorus–iron,[451, 91, 450, 452, 358] nickel–phosphorus–chromium,[91, 308] nickel–phosphorus–manganese,[91] nickel–phosphorus–copper[91–2] and nickel–phosphorus–boron[344] have been made. In the nickel–phosphorus–iron system $X$-ray methods established the presence of $Ni_2P$, $Ni_3P$, $Ni_7P$, $(Fe, Ni)_2P$,$(Fe, Ni)_3P$ and a compound containing more nickel than $Ni_3P$.[358] Defects in German-silver alloys have been traced to the formation of nickel phosphides.[495]

Few uses of nickel phosphides have been noted, the main ones being as catalysts,[73, 490] for bonding metal surfaces,[477, 486–7] as a protection for metal surfaces[496, 316] and as components of friction elements such as brake linings.[75]

## THE SECOND TRANSITION SERIES

### Yttrium

Yttrium monophosphide has been prepared by heating the powdered metal with red phosphorus in a silica tube at 1000° for 30 hr. It forms cubic crystals in the NaCl system, $a=5{\cdot}661$ A.,[564] 5·662 A.[547, 654]

### Zirconium

A phosphide, possibly trizirconium phosphide, has been claimed to be formed by heating powdered metal and red phosphorus in a pressure tube for 7 hr. at 500° to 600°C. followed by 24 hr. at 800°C. and finally 8 days at 900° to 1000°C.[497] If the reaction tube is cooled slowly, at approximately 100°C. per hour, a grey product is obtained. Existence of a phosphide within the range $ZrP_{0{\cdot}3-0{\cdot}5}$ was confirmed by $X$-ray analysis of material obtained by heating zirconium diphosphide with metal powder.[292]

Two methods of preparing zirconium monophosphide both start from the diphosphide. In one case the diphosphide is heated in a vacuum at 750°C. when phosphorus is readily evolved[497] and in the other case it is heated with powdered zirconium. As with some other transition-metal phosphides, zirconium monophosphide has been shown to exist in two forms.[292] The $\beta$-form has the stoicheiometric composition ZrP. It is a grey-black compound which does not oxidize or decompose in air below 1100°C.[497] It has a density of 5·35 g./c.c.[292] It forms hexagonal crystals isomorphous with titanium monophosphide,[292, 570] having the cell dimensions $a=3{\cdot}684$, $c=12{\cdot}554$ A. On heating this compound, these values increase almost linearly with temperature, until at 1425°C. *in vacuo* the system transforms smoothly to the deficient $\alpha$ form, $ZrP_{0{\cdot}9}$, with evolution of phosphorus. The partial molal enthalpy of dissociation of $ZrP_{0{\cdot}92}$ to $P_2$ is 66·8 kcal./mole $P_2$ at 1500°K. and 51·1 kcal./mole at 2000°K.[631] $\alpha$-ZrP forms face centred cubic crystals, $a=5{\cdot}242$ A., stable *in vacuo* above 1425°C.[570] and having a density of 5·1 g./c.c.[292]

Zirconium diphosphide is readily prepared by heating powdered zirconium with red phosphorus in an evacuated sealed vessel[296, 497, 292] or by heating powdered zirconium in a mixture of phosphine and hydrogen.[292] The first method has been patented as a means of manufacture.[306] Zirconium diphosphide has an orthorhombic lattice, with $a=6{\cdot}494$, $b=8{\cdot}744$, $c=3{\cdot}513$ A.[637] Results of v.p. measurements shown in Fig. 30[497] were used to calculate the heat of decomposition according to equation (49):

$$(49) \qquad 4ZrP_2(s) \rightarrow 4ZrP(s) + P_4(g) \qquad \Delta H = +50 \text{ kcal.}$$

The compound is attacked slowly by dilute sulphuric acid to evolve phosphine but is stable in the atmosphere and is not attacked appreciably even by mixtures of bromine with nitric acid.[497]

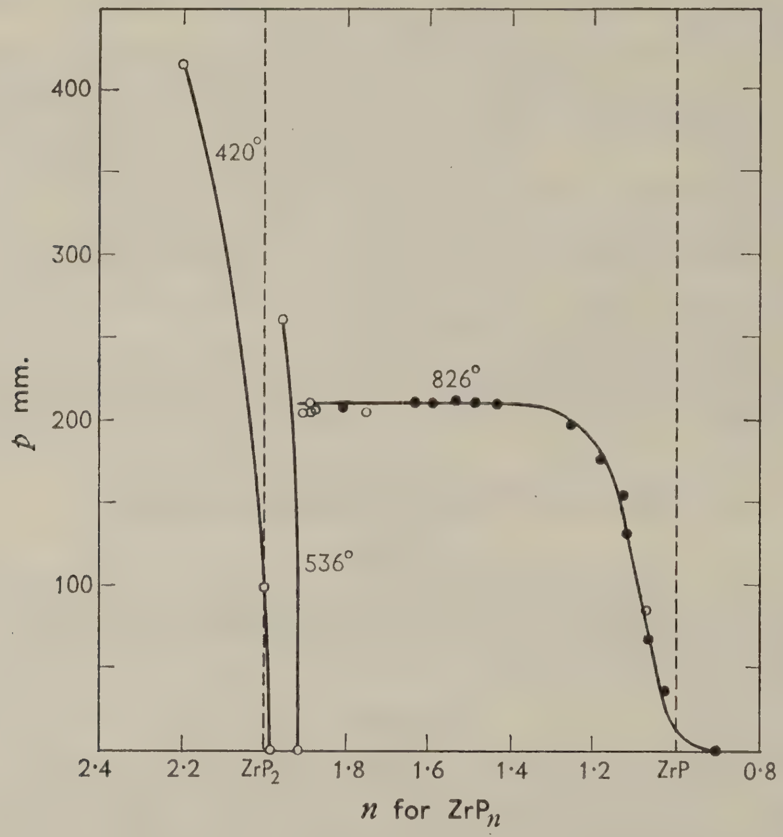

FIG. 30.—Vapour pressure analysis of $ZrP_2$ and ZrP

The ternary systems Zr–Fe–P and Zr–Co–P have been investigated structurally. ZrFeP has space group *Pnma* with $a=6{\cdot}309$, $b=3{\cdot}740$, $c=7{\cdot}172$ A. and ZrCoP has $a=6{\cdot}332$, $b=3{\cdot}698$, $c=7{\cdot}160$ A.[653]

### Niobium [Columbium]

Triniobium phosphide, which has a structure of the $Ti_3P$ type, has been obtained by rapidly annealing in an argon arc furnace an alloy prepared from red phosphorus and niobium in an evacuated silica tube.[655] Heptaniobium tetraphosphide (monoclinic, $a=14{\cdot}950$, $b=3{\cdot}440$, $c=13{\cdot}848$ A., $\beta=104{\cdot}74$) has been made similarly.[686]

Niobium monophosphide is prepared by heating the metal with red phosphorus at 650° to 850°C. for several days[498–9] or with tricalcium diphosphide,[566] or by electrolyzing phosphate melts containing niobium oxide.[304] An *X*-ray investigation has shown that there are two modifications,[292] thus supporting previous work.[498] The $\alpha$ variety is approximately $NbP_{0{\cdot}95}$ and the $\beta$ form is NbP. The $\beta$ form has $d$ 6·15 g./c.c.[292] (5·91 g./c.c.[499]) and molecular volume 21·1 c.c.[499] and it was suggested that the structure was a distorted nickel arsenide type.[305] Later authors, while confirming the tetragonal cell dimensions $a=3{\cdot}33$, $c=11{\cdot}37$ A., have shown that $\beta$-NbP is isomorphous with niobium arsenide.[563, 655] They suggest that the distinction between α-NbP and β-NbP is meaningless since 'α-NbP' compositions are members of a continuous series of structures, in which the NbAs lattice of β-NbP is disordered more and more towards a tungsten carbide lattice as the phosphorus becomes more deficient.[563] The partial molal enthalpy of dissociation to $P_2$ of $NbP_{0{\cdot}95}$ is 55·4 (1000°K.) and 34·0 (1500°K.) kcal./mole $P_2$.[631] The two forms are isomorphous with the corresponding α and β tantalum phosphides.[292, 305, 498] Both forms are greyish black materials having a metallic lustre.[292, 499] They are not attacked by water or dilute acids at room temperature but a brisk reaction takes place with concentrated nitric acid.[499] Heating in air produces a white oxide the nature of which has not been determined.[499] In an inert atmosphere the phosphide is stable up to 1750°C.[566]

Niobium diphosphide could not be prepared by heating the metal with red phosphorus.[498] It was prepared, however, by removing phosphorus from a composition $NbP_{2{\cdot}4}$ under vacuum at 430°C.[498] and by heating the metal powder in a mixture of phosphine and hydrogen.[292] It is isomorphous with the tantalum and vanadium phosphides,[498, 292] having $a=8{\cdot}8715$, $b=3{\cdot}2663$, $c=7{\cdot}5194$ A., $\beta=119{\cdot}007°$,[655] with which it has been compared.[305] As with vanadium diphosphide, it is not attacked by dilute sulphuric acid but is completely dissolved by the concentrated acid.[301] It also has properties similar to molybdenum and tungsten diphosphides since it is not dissolved by concentrated hydrochloric acid or ammoniacal hydrogen peroxide.[499] Above 650°C. it disproportionates to give niobium monophosphide and phosphorus.[498]

Several methods which have been used to study a portion of the Nb–P–Fe system have resulted in the recognition of three ternary compounds. Niobium iron phosphide melts congruently at 1820°C. and has *d* 4·99 g./c.c. whilst diniobium iron phosphide and tetraniobium iron phosphide both melt incongruently. The hardness of these compounds is 1322, 1238 and 1063 H.V., respectively.[443] Unit cell constants have been determined for NbFeP and NbCoP.[653]

## Molybdenum

Trimolybdenum phosphide can be prepared by electrolyzing fused alkali metal phosphates containing molybdenum compounds[10, 500–1, 9, 311–2] or by heating the elements together in a sealed quartz tube.[315] The compound crystallizes as fine black needles having a metallic lustre.[500] Although the crystal lattice is body-centred tetragonal it seems that it may be isostructural with $\alpha\text{-}V_3S$[571] rather than tri-iron phosphide.[315, 292] The space group is $I\bar{4}2m$, and the lattice parameters $a=9{\cdot}794$, $c=4{\cdot}827$ A.[656] Its density has been variously reported as 6·7 g./c.c.[500] and 8·6 g./c.c.[292] The latter value would fit better a straight line plot of density against composition as shown in Fig. 31. Trimolybdenum phosphide becomes superconducting at 7°K.[53, 502] It is attacked by sulphuric acid, nitric acid, molten alkali or oxidizing agents[500] but not by hydrochloric acid.

Besides the three well-established phosphides of molybdenum, a deficient phase of approximate composition $MoP_{0{\cdot}75}$ is said to occur.[571] It crystallizes in space group *Pnma* with $a=12{\cdot}428$, $b=3{\cdot}158$, $c=20{\cdot}440$ A.[657]

Monomolybdenum phosphide is formed in the above electrolytic method when the molybdenum-compound content of the melt is low (approximately 4%).[9–10, 500–1, 311–2] It has also been made by causing the metal to react with tricalcium diphosphide.[566] *X*-Ray and tensimetric analysis confirmed its formation from the elements.[315] The results of the tensimetric analysis are shown in Fig. 32. Monomolybdenum phosphide is a greyish black compound[500] which has *d* 7·2 g./c.c., the tungsten carbide type of structure[292, 571] and no superconductivity.[502, 53] Its average molal enthalpy of decomposition ($\Delta H_{1360°\text{K.}}$) is 107·84 kcal./mole $P_2$. The decomposition products at 1250°C. are phosphorus and an involatile phase $MoP_{0{\cdot}7}$, which is predicted as being unstable below 700° to give the monophosphide and a phosphide of lower phosphorus content.[658] It reacts readily with nitric acid, molten alkali, and oxidizing agents.[500]

The diphosphide is obtained easily by heating a slight excess of red phosphorus with powdered molybdenum at 550°C. for 24 hr.[499] and by passing a mixture of phosphine and hydrogen over the heated metal.[292] It is a black powder having *d* 5·3 g./c.c.,[499] and crystallizing in the orthorhombic system.[571] The heat of dissociation, from tensimetric measurements shown in Fig. 32, is 10 kcal./mole.[315] When the phosphide is free from phosphorus it is stable in dry air. Oxidizing acids attack it but it is stable in concentrated hydrochloric acid and ammoniacal hydrogen peroxide.[499]

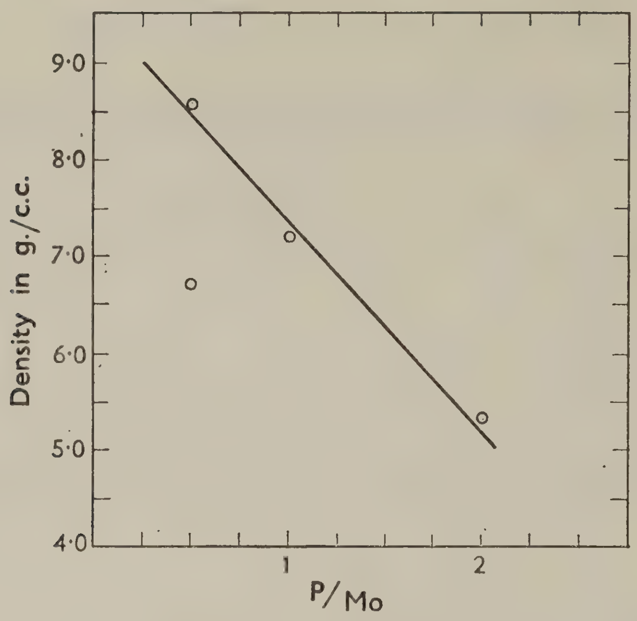

FIG. 31.—Plot of density of molybdenum phosphides against their phosphorus to molybdenum ratio

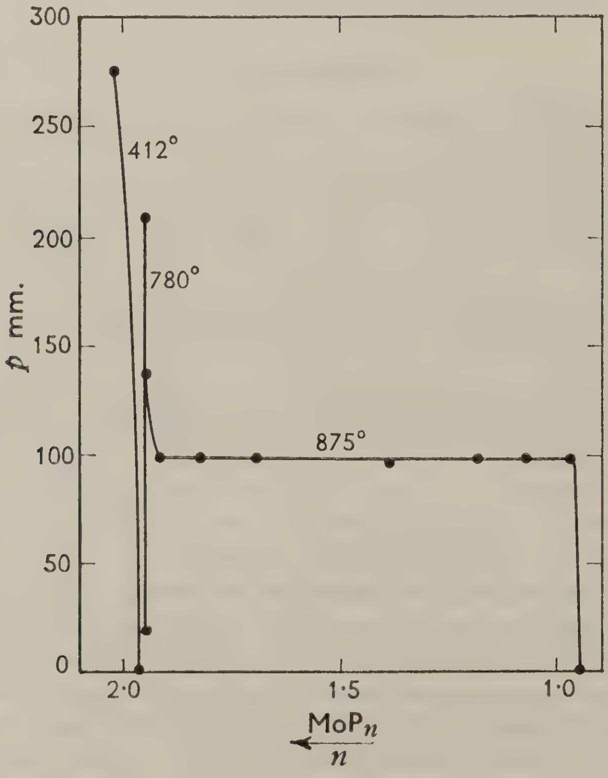

FIG. 32.—Vapour pressure analysis for molybdenum phosphides

A partial investigation of the molybdenum–phosphorus–iron system has been made.[449]

## Ruthenium

Diruthenium phosphide can be prepared by reaction of ruthenium with red phosphorus[472, 503] or by heating ruthenium diphosphide *in vacuo* at a high temperature.[503] It crystallizes with an anti-lead chloride type of structure, space group *Pnma* and unit cell dimensions $a = 5{\cdot}902$, $b = 3{\cdot}859$, $c = 6{\cdot}896$ A.[504, 472] This phosphide, like ruthenium monophosphide but unlike dirhodium phosphide, does not become superconductive at low temperatures.[572] It is very resistant to attack by alkaline solutions and is hardly attacked by aqua regia.[503]

Ruthenium monophosphide has also been obtained by direct reaction of the elements at elevated temperatures.[503, 313] The reverse reaction of formation of ruthenium diphosphide from ruthenium monophosphide and phosphorus proceeds according to equation (50)[503]:

$$(50)\quad 2RuP(s) + P_2(g) \rightarrow 2RuP_2(s) \qquad \Delta H = -65 \text{ kcal.} \qquad t = 650\text{–}680°C.$$

It crystallizes with a manganese monophosphide type of structure, space group *Pnma* and unit cell dimensions $a = 5{\cdot}520$, $b = 3{\cdot}168$, $c = 6{\cdot}120$ A.[313, 504] The compound is blue-black, similar to diruthenium phosphide but not quite as resistant to aqua regia.[503]

Ruthenium diphosphide has been prepared by the same method as the above two phosphides. It is a black compound which has the marcasite type of structure[504, 645] and is resistant to attack by alkaline solutions.[503] It is a semiconductor, having an energy gap of ~1 e.v., a Seebeck coefficient of approximately $350\mu V/°C.$ and a magnetic susceptibility, $\chi_{\text{mol}}$, of $-44 \times 10^{-6}$ c.g.s. units at 295°K.[573]

Similar data have been recorded for the semiconductive compounds RuPS and RuPSe. They have a monoclinic arsenopyrite structure with $a = 5{\cdot}77$, $b = 5{\cdot}77$, $c = 5{\cdot}81$ A., $\beta = 111{\cdot}2°$ (RuPS) and $a = 5{\cdot}97$, $b = 5{\cdot}92$, $c = 5{\cdot}98$ A., $\beta = 111{\cdot}8°$ (RuPSe).[659]

The semiconductive ternary compound RuPAs has been described. It also has the marcasite type of structure, an energy gap of ~0·8 e.v., a Seebeck coefficient of $\sim 400\mu V/°C.$ and a magnetic susceptibility, $\chi_{\text{mol}}$, of $-61 \times 10^{-6}$ c.g.s. units at 295°K.[573]

## Rhodium

All of the known phosphides of rhodium have been prepared by heating rhodium with red phosphorus in a pressure tube at elevated temperatures.[505–6, 493] Dirhodium phosphide, pentarhodium tetraphosphide, rhodium diphosphide and rhodium triphosphide were all identified by *X*-ray and tensimetric analysis; the v.p. measurements are shown in Fig. 33.

Structural investigations have shown that dirhodium phosphide has a structure similar to that of diiridium phosphide which is of the fluorite type: $a = 5{\cdot}505$,[507] 5·490,[508] 5·498,[506] 5·516 A.[572] Its density is 9·13 g./c.c.,[505] the molecular volume is 26 c.c.[507, 505] and the m.p. is above 1500°C. The compound, which is grey, does not show superconductivity,[502] though this statement has been more recently denied.[572] Reaction with hot concentrated nitric acid and aqua regia is slight but with boiling sulphuric acid it is vigorous.[505]

Pentarhodium tetraphosphide reported above[505] has more recently been shown to be tetrarhodium triphosphide and its crystal structure has been determined. The space group is *Pnma* and unit cell dimensions are $a = 11{\cdot}662$, $b = 3{\cdot}317$, $c = 9{\cdot}994$ A. Its structure is related to that of $Fe_2P$ and resembles that of $Ni_4B_3$.[508, 506] Material reported as pentarhodium tetraphosphide, which was said to become superconducting at 1·22°K.,[502] has since been identified with dirhodium phosphide ($T_c$ 1·3°K.).[572]

Rhodium diphosphide is monoclinic with probable space group $P2_1/c$ and unit cell dimensions of $a = 5{\cdot}742(9)$, $b = 5{\cdot}794(2)$, $c = 5{\cdot}837(0)$ A., $\beta = 112{\cdot}91(9)°$.[493] From v.p. measurements[505] the heat of reaction for equation (51):

$$(51)\qquad RhP_2(s) + P(\text{white}) \rightarrow RhP_3(s) \qquad \Delta H = -11 \text{ kcal.}$$

was calculated. Rhodium diphosphide has *d* 5·88 g./c.c. and molecular volume 28 c.c.[505] It reacts vigorously with hot concentrated acids.[505]

Rhodium triphosphide, a grey-black compound, has *d* 5·16 g./c.c. and molecular volume 38·66 c.c. Its crystal structure is of the cobalt triarsenide type with $a=7{\cdot}966$ A.[508, 506] From v.p. measurements the heats of disproportionation for equations (52) and (53) were calculated.[505] Reaction with hot concentrated acids is vigorous.[505]

$$\left.\begin{array}{lll} (52) & 2RhP_3(s) \rightarrow 2RhP_2(s) + P_2(g) & \Delta H = 54 \text{ kcal.} \\ (53) & 4RhP_3(s) \rightarrow 4RhP_2(s) + P_4(g) & \Delta H = 60 \text{ kcal.} \end{array}\right\} t \sim 1000°\text{C.}$$

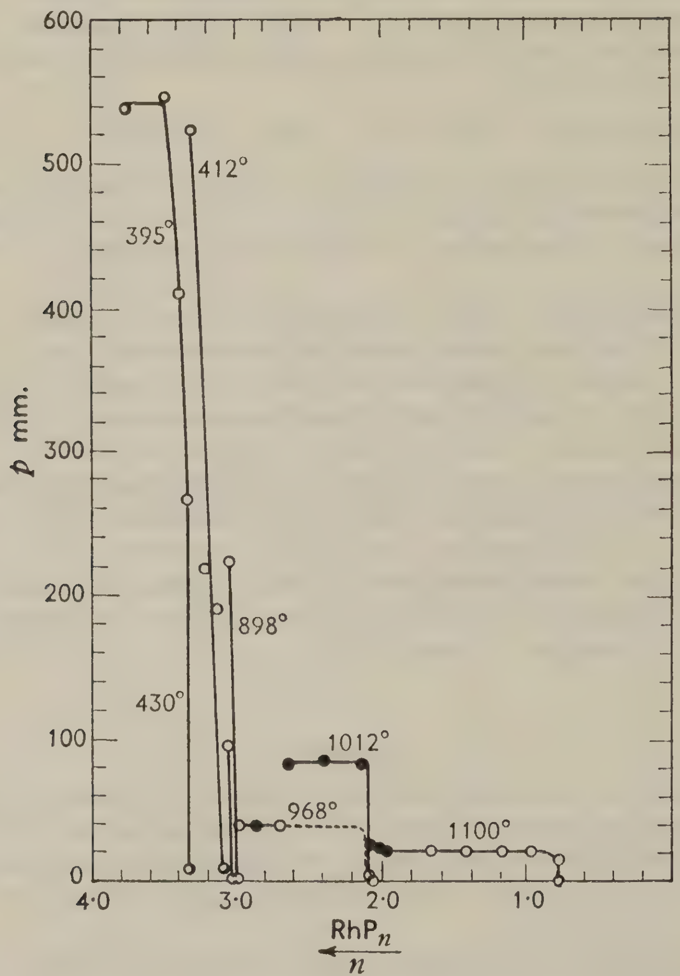

FIG. 33.—Vapour pressure analysis of rhodium phosphides

The depression of the m.p. of rhodium by phosphorus has been studied.[509]

Two ternary rhodium compounds with a cobaltite-type (CoAsS) structure have been described. RhPS has the unit cell dimension $a=5{\cdot}640$ A., and RhPSe, which has a superstructure of the pyrite (e.g. ullmannite) type, has $a=5{\cdot}795$ A.[569]

## Palladium

All of the known phosphides of palladium have been prepared by heating palladium with red phosphorus in evacuated sealed tubes.[510–1] In one preparation the elements were heated at 450° to 550°C. for several hours and then at 600° to 700°C. for 24 hr. The phase diagram is shown in Fig. 34.[510] Pentapalladium phosphide is the average composition of a homogeneous range.[510] It has now been established that this phase has the composition $Pd_{4\cdot8}P$.[661] It forms monoclinic crystals of space group $P2_1$, with $a=5{\cdot}004$, $b=7{\cdot}606$, $c=8{\cdot}416$ A., $\beta=95{\cdot}63°$. The structure in some ways resembles that of tri-iron carbide.[662] Tripalladium phosphide is orthorhombic and of the cementite type[510, 512, 572] with $a=5{\cdot}947$, $b=7{\cdot}451$, $c=5{\cdot}170$ A.,[513] $a=5{\cdot}18$, $b=6{\cdot}00$, $c=7{\cdot}46$ A.[572] and $a=5{\cdot}166$, $b=5{\cdot}971$, $c=7{\cdot}445$ A.[511] The composition is not constant, the homogeneity range varying from $Pd_3P_{0\cdot 75}$ to $Pd_3P_{1\cdot 0}$.[513] The lattice parameters for the phosphorus-rich limit are $a = 5\cdot 980$, $b = 7\cdot 440$, $c = 5\cdot 164$ A. and for the palladium-rich limit are $a = 5\cdot 645$, $b = 7\cdot 558$, $c = 5\cdot 071$ A.[513] Changes in the unit cell dimensions are explained by gaps in the space lattice due to lack of phosphorus atoms when $P < 8\cdot 83\%$ and by interstitial insertion of phosphorus atoms when $P > 8\cdot 83\%$.[514] Although all of the lattice parameters vary only one, $a = 5\cdot 166$ A., shows a sharp change at the stoicheiometric composition.[514] Tripalladium phosphide exhibits superconductivity, with a transition temperature of 0·75°K.[572] Pentapalladium diphosphide,[510] which is more probably heptapalladium triphosphide,[572] exists in two modifications, a high temperature form made by rapid quenching from 750°C. and a low temperature form made by annealing at 400°C. The high temperature form has a rhombohedral crystal lattice ($a = 7\cdot 28$ A., $\alpha = 110\cdot 12°$) and is a superconductor below 1·00°K., while the low temperature form is a superconductor below 0·70°K.[572] Palladium diphosphide, $PdP_2$, is monoclinic, $a = 6\cdot 207$, $b = 5\cdot 857$, $c = 5\cdot 874$ A., $\beta = 111\cdot 80°$[572, 663]; $a = 6\cdot 777$, $b = 5\cdot 856$, $c = 6\cdot 206$ A., $\beta = 126\cdot 42°$.[493] The electrical properties of palladium diphosphide and the corresponding ternary compound PdPAs have been determined.[660] Palladium phosphides are oxidized by air and the higher ones are hygroscopic.[510]

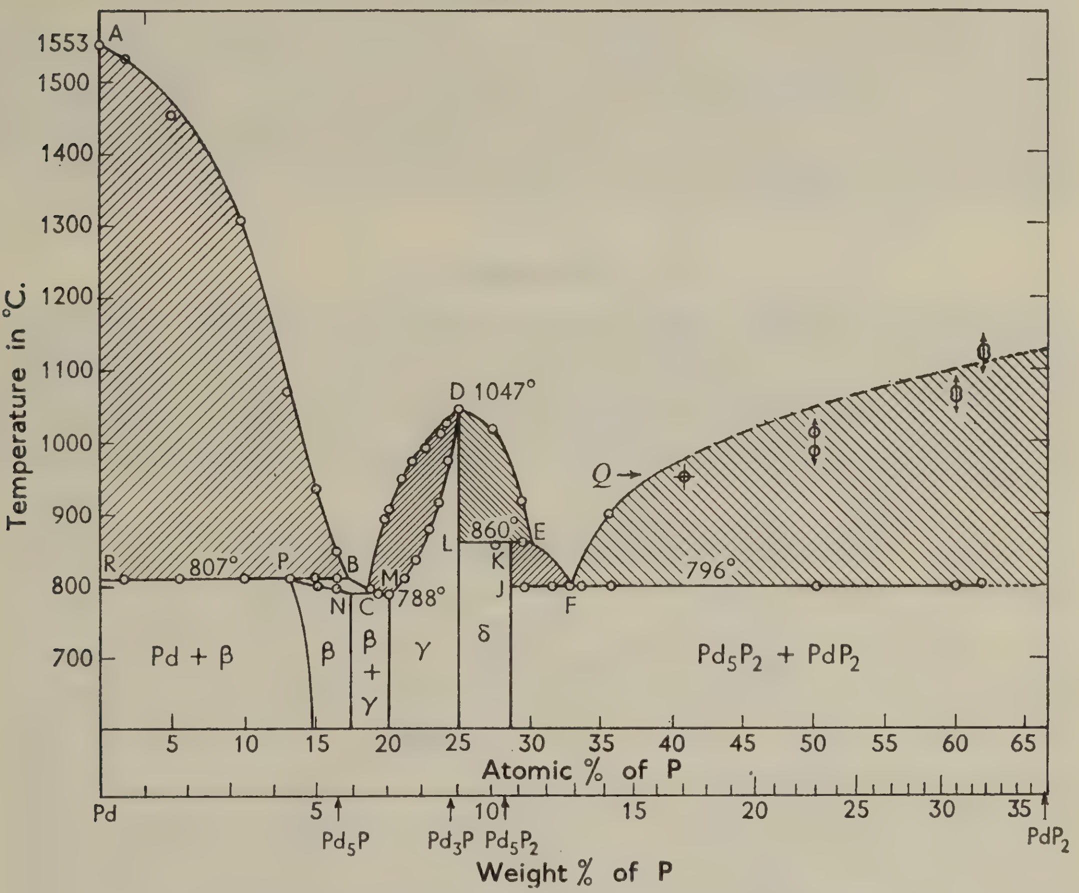

FIG. 34.—Phase diagram of the palladium–phosphorus system

## THE THIRD TRANSITION SERIES

### Lanthanum

At a temperature of 400° to 500°C., in a sealed tube, lanthanum reacts violently with red phosphorus to form lanthanum monophosphide.[515] This phosphide has also been obtained by fusion of stoicheiometric quantities of the elements at 1450°C. in an argon atmosphere followed by slow cooling to 700° to 800°C.,[516] or by the action of phosphine on dilanthanum trioxide at 1300°C.[664] $X$-Ray studies have shown it to have a similar structure to those of cerium and praseodymium phosphides which have the sodium chloride type of structure. The unit cell dimension is reported as being $a=6{\cdot}01(3)$ A.,[517] $a=6{\cdot}016$ A.[664] or $a=6{\cdot}025$ A.[516] The compound is a dark grey powder $d_{\text{calc.}}$ 5·18 g./c.c., insoluble in alkalis, soluble in nitric acid, slowly soluble in hydrochloric acid or aqua regia, and sparingly soluble in sulphuric acid.[664] It is decomposed by atmospheric moisture with evolution of phosphine.[515]

### Hafnium

Monohafnium phosphide exists in two forms. $\beta$-HfP (like TiP and $\beta$-ZrP) has a hexagonal lattice[574] which is transformed to a face-centred cubic lattice on heating above 1600°C. *in vacuo*. Presumably the transformation to $\alpha$-HfP occurs with loss of phosphorus as in the case of $\alpha$-ZrP (q.v.),[570] although the stability of this phosphide is very high, resembling that of $ThP_{0\cdot7}$ or UP.[631] Hafnium diphosphide, $HfP_2$, has been described. It is orthorhombic, with $a=6{\cdot}467$, $b=8{\cdot}646$, $c=3{\cdot}497$ A.; a metallic conductor with a positive thermoelectric power.[637]

### Tantalum

Tritantalum phosphide has a $Ti_3P$ lattice with $a=10{\cdot}154$, $c=5{\cdot}012$ A. Ditantalum phosphide is orthorhombic, with $a=14{\cdot}419$, $b=11{\cdot}552$, $c=3{\cdot}399$ A. Pentatantalum tetraphosphide is also orthorhombic with $a=14{\cdot}420$, $b=11{\cdot}547$, $c=3{\cdot}400$ A. All have been made by rapidly heating in an argon arc furnace an alloy of the appropriate stoicheiometry, made from red phosphorus and the metal in a heated evacuated silica tube.[655, 685]

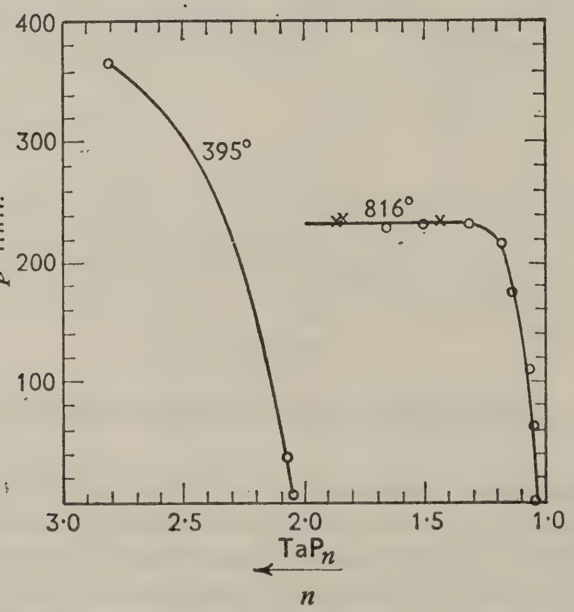

Fig. 35.—Vapour pressure analysis of tantalum phosphides

Monotantalum phosphide exists in two forms, $\alpha$-TaP and $\beta$-TaP which are prepared by heating tantalum diphosphide under high vacuum. Below 900°C. the $\alpha$-form is obtained and above 900°C. the $\beta$-form is produced.[518] Electrolysis of fused phosphate melts has also been shown to produce monotantalum phosphide,[304] as has the reaction of tricalcium diphosphide with tantalum metal.[566] In a comparison of vanadium, niobium and tantalum phosphides, it was suggested that the tantalum compounds are isomorphous with those of niobium.[305] This was confirmed for the $\alpha$ and $\beta$ forms of monotantalum phosphide both of which are greyish black with a metallic lustre.[292] The $\beta$-form has a NbAs lattice, with $a=3{\cdot}334$, $c=11{\cdot}377$ A.[655] and has a high thermal stability.[631] V.p. measurements (shown in Fig. 35[518]) enabled the heat of reaction for equation (54) to be calculated:

$$(54) \qquad TaP(s) + P(white) \rightarrow TaP_2(s) \qquad \Delta H = -12 \text{ kcal.}$$

Both the $\alpha$ and $\beta$ modifications are very resistant to chemical attack. Nitric acid and alkali react only at elevated temperatures and appreciable reaction is only obtained by alkali fusion with oxidizing agents.[518]

Heating the metal with excess of red phosphorus or a mixture of phosphine and hydrogen gives tantalum diphosphide.[518, 292] Fig. 35 shows the results of a tensimetric analysis from which equation (55) was established[518]:

$$(55) \qquad 4TaP_2(s) \rightarrow 4TaP(s) + P_4(g) \qquad \Delta H = +61 \text{ kcal.}$$

Tantalum diphosphide has similar chemical properties to the monophosphide and both phosphides are classed as hard metals.[518] The diphosphide has a monoclinic structure with $a = 8{\cdot}8608$, $b = 3{\cdot}2677$, $c = 7{\cdot}4882$ A., $\beta = 119{\cdot}308°$.[655] It is a metallic conductor, with a positive thermoelectric power.[637]

Crystal data have been determined for the ternary phosphides TaFeP, TaCoP, TaNiP.[653]

## Tungsten (Wolfram)

Electrolysis of lithium and sodium metaphosphate melts containing oxides of tungsten gave a cathodic product which analysis showed to be tetratungsten phosphide.[519] The reaction appears to depend on the formation of phosphine and hydrogen at the cathode. The density of this phosphide is 16·03 g./c.c. and it is decomposed irreversibly at 500° to 550°C. into ditungsten phosphide and $\alpha$-tungsten. Chemically it is not very reactive, since concentrated sulphuric acid reacts slowly whilst nitric acid, hydrochloric acid, and alkali do not attack it. Alkaline hydrogen peroxide produces phosphates and tungstates.[519] Other workers[315] suggest that tetratungsten phosphide is unstable and that it decomposes to give monotungsten phosphide rather than ditungsten phosphide.

Tritungsten phosphide has been prepared by the fused-salt method and identified by means of its $X$-ray diffraction pattern.[311–2] It has also been obtained by rapid chilling of a melt from an argon arc furnace. It appears to be metastable below 1000°C.[655]

The preparation of ditungsten phosphide has been accomplished by the Andrieux method of electrolyzing fused phosphate melts.[9, 10, 520] One of these products[520] has, however, been shown by $X$-ray methods to correspond to monotungsten phosphide.[315]

Monotungsten phosphide is obtained by the above method,[9–10, 311–2] by causing tricalcium diphosphide to react with tungsten or tungsten chloride,[566] or by heating the metal with red phosphorus in a silica tube.[313] It is isomorphous with the corresponding manganese, iron, cobalt and chromium compounds.[292] $X$-Ray measurements have shown it to possess the MnP type of structure[313] which can be regarded as a distorted nickel arsenide type.[315] Its unit cell dimensions are $a = 5{\cdot}734$, $b = 3{\cdot}249$, $c = 6{\cdot}222$ A.[313] (see also reference 571); densities of 12·3 g./c.c.[315] and 11·7 g./c.c.[292] have been reported. V.p. measurements are shown in Fig. 36.[315] The thermal stability of tungsten monophosphide is relatively low.[631] It is a greyish black compound which is not attacked by water or dilute acids at room temperature.[292]

Attempts to prepare tungsten diphosphide by reaction of the elements at high temperatures were unsuccessful.[499] The method finally used was to cause $WO_3$ to react with red phosphorus for two days at 500°C. The product was purified by reaction with 10% by weight of phosphorus at 550°C. for 24 hr.[499] Other workers have claimed a synthesis from the elements.[315] Tungsten diphosphide disproportionates according to equation (56):

$$(56) \qquad WP_2(s) \rightarrow WP(s) + P(white) \qquad \Delta H = +12 \text{ kcal.}$$

Densities of 8·6 g./c.c.[499] and 9·17 g./c.c.[315] have been reported for this black compound which exists in two forms. The first ($\alpha$-$WP_2$) has a monoclinic structure similar

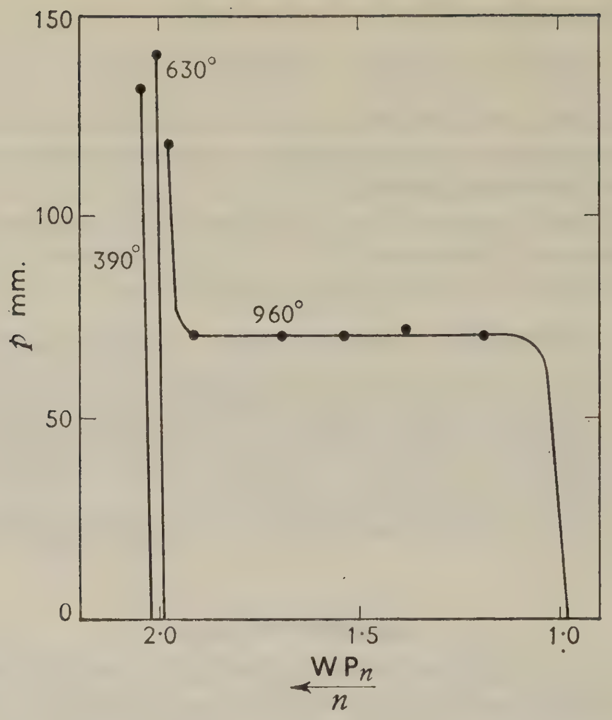

FIG. 36.—Vapour pressure analysis of tungsten phosphides

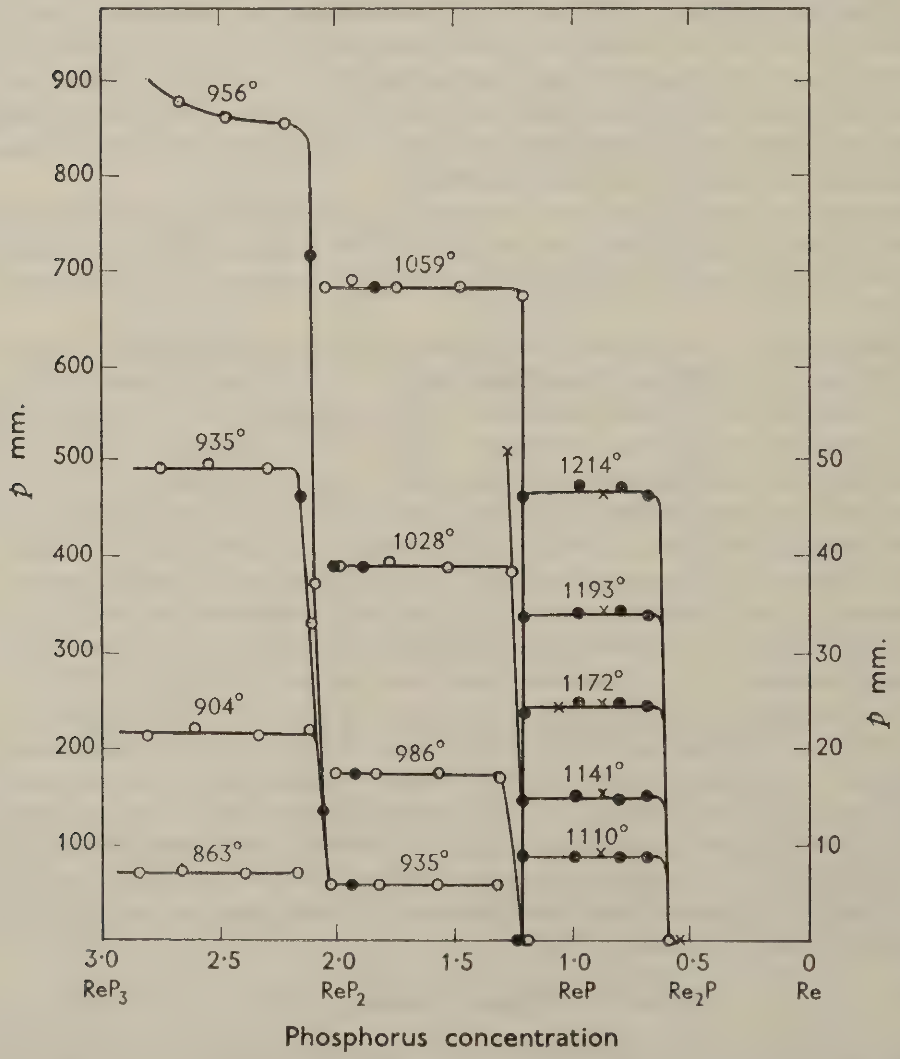

FIG. 37.—Pressure–concentration diagram for the rhenium–phosphorus system

to that of niobium diarsenide, with $a = 8{\cdot}5022$, $b = 3{\cdot}1695$, $c = 7{\cdot}4660$ A., $\beta = 119{\cdot}367°$.[637, 655] The second ($\beta$-$WP_2$) has an orthorhombic ($MoP_2$) structure with $a = 3{\cdot}166$, $b = 11{\cdot}161$, $c = 4{\cdot}973$ A.[571, 655] In its chemical properties $\beta$-$WP_2$ also resembles molybdenum diphosphide, since it is insoluble in concentrated hydrochloric acid or ammoniacal hydrogen peroxide, and is oxidized by concentrated sulphuric acid or aqua regia.[499]

The system tungsten–phosphorus–iron has been investigated up to 22% of phosphorus and 100% of tungsten.[457]

## Rhenium

The reaction of red phosphorus with rhenium was shown to commence at a temperature of approximately 750°C.[521] V.p. and *X*-ray measurements on the reaction product showed it to contain dirhenium phosphide, monorhenium phosphide, rhenium diphosphide and rhenium triphosphide. An *X*-ray determination of the structure of dirhenium phosphide has been made.[522] It is orthorhombic with $a = 5{\cdot}540$, $b = 2{\cdot}939$, $c = 10{\cdot}040$ A., space group *Pnma*. The calculated density is 16·4 g./c.c.[522] as compared with a previously measured density of 15·5 g./c.c.[521] The structure has been compared with that of diruthenium phosphide and the metal–metal distances are found to be shorter whilst the metal–phosphorus distances are longer.[522] The v.p. data shown in Fig. 37 enabled equations (57), (58) and (59) to be established[521]:

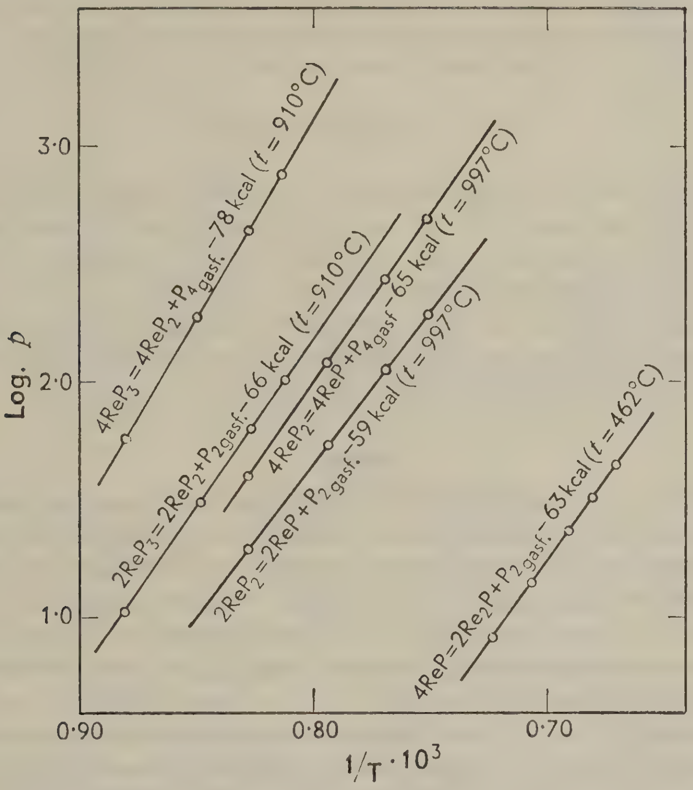

FIG. 38.—Decomposition pressure of rhenium phosphides

(57) For rhenium triphosphide $\log p_{(\text{mm.})} = -17060/T + 16{\cdot}77$

(58) For rhenium diphosphide $\log p_{(\text{mm.})} = -14220/T + 13{\cdot}37$

(59) For rhenium monophosphide $\log p_{(\text{mm.})} = -13780/T + 10{\cdot}90$

Heats of formation or disproportionation shown in Fig. 38 were calculated using the vapour pressure data. Densities and molecular volumes are collected together in Table VIII.[521] The molecular volumes are space additive. These phosphides react slowly with acids.[521]

*Table VIII.—Densities and Molecular Volumes for Rhenium Phosphides*

| Compound | Mol. vol. c.c. | $d_{25}$ g./c.c. |
|---|---|---|
| $Re_2P$ | 13·01 | 15·50 |
| ReP | 18·13 | 11·99 |
| $ReP_2$ | 28·06 | 8·83 |
| $ReP_3$ | 38·19 | 7·30 |

### Osmium

The system osmium–phosphorus has been studied[503] and only one phosphide, the diphosphide, recognized. Osmium and phosphorus when heated together at 1190°C. produce this phosphide which has a v.p. of only 8 mm. of mercury at this temperature. Its heat of formation from solid osmium and phosphorus gas is

$$\Delta H = -70 \text{ kcal./mole}^{503}$$

and its crystal structure is of the marcasite type with space group *Pnnm*.[504] This phosphide is a semiconductor having an energy gap of *ca.* 1·2 e.v. and a magnetic susceptibility, $\chi_{\text{mol}}$, of $-74 \times 10^{-6}$ c.g. units at 295°K.[573] Chemically it is very inert, air, acids and oxidizing agents having no effect upon it.[503]

A ternary compound, OsPAs, has been reported, also having a marcasite-type structure.[573] The semiconducting compounds OsPS and OsPSe, with an arsenopyrite structure, have also been described.[659]

### Iridium

Of the phosphides of iridium, the diphosphide has been prepared by heating iridium powder with red phosphorus for many hours, after which excess of phosphorus was distilled off.[523] The other phosphide, di-iridium phosphide can be obtained from this by heating at 1150°C. under reduced pressure. If the heating is prolonged for many hours the di-iridium phosphide gradually loses phosphorus.[523] The lower phosphide is a grey-blue compound having a m.p. of between 1310°C. and 1360°C. It has the anti-fluorite structure[507, 504] with $a = 5{\cdot}53(5)$ A. and a calculated molecular volume of 25·7 c.c.[507] Its resistance to chemical attack is greater than that of the diphosphide which is a deep black compound having *d* 9·15 g./c.c. and molecular volume 27·9 c.c. Iridium diphosphide is diamagnetic.[575] It is stable towards hydrochloric acid and nitric acid but is attacked by aqua regia, boiling concentrated sulphuric acid and a mixture of bromine and hydrochloric acid.[523] Iridium triphosphide is reported as having a structure of the skutterudite type with space group *Im*3.[504, 665]

Ternary compounds IrPS and IrPSe have been described. The sulphide has a cobaltite-type lattice, $a = 5{\cdot}650$ A. and the selenide a superstructure of the pyrite (ullmannite) type, with $a = 5{\cdot}798$ A.[569]

### Platinum

Platinum has been heated in phosphorus vapour in a closed quartz tube to give platinum diphosphide for *X*-ray studies.[524] The only other investigation was a thermal, *X*-ray and tensimetric analysis of the platinum–phosphorus phase system which is shown in Fig. 39.[525] Although it is not shown in the figure platinum diphosphide has m.p. above 1500°C. Its crystal structure is cubic with $a = 5{\cdot}683 \pm 0{\cdot}004$ A.,[524] $a = 5{\cdot}6956 \pm 0{\cdot}0005$ A.[666–7] Its electrical properties and those of the isomorphous PtPAs have been recorded.[660] The oxidation of phosphorus by steam has been catalyzed by platinum diphosphide.[74] An unusual compound, $Pt_{20}P_7$, is important because of its low m.p. and the ease with which it can be formed. It has

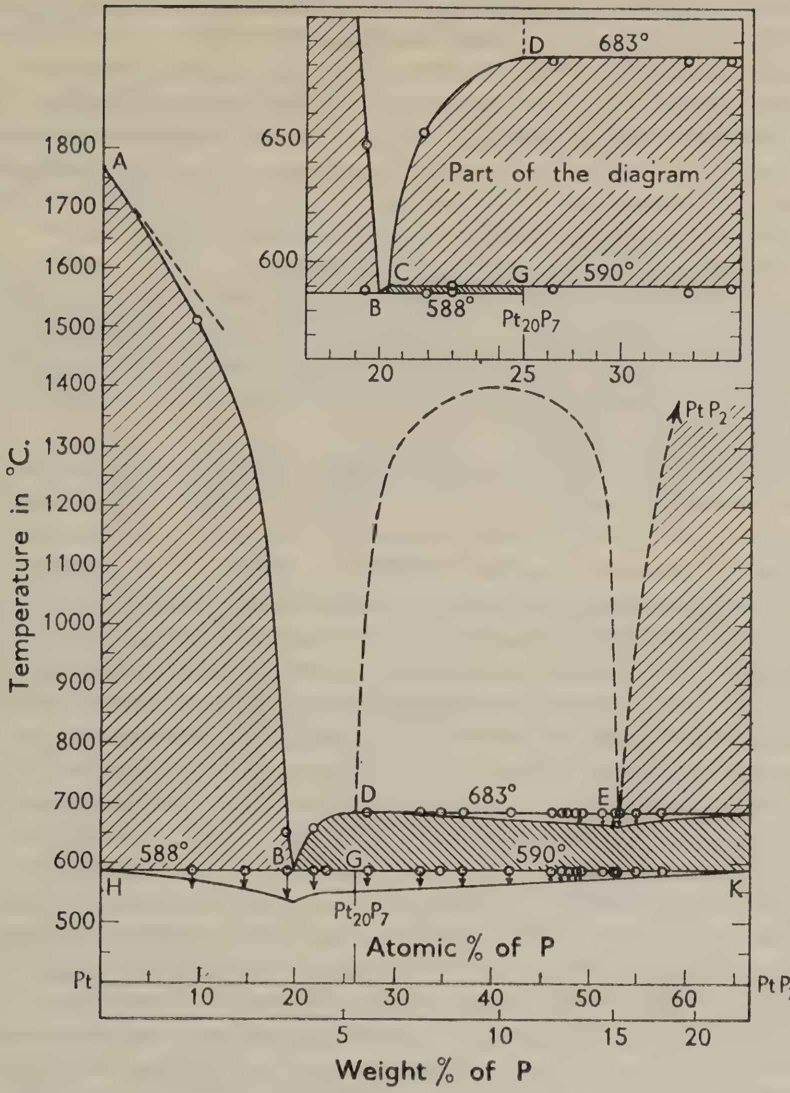

FIG. 39.—Phase diagram of the platinum–phosphorus system

been shown to have no superconducting properties at temperatures down to 0·35°K.[572] Care has to be taken in the use of platinum apparatus when phosphorus is likely to be present.[525–7]

## The Rare Earths

In this group, the phosphides of general formula MP (where M is the rare earth metal) have been prepared by heating phosphorus with the rare earth metal in a sealed tube or in argon atmosphere at elevated temperatures. The unit cell dimensions and magnetic susceptibilities of a series of rare earth monophosphides have been reviewed.[547] The magnetic properties of the series of phosphides GdP–ErP are determined largely by the crystal structure and lattice spacings.[672] The Fermi momentums $k_F$ of the conduction electrons have been calculated from the paramagnetic Curie temperatures and the lattice spacings of a series of rare earth phosphides.[668]

Cerium reacts violently with phosphorus at 400° to 500°C.[515] The monophosphide has a sodium chloride type of structure with $a = 5{\cdot}89(7)$,[517] 5·909 A.[516] Its magnetic properties have been determined over the range 4–300°K.[669] Heating cerium phosphide in air causes only slight oxidation and it is probably the most stable rare earth phosphide known, though it evolves phosphine when treated with water.[515]

Praseodymium monophosphide was prepared as above.[515] It too has the sodium chloride type of structure with $a = 5{\cdot}86(0)$,[517] 5·87(2) A.,[516] is oxidized slowly in the atmosphere and liberates phosphine when treated with water.[515] Its magnetic properties between 4 and 300°K. have been reported.[669]

Neodymium monophosphide is formed by a vigorous reaction between the elements at 400° to 500°C.,[528] or by passing phosphine over $Nd_2O_3$ at 1300–1350°C. or over neodymium metal at 1000–1100°C.[670–1] The compound is a black powder, insoluble in water or alkalis, but soluble in acids, and reacting violently with nitric acid.[671] It has the sodium chloride structure with $a = 5{\cdot}82(6)$,[528] 5·838,[516] 5·843 A.[671] and is unstable, liberating phosphine when attacked by moist air.[528]

The reaction of samarium with phosphorus is slow, but a pure product can be obtained by pulverizing the product and reheating.[529] The phosphide can also be prepared by passing phosphine over samarium oxide at 1300–1350°C. or over the metal at 900–950°C. Samarium phosphide is readily soluble in nitric acid.[670] It has a sodium chloride type of structure with $a = 5{\cdot}760$ A.[529] Magnetic susceptibility measurements show that at 289°K. $\chi \times 10^3 = 1{\cdot}1$.[530]

Europium monophosphide is reported briefly to have a cubic lattice.[654]

Gadolinium monophosphide has been prepared by treating gadolinium chips in evacuated quartz tubes with phosphorus vapour, then compressing the material which is heated *in vacuo* or in argon at 1100° to 1400°C.[516] As with other rare earth phosphides it has a sodium chloride type of structure with $a = 5{\cdot}723$ A.[516] Magnetic susceptibility measurements[530] indicate that it conforms to the Curie–Weiss law.[326] It has a moment of 7·9 Bohr magnetons corresponding to $Gd^{3+}$ and $\chi \times 10^3$ at 298°K. is 28·5.[530] The induced ferromagnetism of GdP has been studied.[688]

Terbium monophosphide, as prepared by heating the elements *in vacuo* at 300° to 600°C., pressing, and then heating for some hours at 1100° to 1300°C. is dark grey and has the sodium chloride type of structure with $a = 5{\cdot}688$ A. It conforms to the Curie–Weiss law[326] in the range 73° to 473°K. and $\chi \times 10^3$ at 298°K. is 39·5.[531]

Dysprosium monophosphide has been synthesized by heating the metal with phosphorus at 550°C. for 5–7 days followed by compression of the powder and further heating at 1100° to 1300°C. until the reaction is complete. It has the sodium chloride type of structure and magnetic susceptibility measurements show that it follows the Curie–Weiss law[326] down to approximately 100°K. It has a paramagnetic Curie point ($\theta p$) of 6°K.[576] The magnetic moment indicates the presence of $Dy^{3+}$.[532]

The synthesis of holmium monophosphide has been accomplished by heating the elements together in an evacuated tube at 1100° to 1400°C. It is grey, has the sodium chloride type of structure with $a = 5{\cdot}626$ A. and a magnetic susceptibility of 0·0461,[533] with a Curie point of 4·2°K.[576]

Erbium monophosphide was synthesized by heating the metal in phosphorus vapour at 500° to 800°C. and finally at 1100°C. for 1 hr. It has the sodium chloride type of structure and magnetic susceptibilities showed it to follow the Curie–Weiss law[326] at low temperatures. Magnetic moment measurements indicate that the structure contains $Er^{3+}$ ions.[534]

Ytterbium monophosphide is reported to have a cubic lattice,[654] as have the monophosphides of thulium ($a = 5{\cdot}573$ A.) and lutetium ($a = 5{\cdot}533$ A.). Curie temperatures, magnetic susceptibilities and magnetic moments have been recorded for the latter two phosphides.[673]

## THORIUM, URANIUM AND TRANS-URANIC ELEMENTS

### Thorium

Two phosphides of thorium have been prepared. Trithorium tetraphosphide has been obtained by passing phosphine over the heated hydride[535–7] and by heating thorium metal in phosphorus vapour.[306, 538] This phosphide has a body-centred cubic structure with $a = 8{\cdot}624 \pm 0{\cdot}020$ A.,[535] $a = 8{\cdot}600 \pm 0{\cdot}002$ A.,[539] $d$ 8·44 g./c.c.[538] Values for the thermoelectric power and electrical conductivity up to 950°C. have been given.[674] It liberates phosphine when treated with dilute acids but is unattacked by cold water and heating to 1100°C. has no effect upon it.[538]

By heating trithorium tetraphosphide at 1100–2400°,[634, 675] or by heating thorium with phosphorus,[539, 675] or trithorium tetraphosphide,[675] a new cubic phase of variable composition is formed, approximating to thorium monophosphide. The lattice dimensions are a linear function of composition from $ThP_{0\cdot55}$ ($a = 5\cdot830$ A.) to $ThP_{0\cdot96}$ ($a = 5\cdot840$ A.) (cf. $a = 5\cdot818$ A.[539]). Thermodynamic information has been obtained for the system by experiments on high-temperature solid electrochemical cells. These showed that for the reaction:

$$Th + Th_3P_4 \rightarrow 4ThP$$

at 1173°K. the free energy change is $-53\cdot7 \pm 2\cdot8$ kcal./g. atom Th, the entropy change $-9\cdot3 \pm 3\cdot7$ g.-cal./mole, and the enthalpy change $-64\cdot6 \pm 7\cdot1$ kcal./g. atom Th. Hence free energies of formation at 1173°K. were deduced for ThP ($-71\cdot5$ kcal./deg. mole) and $Th_3P_4$ ($-232$ kcal./mole), while the enthalpy of formation of ThP at the same temperature is $-106$ kcal./mole.[676] Thorium monophosphide which does not melt up to 2400°C. is a blue substance possessing great chemical resistance.[675] The chemical analysis of the thorium phosphides has been discussed.[677]

### Uranium

Monouranium phosphide, triuranium tetraphosphide and uranium diphosphide were all prepared by reaction of the elements at elevated temperatures,[540, 581, 678] whilst diuranium triphosphide has been prepared by the reaction of uranium hydride with phosphine.[541] A patent dealing with the preparation of uranium phosphide from the hydride and phosphine has been granted.[542] All of the phosphides are grey. Uranium monophosphide has a cubic face-centred structure with $a = 5\cdot589$ A.,[543, 679] and a molecular volume of 27 c.c.,[540] triuranium tetraphosphide is structurally similar to the thorium compound with $a = 8\cdot19(7)$ A.[543] and molecular volume 35 c.c.,[540] whilst uranium diphosphide is structurally similar to $UAs_2$ with cell dimensions for the tetragonal unit cell $a = 3\cdot800$ and $c = 7\cdot762$ A.[581] The magnetic properties of the three phosphides have been studied, triuranium tetraphosphide being ferromagnetic, and the others antiferromagnetic.[680] The thermoelectric power and electrical conductivity of uranium monophosphide[681] and triuranium tetraphosphide[682] have been determined. From tensimetric measurements shown in Fig. 40 equations (60) and (61) were established:

$$(60) \qquad 6UP_2(s) \rightarrow 2U_3P_4(s) + P_4(g) \qquad \Delta H = +52 \text{ kcal.}$$

$$(61) \qquad \tfrac{1}{2}U_3P_4(s) + P(\text{white}) \rightarrow \tfrac{3}{2}UP_2(s) \qquad \Delta H = -10 \text{ kcal.}$$

Triuranium tetraphosphide is the most reactive of these phosphides and produces phosphine when treated with hydrochloric acid. Uranium monophosphide is inert to atmospheric moisture and is also resistant to oxidation,[679] probably because of the formation of a protective surface layer of amorphous uranyl phosphate.[683] Uranium diphosphide, the least reactive, is not attacked by dilute hydrochloric acid but dissolves in nitric acid.[540]

### Neptunium

Neptunium, heated with excess of red phosphorus in an evacuated, sealed quartz tube at 750°C. for 16 hr. gives a product trineptunium tetraphosphide which is isomorphous with the corresponding thorium compound.[544] It is unaffected by water but a vigorous reaction, probably represented by equation (62), takes place with hydrochloric acid[544]:

$$(62) \qquad Np_3P_4 + 12HCl \rightarrow 3NpCl_4 + 4PH_3$$

### Plutonium

Plutonium monophosphide is formed by reaction of the elements *in vacuo* or helium[545, 580] or from plutonium trihydride and phosphine at 400–600°C. followed

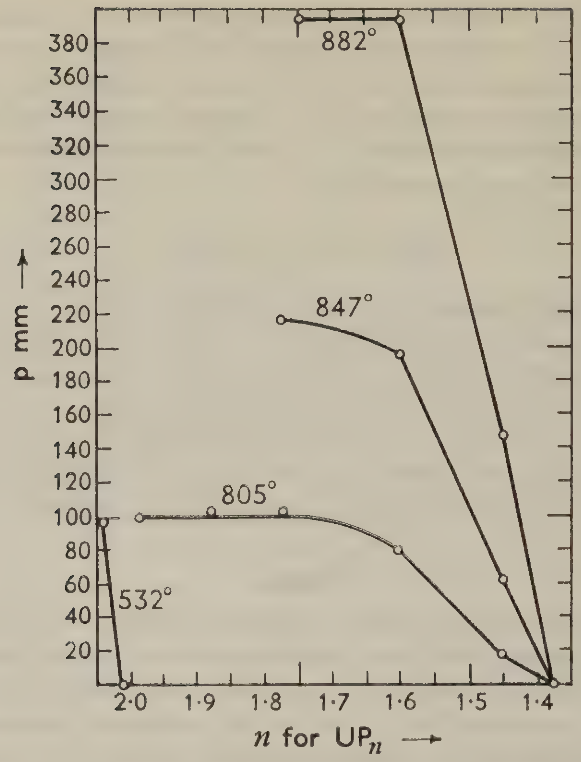

FIG. 40.—Vapour pressure analysis of the higher uranium phosphides

by tempering at 1400°C. *in vacuo*.[684] The phosphide is dark grey, and decomposes at 2600°C. and 2 atm. pressure. It is reported to have a cubic structure with $a$ = 5·644 ± 0·004 A., $d$ = 9·87 g./c.c.[545] or $a$ = 5·6598 A., $d_{\text{calc.}}$ = 9·893 g./c.c.[684]

## SECTION VIII

# PHOSPHIDES OF NON-METALS

BY A. WILSON AND N. L. PADDOCK

## GROUP 0

### Helium

Helium is the only rare gas for which any evidence of reaction with phosphorus has been reported. At liquid-air temperatures and under the influence of electron bombardment, helium is absorbed by, or forms an interstitial compound with, phosphorus. The product decomposes suddenly at $-125$°C. with evolution of helium. The vapour pressure is of the order 0·0005 mm. Hg at $-185$°C.[112]

## GROUP 3

### Boron

When boron monophosphide, BP, is decomposed by heating it to a temperature between 1000° and 1700°C. in an inert atmosphere, the compound tridecaboron diphosphide is formed.[1, 117–20, 122] Tridecaboron diphosphide is also formed when aluminium monophosphide is caused to react with amorphous boron[1] or boron trichloride[105] under similar conditions. *X*-Ray data show that the crystalline compound has rhombohedral symmetry with $a = 5{\cdot}984$ and $c = 11{\cdot}850$ A.[2]; other workers give $a = 5{\cdot}231$ A., $\alpha = 69{\cdot}50°$.[105] The space group is probably $R\bar{3}m$ since the compound is isomorphous with $B_4C$ and $B_4Si$. This *X*-ray work gives *d* $2{\cdot}74 \pm 0{\cdot}02$ g./c.c.,[1] 2·76 g./c.c.[105] The electrical conductivity of tridecaboron diphosphide has been recorded.[119] Other less well-defined phosphides containing higher proportions of boron, and made in similar manner, have been described.[106, 119]

If boron monophosphide, at a pressure of approximately 1 mm. of mercury, is heated to a temperature above 1100°C. it decomposes and hexaboron monophosphide is formed.[3, 106] Using the appropriate data, $\Delta H^\circ_{298°\text{K.}} = -31{\cdot}0$ kcal./mole has been calculated for the reaction:

$$6B(\text{cubic}) + P(\text{white}) \rightarrow B_6P$$ [4]

Hexaboron monophosphide has a hardness of 9·0–9·7 on Mohs' scale, and *d.* 2·45 g./c.c. It is stable at 2000° in air.[107, 121] This compound is extremely inert chemically and elevated temperatures are required for attack by alkali, whilst temperatures of 500° and 800°C. are required for attack by chlorine and oxygen, respectively.[3] There is some doubt as to whether hexaboron monophosphide exists or whether it is identical with tridecaboron diphosphide.[2] Other investigators using implosive shock techniques were unable to prepare this phosphide,[5] but an *X*-ray examination should either confirm or disprove its existence, e.g. [121].

Boron monophosphide has been studied to some extent because of its semiconducting properties. Much of this work belongs to the realm of physics and a comprehensive survey of these properties has been given in more appropriate places.[6–8]

Direct reaction of boron and red phosphorus at temperatures between 1000°C. and 1100°C. produces boron monophosphide.[3, 9–11, 122–5] The reaction shows three regions of kinetics, at 1000–1150°; a 'kinetic' phase in which the reaction is of the second order in $P_2$ and independent of the boron concentration, a transitional phase, and a 'diffusion' phase (first order in $P_2$).[125] At temperatures up to 1350°C., under pressures of 9000–15,000 kg./cm.$^2$, cubic boron monophosphide is formed,[126] while some tridecaboron diphosphide is formed at 100 atm. and 1600°C.[127] It has also been prepared by heating the addition compounds of boron trichloride with phosphorus pentachloride, and of boron tribromide with phosphine, to 300°C. in sealed tubes.[12, 3] The product obtained by the decomposition of the boron trichloride–phosphorus pentachloride complex varied in composition between boron monophosphide and pentaboron triphosphide but no evidence for the latter compound was found.[3] Boron monophosphide is also formed by passing boron trichloride over aluminium monophosphide heated to 1000°C.,[3] or zinc phosphide heated to 900–1085°C.,[118, 128] by carbon reduction of a borate–phosphate mixture dissolved in a sodium chloride melt at 480–1820°,[108] or by the reaction of boron trichloride, hydrogen and phosphorus at 1000°C.[3, 118] This last method is said to give the purest product.[3] Boron tribromide has been used in place of boron trichloride.[129] Although the material, as prepared, is usually amorphous, it can be crystallized by heating to over 1400°F. in phosphorus vapour[13, 130]; the volatility is enhanced by the addition of a trace of iodine to the system.[131] The crystalline material has the cubic zinc-blende type structure with $a = 4{\cdot}55$,[9] 4·538,[10, 11] 4·537,[14] 4·547 A.,[13] $d$ 2·94 g./c.c.[109] It is extremely hard and by analogy with boron nitride and carbon it was expected to be harder than silicon carbide[9] but this appears not to be borne out by experiment.[14–5] Although material produced so far is impure by semiconductor standards, indications are that it may prove to be useful in this application and this, together with its possible use as an abrasive, has led to methods of manufacture being patented.[13–4, 16–22, 123–4, 132] The electrical resistivities of boron–phosphorus alloys are shown in Fig. 1.[23] A single crystal of boron monophosphide, prepared by vacuum sublimation, had a thermal e.m.f. of 260 $\mu$v/°C. at 20–150°C. and a microhardness of 4000 kg./mm.$^2$,[130] The infra-red dielectric constant and the ultra-violet optical properties of the phosphide have been determined.[134] Thermodynamic studies have been made on certain equilibria. For equation (1):

$$(1) \qquad BCl_3 + \tfrac{3}{2}H_2 + \tfrac{1}{4}P_4 \rightleftharpoons BP + 3HCl, \qquad T = 1193°\text{–}1543°\text{K.}$$

the equilibrium constant is given by equation (2):

$$(2) \qquad \log K = 1{\cdot}377 - 1550/T$$

From this there were obtained: $\Delta H° = 7090$ g.-cal., $\Delta S° = 6{\cdot}30$ g.-cal./degree, and $\Delta G° = -1730$ g.-cal. (all mole$^{-1}$) at 1400°K.[4] Using the above data and literature values, $\Delta H^{\circ}_{298°\text{K.}} = -19{\cdot}90$ kcal./mole was calculated for the reaction given in equation (3):

$$(3) \qquad B(\text{cubic}) + P(\text{white}) \rightarrow BP(\text{cubic})$$

Also for the reaction shown in equation (4) the following data were obtained: $\log K = 3{\cdot}134 - 5900/T$, $\Delta H° = 27{,}000$ g.-cal., $\Delta S° = 14{\cdot}34$ g.-cal./degree, and $\Delta G°$ at 1500°K. = 5480 g.-cal. (all mole$^{-1}$)

$$(4)^4 \qquad BP \rightleftharpoons \tfrac{1}{6}B_6P + \tfrac{5}{12}P_2, \qquad T = 1473\text{–}1573°\text{K.}$$

A 'third law' calculation using estimated entropies and heat capacities gave a heat of dissociation at 298·16°K. of 73·2 kcal./mole of $P_2$(g) for equation (5):

$$(5)^{24} \qquad \tfrac{26}{11}BP(s) \rightarrow \tfrac{2}{11}B_{13}P_2(s) + P_2(g)$$

A heat of formation for gaseous boron monophosphide of 62 kcal./mole was estimated using oxide systems as a guide,[25] while the heat of formation of the solid monophosphide at 1200°C. has been estimated as $99{\cdot}6 \pm 0{\cdot}3$ kcal./mole.[129] From observations of *K*-emission line shifts it was concluded that the compound has a strong ionic component.[26] The dependence of vapour pressure on temperature can be expressed as in equation (6):

$$(6) \qquad \log p_{(\text{mm.})} = -13{,}700/T + 10{\cdot}1$$

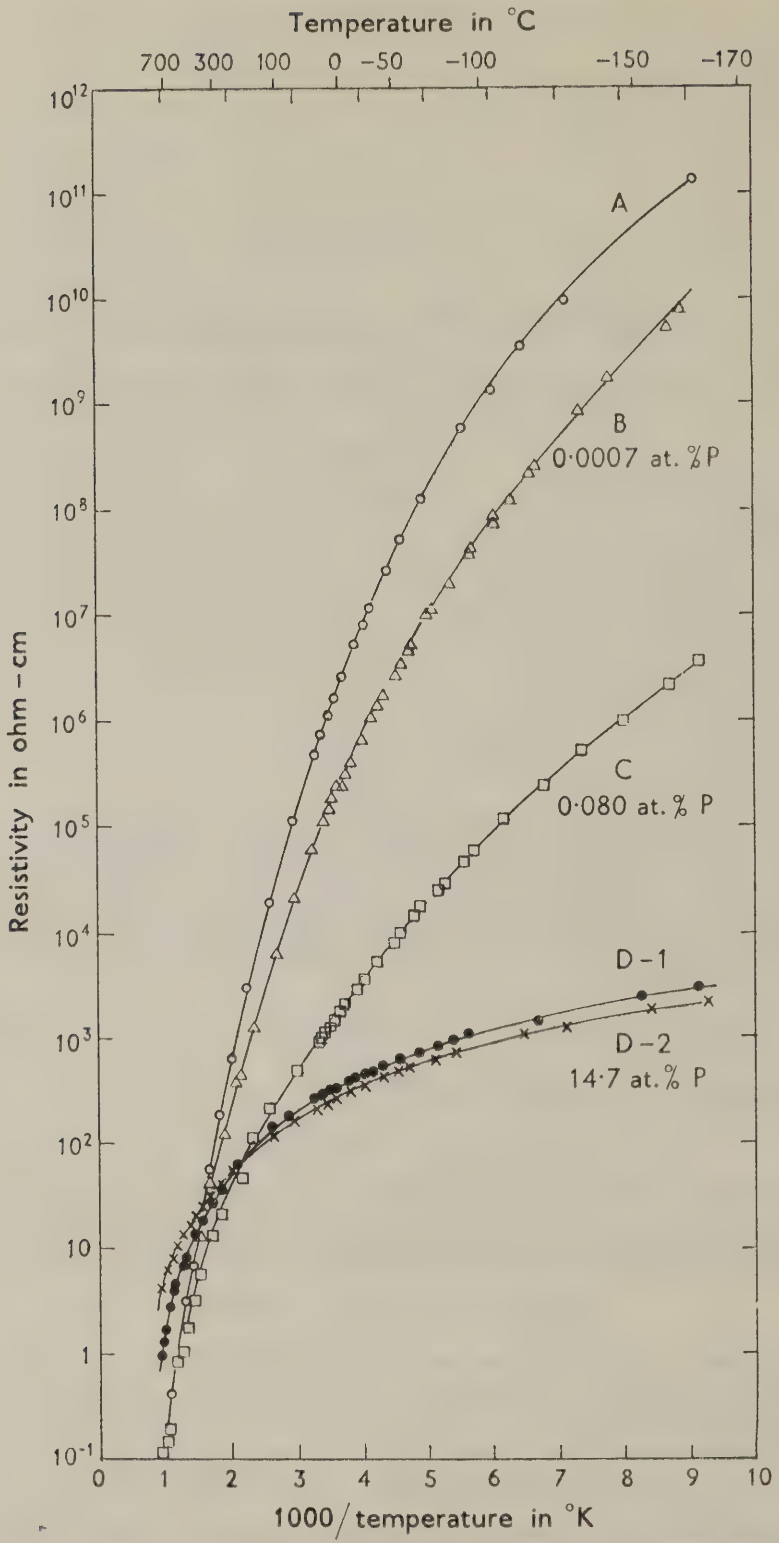

FIG. 1.—Resistivity of boron and boron–phosphorus alloys as a function of the reciprocal of the absolute temperature

Boron monophosphide, like the other boron phosphides, is extremely resistant to chemical attack[3, 118, 133] although molten alkali, oxygen at 800°C. and chlorine at 500°C. show some reaction.[3] When it is heated in air there are no signs of decomposition at 1000°C.[12]; it does not burn at 1200°C.[14] and it is resistant to decomposition even at 5400°F.,[13] though this is probably due to the formation of inert oxide layers. No signs of decomposition are apparent at 1250°C. in phosphorus vapour.[10] It is resistant to hydrolysis[12] and acids[13–4] and it is necessary to heat it to 800°C. before it will react with ammonia to produce phosphine and cubic boron nitride.[12]

A material containing boron and phosphorus in equal atomic proportions has been prepared in a series of high pressure, high temperature studies. At a pressure of 94,500 atm. and a temperature of 2500°C. boron and phosphorus react to give a black, soft material which is a moderately good conductor of electricity. It has a face-centred cubic structure with $a = 4{\cdot}54$ A.[27]

A patent has been granted for the stabilization of a material having composition $B_3P_4$ against oxidation in the region of 2000° to 2500°F. Stabilizers include boron as well as oxides of sodium, potassium, magnesium and beryllium.[28]

Ternary systems investigated are Fe–P–B, Cr–P–B, Mn–P–B, Co–P–B and Ni–P–B.[29, 135–6] In the Fe–P–B system two ternary phases exist. These are $Fe_5PB_2$ and $Fe_3P_{1-x}B_x$; the latter is homogeneous in the approximate range $0{\cdot}48 < x < 1$ at 1000°C. $Fe_3P_{0\cdot37}B_{0\cdot63}$ crystallizes in the space group $P4_2/n$ with $a = 8{\cdot}812$, $c = 4{\cdot}375$ A. $Fe_5PB_2$ crystallizes in the space group $I4/mcm$ with $a = 5{\cdot}482$, $c = 10{\cdot}332$ A.[29] In the Mn–P–B system a ternary phase $Mn_5PB_2$ exists which is isostructural with $Fe_5PB_2$, whilst in the Co–P–B system three ternary phases exist. $Co_3P_{1-x}B_x$ is homogeneous in a narrow range near $x = 0{\cdot}7$, $Co_3P_{1-y}B_y$ is homogeneous near $y = 0{\cdot}5$ and $Co_5PB_2$ is isostructural with $Fe_5PB_2$ and $Mn_5PB_2$.[29]

## GROUP 4

### Carbon

Although no crystalline phosphides of carbon stable at room temperature exist, spectra observed when an electrical discharge was passed through a mixture of argon and phosphorus vapour were thought to be due to a species carbon monophosphide[30] arising apparently from tap grease or sealing wax. Wave numbers have been calculated for this compound[31] and a complete vibrational–rotational analysis of the band system between 2900 and 4400 A. has been carried out.[32] A heat of formation of 74 kcal./mole was estimated using oxides as a guide[25] and tables of $(G° - H°)/T$, $S°$, $C_p^{\circ}$ include values for CP.[33] These values at 273·15°K. are:

$$-(G° - H°)/T = 44{\cdot}064 \text{ g.-cal. deg.}^{-1} \text{ mole}^{-1}$$
$$S° = 51{\cdot}038 \text{ g.-cal. deg.}^{-1} \text{ mole}^{-1}$$

and

$$C_p^{\circ} = 7{\cdot}090 \text{ g.-cal. deg.}^{-1} \text{ mole}^{-1}$$ [33]

It is reported that an amorphous yellowish compound, $P_2C_6$, is obtained when an ether solution of phosphorus trichloride is caused to react with magnesium acetylene iodide at room temperature. It is insoluble in ordinary solvents, is not attacked by acids or alkalis and ignites when slightly heated, burning to $P_2O_5$ without the liberation of carbon.[113]

Some work has been done on the carbon–phosphorus–iron system[34–6] and the carbon–phosphorus–iron–silicon system.[36] It is thought that in the low phosphorus range the carbon–phosphorus–iron system may be similar to the carbon–silicon–iron system.[37]

### Silicon

Mixtures of monosilane and phosphine in the ratio 1:1 or 1:2 give as product disilicon monophosphide when heated at 450°C. under a total pressure of 200 mm. of mercury.[38] It is a blue-black amorphous solid which decomposes when heated to 600°C. giving silicon and silicon monophosphide.[38]

The above work supports earlier evidence for the existence of silicon monophosphide which was prepared by heating together silicon and phosphorus at high temperatures.[39] A heat of formation of 80 kcal./mole has been estimated for this compound[25] which, if heated to above 1000°C., decomposes according to equation (7)[39]:

$$(7) \qquad 4SiP(s) \rightarrow 4Si(s) + P_4(g), \quad \Delta H = 72 \text{ kcal.}, \quad t \sim 1100°C.$$

Its vapour pressure varies with temperature according to equation (8):

$$(8)^{39} \qquad \log p_{(\mathrm{mm.})} = -15{,}710/T + 13{\cdot}769$$

It crystallizes as needles having a density of 2·4 g./c.c. and is hydrolyzed by hot water.[40]

Silicon monophosphide was recognized in a study of the binary system silicon–phosphorus; the results are shown in Fig. 2.[40] Ternary systems which have been studied are silicon–phosphorus–copper,[41] silicon–phosphorus–iron[42–3] and silicon–phosphorus–aluminium.[44] A compound $CuSi_2P_3$ exists in the silicon–phosphorus–copper system. It belongs to a class of semiconductors of the general form $A^{I}B_2^{IV}C_3^{V}$ and has a distorted zinc-blende structure with $a = 5{\cdot}25$ A.[45] In the system silicon–phosphorus–iron a new compound $FeSi_4P_4$ was established.[43]

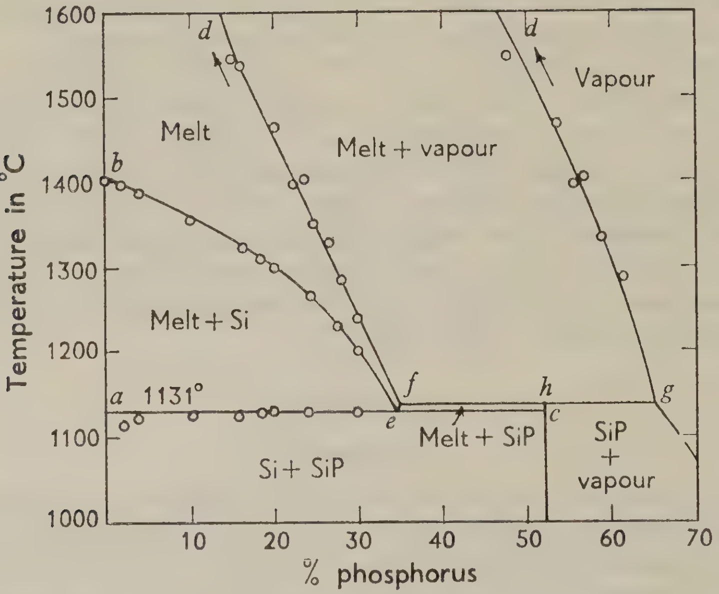

FIG. 2.—The silicon–phosphorus phase system

## Germanium

Germanium monophosphide was prepared by heating germanium with excess of phosphorus in an evacuated tube at 400°C. The product was identified by *X*-ray analysis and vapour pressure measurements. From the results shown in Fig. 3 the heats of formation according to equations (9) and (10) were calculated[46]:

$$(9) \qquad 4Ge(s) + P_4(g) \rightarrow 4GeP(s), \qquad \Delta H = -37 \text{ kcal.}; \qquad t = 540°C.$$

$$(10) \qquad Ge(s) + \tfrac{1}{4}P_4(\text{white}) \rightarrow GeP(s), \qquad \Delta H = -6 \text{ kcal.}$$

The free energy of formation of solid GeP from the gaseous elements has been estimated as $\Delta G_{T°K} = -17{,}900 + 11{\cdot}3\,T$ g.-cal. mole$^{-1}$ [110]

The semiconducting phosphides zinc germanium diphosphide, $ZnGeP_2$, and cadmium germanium diphosphide, $CdGeP_2$, have been discussed from a practical point of view.[47] They have the chalcopyrite type of structure with $a = 5{\cdot}46$ and $a = 5{\cdot}73_8$ A., respectively.[45] Other phosphides involving three elements are magnesium germanium diphosphide $MgGeP_2$ which has a zinc-blende structure with $a = 5{\cdot}65_2$ A.[45] and copper digermanium triphosphide, $CuGe_2P_3$. The last compound belongs to a new group of semiconductors of general formula $A^{I}B_2^{IV}C_3^{V}$ and has a disordered zinc-blende structure with $a = 5{\cdot}37_5$ A.[45] Germanium monophosphide, GeP, has been considered as a heat transfer fluid in atomic energy work.[48]

The binary system, germanium–phosphorus and the ternary system germanium–phosphorus–aluminium have been studied at low phosphorus concentrations.[44] The

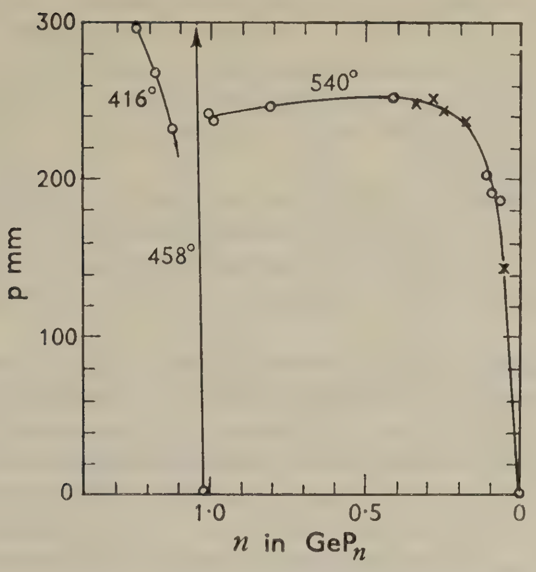

FIG. 3.—Vapour pressure analysis of the germanium–phosphorus system

ternary glasses $Ge_3PS_6$ and $Ge_7PS_{12}$ have good infra-red transmissivities in the 3–5μ region as well as low refractive indices.[137]

## GROUP 5

### Nitrogen

The existence of two nitrides of phosphorus, PN and $P_3N_5$, has been established; a third nitride, $P_4N_6$, has been reported, but there is some doubt about its individuality.

PHOSPHORUS NITRIDE (PHOSPHORUS MONONITRIDE)

Phosphorus nitride, PN, is formed from the elements, either thermally,[49] or under the influence of an electrical discharge.[50, 116] The thermal reaction requires a high temperature (1500° to 1800°) for the dissociation of the phosphorus molecule. On a tungsten surface above 1800° the rate of synthesis is proportional to the square root of the concentration of phosphorus,[51] the rate-determining step being the dissociation of the $P_2$ molecule, with an activation energy of 59 kcal./mole.

The diatomic product PN is thermodynamically unstable at lower temperatures, though it dissociates only slowly,[51] and may be trapped on relatively cool walls at 400° to 500° as a yellow, amorphous,[52] polymeric solid. The PN molecule was discovered in gas discharges through mixtures of nitrogen and phosphorus,[53] the frequencies of the series of band-heads in a system due to a $^1\Pi \rightarrow {}^1\Sigma$ transition being closely represented by

$$\nu(\text{cm.}^{-1}) = 39{,}699{\cdot}3 + (1094{\cdot}75v' - 7{\cdot}25v'^2) - (1329{\cdot}38v'' - 6{\cdot}98v''^2)$$

for transitions between states with vibrational quantum numbers $v'$, $v''$. By analysis of the rotational structure, interatomic distances of 1·487 and 1·542 A. were found for the ground and excited states, respectively.[54] A linear Birge–Sponer extrapolation gives 7·8[54] or 7·9[55] e.v. for the dissociation energy from the ground state to atoms in the ground state.[55] From a measurement of the equilibrium of phosphorus, nitrogen and phosphorus nitride at a single temperature,[51] and from a knowledge of the thermodynamic functions of the homonuclear molecules, the dissociation energy of PN has been found[51] to be 7·1 ± 0·05 e.v. (163·7 kcal./mole), a value which supersedes both the higher values quoted above, and the lower values (6·0 ± 0·8 e.v.) recommended by Gaydon[56] on the basis of the negative curvature of the Birge–Sponer plot. Its heat of formation, calculated from the new value for the dissociation energy, is $\Delta H_f^\circ(\text{PN, g}) = +24{\cdot}4$ kcal./mole; $\Delta H_f^\circ(\text{P, g})$ is taken to be 75·18 kcal./g. atom[57] and

$\Delta H_f^\circ$(N, g) to be 112·9 kcal./g. atom.[58] For the reaction $P_2(g)+N_2(g) \rightarrow 2PN(g)$, $\Delta H = 15{\cdot}0$ kcal., the value for $\Delta H_f^\circ$($P_2$, g) being taken from reference 57. Earlier calculations[59] of the thermodynamic functions of PN have been corrected for the change in dissociation energy, the equilibrium constant for the formation reaction above ranging[61] from 0·01 at 900° to 0·2 at 2000°, now agreeing qualitatively with earlier experimental results.[60]

The spectroscopic similarity of PN and the isoelectronic molecule CS has been stressed by Jevons[61–2]; its stretching constant, corrected for anharmonicity, is[63] 10·1 md./A. Empirical equations connecting internuclear distance and potential energy have been applied to PN (among other diatomic molecules), by several authors.[64–6]

Solid phosphorus nitride is also formed by the action of heat on triphosphorus pentanitride[67–9] (see below), in the reaction between active nitrogen and phosphine,[70] and, in an impure form, in the reaction between triphosphonitrilic chloride $(PNCl_2)_3$ and sodium and between phosphorus trichloride and ammonia.[71–2] It is one of the final products of decomposition[73] of phosphonitrilic oxide PNO. It may be prepared from phosphorus trichloride and ammonia[74] at −78°. Possible manufacturing processes include the thermal[75–6] and electrothermal[77] methods, and the reaction of a phosphorus halide with metallic nitrides,[78] but none of these is used in practice.

The dissociation pressure of phosphorus nitride appears not to have been measured. The solid is in equilibrium[60] with the spectroscopically detectable diatomic species at 450°, and can be sublimed[71] slowly at 500°, rapidly[51] at 900°. The yellow form is converted[67, 69] into an orange-red modification at 700° to 800°. Its heat of formation, recalculated[57] from the data of Wetroff,[79] is $\Delta H_f^\circ(\text{PN, amorp.}) = -16{\cdot}8$ kcal./mole. Its heat of depolymerization is therefore $\Delta H_{\text{depolym.}} = 41{\cdot}2$ kcal./mole, corresponding to an average P–N bond energy term of 68·3 kcal.

Phosphorus nitride is hydrolyzed when heated with water for 3 days at 215°, with formation of ammonium phosphite, ammonium phosphate and hydrogen.[80–1] It dissolves in sulphuric acid with the formation of phosphoric acid, ammonium sulphate and sulphur dioxide[69]; it is easily oxidized by sodium peroxide and by sodium nitrate.[71] It is chlorinated at 500° to trimeric phosphonitrilic chloride containing some phosphorus pentachloride,[82–3] and reacts with either atomic nitrogen[84] or ammonia[52] to give triphosphorus pentanitride (see below).

### TRIPHOSPHORUS PENTANITRIDE

Triphosphorus pentanitride is formed[85] on heating diamidotetrachloro triphosphonitrile, $P_3N_3Cl_4(NH_2)_2$, at 800° to 825°. Most of the reactions in which it is produced depend on the de-ammonation of phospham $PN_2H$ (q.v.) at temperatures[67, 69] in the range 400°–700°C. Phospham itself may be prepared by the de-ammonation of the ammonolysis products of phosphorus pentachloride[67–8, 86] or tri-[67] or tetra-phosphonitrilic chloride.[87] Triphosphorus pentanitride can be synthesized from the elements[88] by the action of a silent electric discharge in the presence of such catalysts as nickel oxide or platinum asbestos. Although normally amorphous, it can be obtained crystalline by heating in a current of ammonia[69] at 800°; the following interplanar spacings have been obtained from the *X*-ray powder pattern[52] (Table I). The conversion of PN to $P_3N_5$ is accompanied by an expansion.

Triphosphorus pentanitride is a white solid, insoluble in water,[69] but slowly hydrolyzed by hot sulphuric acid[88] or by water[88] at 180° to ammonium phosphate.[88, 81, 80] It is less stable than phosphorus mononitride to sulphuric acid,[50] but is insoluble in dilute nitric or hydrochloric acid or alkalis.[88] It decomposes in nitrogen or *in vacuo*[67, 69, 88] above 720° to phosphorus mononitride, itself unstable at this temperature, and is oxidized by air to phosphorus pentoxide.[88] Like phosphorus mononitride, it is chlorinated (at 700°) to triphosphonitrilic chloride,[89] and fluorinated to a mixture of trimeric and tetrameric phosphonitrilic fluorides.[90] Triphosphorus pentanitride reacts explosively with magnesium at the m.p. of the latter. In the reaction trimagnesium diphosphide $Mg_3P_2$ and magnesium phosphonitril-

*Table I.—Interplanar Spacings of Triphosphorus Pentanitride* ($CuK\alpha$ *Radiation*)[52]

| *d* (A.) | Intensity | *d* (A.) | Intensity | *d* (A.) | Intensity |

M = medium, V = very, S = strong, W = weak.

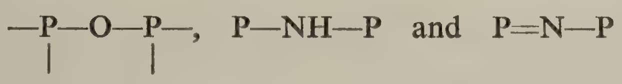
amide $PN(NMg)_2$ are formed. Calcium undergoes a similar reaction which is more violent and starts at 200°C.[115]

### TETRAPHOSPHORUS HEXANITRIDE (PHOSPHORUS PERNITRIDE)

Phosphorus trichloride reacts with ammonia to give the imide, $P_2(NH)_3$; if this is heated at 500° to 600° hydrogen is evolved rather than ammonia and a white substance of empirical composition $P_4N_6$ remains.[80, 91] More recent work, however, suggests[52] that the principal product of this reaction is $P_3N_5$. It is spontaneously inflammable in air, and is more sensitive to hydrolysis than the phosphorus mononitride into which it is converted[91] at 750°; its higher reactivity may be a consequence of the lower temperature at which it is formed. Its hydrolysis products[80–1] show that pentavalent and tervalent phosphorus atoms are present in the ratio 3:1. No evidence could be obtained from *X*-ray powder photographs[52] of a phase with $N:P=1{\cdot}5:1$. Although the existence of a compound of this formula cannot be regarded as established, the disappearance of the yellow colour of the mononitride on further nitridation shows that the product cannot be a simple mixture of the two better-known nitrides.

### PHOSPHORYL NITRIDE (PHOSPHONITRILIC OXIDE, PHOSPHORYL NITRILE)

This substance has been very little studied since its discovery by Gerhardt in 1846 (Mellor, VIII, 709). Besides the classical preparation by the thermal decomposition of phosphoramide,[138–9] the reaction of phosphonitrilic chlorides with metal oxides has also been used for its preparation.[140] The thermal decomposition of phosphoramide has been shown by infra-red studies to proceed by the elimination of ammonia and the formation of



$$-\underset{|}{P}-O-\underset{|}{P}-,\quad P-NH-P \quad \text{and} \quad P{=}N-P$$

bridges. This, together with its physical and chemical properties, shows phosphoryl nitride to be a highly polymeric substance.[138]

Phosphoryl nitride is a white powder which fuses to a black glass. A transparent form has also been described.[141] The nitride is amorphous, insoluble in the common solvents, involatile and unaffected by heating to 750°C. in air. At 1000°C. under reduced pressure it slowly decomposes to phosphorus pentoxide and polymeric phosphorus nitride. It is slowly hydrolyzed by water at 175° to ammonium dihydrogen phosphate.[139] The action of chlorine at 800°C. yields phosphorus oxychloride and a trace of phosphonitrilic chloride.[142] Phosphoryl nitride has been used as the basis of heat resistant polymers.[140]

### THIOPHOSPHORYL NITRIDE (THIOPHOSPHORYL NITRILE, PHOSPHORUS THIONITRIDE)

This compound has only been obtained by decomposing the ammonolysis products of tetra-phosphorus decasulphide (Mellor, VIII, 726). Like phosphoryl nitride it appears to be a high polymer. It is an insoluble grey-white diamagnetic solid which does not melt but decomposes with loss of nitrogen and sulphur at about 600°C. Its infra-red spectrum shows a diffuse band in the P–N stretching region (1150 cm.$^{-1}$).[143]

Thiophosphoryl nitride reacts with hydrogen at 450°C., yielding hydrogen sulphide, ammonia and phosphine. The yellowish white residue is probably a lower phosphorus hydride. The nitride reacts with chlorine at 250°C. giving phosphonitrilic chloride polymers and disulphur dichloride:

$$2(\mathrm{NPS})_n + 3n\mathrm{Cl}_2 \rightarrow 2(\mathrm{PNCl}_2)_n + n\mathrm{S}_2\mathrm{Cl}_2$$

Dry hydrogen chloride at 350°C. also breaks down the polymer:

$$(\mathrm{NPS})_n + 4n\mathrm{HCl} \rightarrow n\mathrm{NH}_4\mathrm{Cl} + n\mathrm{PSCl}_3$$

Thiophosphoryl nitride reacts with aluminium chloride at 350° to give a 1:1 adduct, $\mathrm{AlCl_3,NPS}$. This is remarkably stable, being unaffected by heating at 700°C., insoluble in the common solvents, and unaffected by water. It is cleaved by dry hydrogen chloride to give thiophosphoryl chloride and the complex $\mathrm{AlCl_3,NH_3}$.[143]

### NITRIDO-ANIONS

Compounds of lithium with phosphorus and nitrogen have been reported, such as[92] $\mathrm{Li_7PN_4}$ and[93] $\mathrm{LiPN_2}$. It is not known whether the non-metallic atoms in these compounds form simple or complex anions.

## Arsenic

*X*-Ray and thermal methods have been applied to the study of the arsenic–phosphorus system, the results being shown in Fig. 4. The phase which exists between 53% and 70% of arsenic forms dark laminæ having a graphite-like appearance and a specific resistance of between 1 and 10 ohm cm. The variation of atomic volume with composition suggests that it is structurally similar to black phosphorus or to $\beta$ or $\gamma$ arsenic.[94]

## GROUP 6

### Selenium

Compared with the phosphorus sulphides (Section XI) little is known of the corresponding selenium compounds. The structure of the blackish-violet 'pentaselenium diphosphide' made by melting red phosphorus with metallic selenium[144] has not been determined. It is amorphous, very insoluble in benzene, carbon disulphide, or carbon tetrachloride, and probably polymeric.[145] It reacts with liquid ammonia at −33° to give a mixture of $(NH_4)_2[PSe_3NH_2]$, $(NH_4)_3PSe_4$ and $(NH_4)_2[PSe_2(NH_2)NH]$ which can be separated by their differing solubilities in liquid ammonia. No monoselenophosphate has been detected.[145] Absorption spectra measurements on pentaselenium diphosphide show an absorption maximum at 2780 A.[95] Dissociation processes, as given in equations (11) and (12), are thought to account for the absorptions observed

$$\tfrac{1}{2}P_2Se_5 \rightarrow \tfrac{1}{2}P_2Se_3 + Se(^3P) \tag{11}$$

$$\tfrac{1}{2}P_2Se_5 \rightarrow \tfrac{1}{2}P_2Se_3 + Se(^1D) \tag{12}$$

Meyer[146] described a red form of triselenium tetraphosphide, m.p. 300°, which he obtained by distilling a melt of the correct composition. This form, which can also be purified by vacuum sublimation[145] is sparingly soluble in carbon disulphide. On this basis, it was suggested that the product made by heating selenium with yellow phosphorus in tetralin at 215–220°C. was a different modification.[96–7] A simple method for the preparation of this form in high purity and yield is the carbon-catalyzed reaction of yellow phosphorus with grey selenium in heptane, the product being recrystallized from tetralin.[147] 'Soluble' triselenium tetraphosphide forms fine yellow-orange crystals, m.p. 245–6°C.,[147] crystallizing in the orthorhombic system with space group *Pmnb*, $a = 9{\cdot}739$, $b = 11{\cdot}797$, $c = 26{\cdot}270$ A. The structure of the molecule is analogous to that of tetraphosphorus trisulphide (q.v.).[114] It has a density of 3·16,[96] 3·17[114] g./c.c. The infra-red and Raman spectra show strong absorptions at 360(363) and 317 $cm.^{-1}$, assigned to the symmetrical stretching frequencies of the apical P–Se and basal P–Se bonds respectively. The $^{31}P$ nuclear magnetic resonance spectrum is in accord with the structure deduced by *X*-ray methods, since it shows a doublet at +106 p.p.m. and a quartet at −38 p.p.m. (85% $H_3PO_4$).[147] The entropy of triselenium tetraphosphide at 298·15°K. is 57·26 g.-cal.deg.$^{-1}$mole$^{-1}$. It shows signs of an anomalous increase in heat capacity just above 350°K., suggesting a transformation to the plastic crystalline state similar to that occurring in tetraphosphorus trisulphide.[148] Triselenium tetraphosphide evolves phosphine and hydrogen selenide in a moist atmosphere, while with alkali it evolves phosphine, yielding a solution containing polyselenides and hypophosphite, which slowly deposits amorphous selenium.[96, 146] It burns in air,[146] and is readily oxidized by concentrated nitric acid.[96] By its reaction with liquid ammonia at −33° there results the compound $(NH_4)_2[P_4Se_3(NH_2)_2]$ which decomposes on warming. The final product is $P_4Se_3$, and no P=NH compounds can be detected as are formed in the analogous case of tetraphosphorus trisulphide[145]

$$P_4Se_3 + NH_3 \longrightarrow (NH_4)_2[P_4Se_3(NH_2)_2] \xrightarrow[-NH_3]{20^\circ} (NH_4)_2[P_4Se_3NH]$$

$$\xrightarrow[-NH_3]{90^\circ} NH_4[P_4Se_3NH_2] \xrightarrow{200^\circ} P_4Se_3 + 2NH_3$$

Patents on the use of triselenium tetraphosphide as an additive to petrol in anti-knock compositions have been granted.[98–9]

When powdered iodine is added to a solution of triselenium tetraphosphide in dry $CS_2$, a red compound $P_4Se_3I_2$ is formed. This reacts almost explosively with nitric acid and melts at 154–155°C.[111]

Substances believed to be $P_4S_2Se$ and $P_4SSe_2$[146] were prepared from the elements but m.p. measurements indicate that these are simply mixtures of $P_4Se_3$ and $P_4S_3$.[96]

Triselenium diphosphide and the compound with arsenic selenide, $As_2Se_3,P_2Se_3$, have been obtained in a vitreous state. Variations of conductivity with temperature for these glasses follow an exponential law which is usually found in crystalline semiconductors.[100]

A ternary compound, SePCu, can be obtained by direct combination of elements. Heating is carried out in a sealed tube for 2 to 3 days at 800°C. and then for 3–4 hr. at 1200°C.[101] The compound is cubic with $a=10{\cdot}15$ A. and $\rho=6{\cdot}40$ g./c.c. It is fairly inert towards acids; aqua regia attacks it slowly in the cold, concentrated nitric acid attacks it on prolonged boiling, and it is attacked by concentrated sulphuric acid. Decomposition takes place if it is heated under vacuum.[101]

Phase rule studies have shown that selenium and phosphorus form solid solutions.[102] The dotted curve *b* in Fig. 5 is due to Meyer[103] and as with curve *a* is thought not to have reached equilibrium.[102]

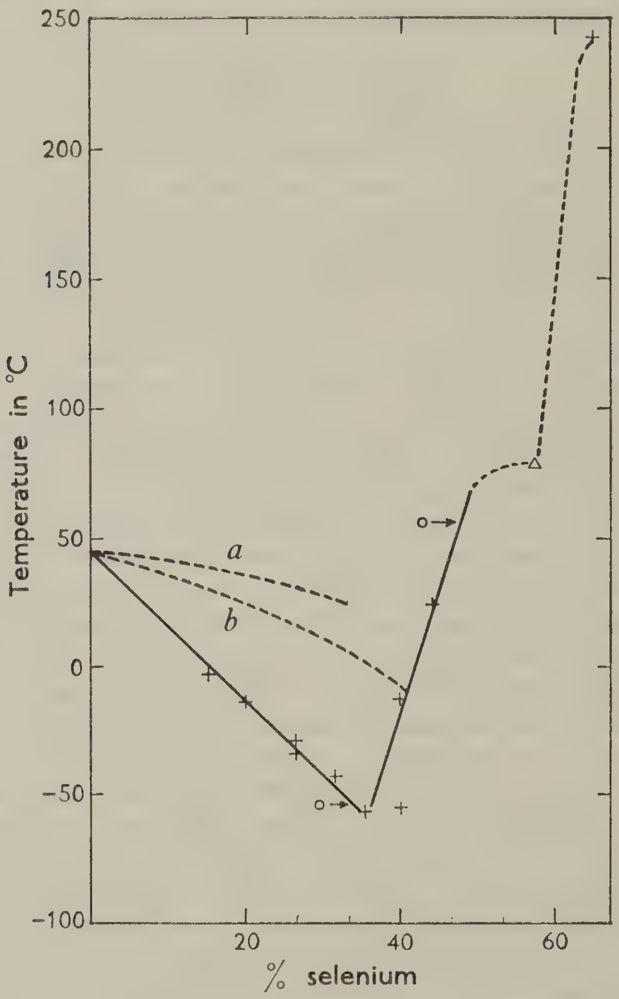

FIG. 5.—Phosphorus–selenium phase system

## Tellurium

White phosphorus and tellurium form tritellurium diphosphide $Te_3P_2$ when heated together for 1 hr. in a sealed tube at 320°C. Red phosphorus cannot be used instead of the white variety, though if red phosphorus is heated with tellurium dioxide in an open crucible at 200°C. tellurium and phosphorus pentoxide are formed which then react to give the phosphide if heated in a sealed tube at 300°C.[104] It is a black brittle compound which has a *d* 4·13 g./c.c. Chemically it is quite reactive. It is insoluble in organic solvents and water although it slowly forms phosphine in moist air. Solutions containing permanganate, dichromate, persulphate, ferric ions, mercuric ions, alkaline silver salt solutions and Fehling's solution are all reduced. Reaction of sulphur with tritellurium diphosphide produces phosphorus pentasulphide whilst tellurium dioxide is slowly formed by reaction with bromine water. If it is heated in air the phosphorus forms phosphorus pentoxide and eventually tellurium is left as a residue. Even in a sealed tube decomposition precedes melting.[104] Tritellurium diphosphide reacts with iodine in carbon disulphide solution to form tritellurium di-iodide diphosphide, $Te_3I_2P_2$. This compound is also formed when white phosphorus in carbon disulphide is allowed to react with tellurium di-iodide. The compound, which is black in colour, sublimes at 120°C. with loss of iodine; it is insoluble in water, slightly soluble in chloroform and carbon disulphide, reacts with hot 30% aqueous potassium hydroxide to form potassium telluride, is oxidized by concentrated nitric acid and decolorizes cold potassium permanganate.[104]

Tritellurium tetraphosphide has been mentioned in patents as a possible additive for lubricant and anti-knock compositions.[99, 98]

## SECTION IX

# THE LOWER PHOSPHORUS OXIDES

BY J. E. SUCH

Only two phosphorus oxides, $P_4O_{10}$ and $P_4O_6$, have been studied extensively; some of the properties of a third, $(PO_2)_n$, have been described, but the existence of two lower oxides, $P_4O$ and $P_2O$, and one higher oxide, $P_2O_6$, is less certain.

The diatomic molecule, PO, has been observed spectrographically in the vapour state, but is unstable under ordinary conditions.[1–7, 49] Its excitation energy is 143 kcal./mole and when it dissociates, a normal oxygen and an excited phosphorus atom are produced. The dissociation energy has been reported as 6·2 e.v., a value said to be in harmony with those observed for other isoelectronic diatomic oxides, such as SO, AlO, SiO and MgO.[8] More recently a value of 6·8[50] and 5·30[51] e.v. have been reported.[50] The P–O bond length in the PO molecule is 1·447 A., and the free energy function, $-(G_T^\circ - H_0^\circ)/T$, expressed as the sum of the electronic, rotation, vibration and translation contributions, has been calculated to be[9]:

| °K. | 298 | 1000 | 1500 | 2000 | 2500 | 3000 |
|---|---|---|---|---|---|---|
| Total free energy function in entropy units | 45·23 | 55·03 | 58·51 | 61·04 | 62·98 | 64·53 |

## PHOSPHORUS TRIOXIDE, $P_4O_6$

Phosphorus trioxide, tetraphosphorus hexoxide, phosphorous oxide or phosphorous anhydride is formed when phosphorus is burnt in air or oxygen under suitable conditions. The method originally described[10] has been modified and improved[11–3] so that yields of 50–60%, based on the phosphorus burnt, have been claimed by oxidizing pure phosphorus at 46–50°C. in an atmosphere containing 75% of oxygen and 25% of nitrogen at a pressure of 90 mm. Hg and a gas flow-rate of 30 l./hr. in a 17 mm. diameter quartz tube. Phosphorus trioxide prepared in this way always contains some dissolved elementary phosphorus and can be purified by ultraviolet irradiation to convert the yellow phosphorus to the red form,[14] from which the trioxide can be separated by distillation.

Attempts to prepare phosphorus trioxide by methods other than burning phosphorus have been reported. For example, it has been claimed that phosphorus trichloride reacts with phosphorous acid to form the trioxide,[15] but this was not confirmed by later work[16–7, 20] in which the formation of an orange syrup was reported; however, 0·5% yields of the trioxide could be obtained by pyrolysis of this product.[52] Neither was any trioxide produced when the trihalide was allowed to react with acetic acid, trichloracetic acid or sodium formate.[17] The trioxide has also been reported as arising from the interaction of trimethylammonium sulphite and phosphorus trichloride in liquid sulphur dioxide,[18] and in the metathesis of phosphorus trihalides with organic metal oxides.[19] Later workers[52] have confirmed the first of these two preparations, but emphasize the difficulty of separating pure trioxide by this route.

The oxidation of yellow phosphorus by nitrous oxide at 70 mm. Hg and 550–625°C. gives good yields (30–50% on $P_4$, 70–90% on $N_2O$) of phosphorus trioxide. The product can be purified by fractional distillation under nitrogen at 30°C. and 1–3 mm. Hg.[52–3]

## Structure

### VAPOUR STATE

Evidence from vapour density[21] and electron diffraction measurements,[14, 22] indicates that the vapour of phosphorus trioxide contains $P_4O_6$ molecules, in which the phosphorus atoms are situated at the apices of a regular tetrahedron, and each of the six oxygen atoms lies on an edge equi-distant from two phosphorus atoms.

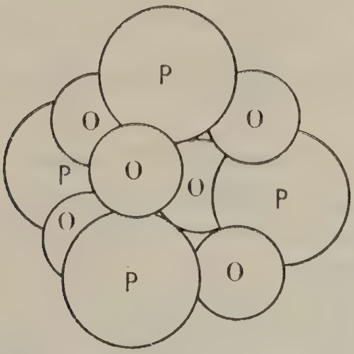

FIG. 1.—The structure of $P_4O_6$

### SOLID STATE

The Raman spectrum of solid phosphorus trioxide shows two shifts, which correspond to the strongest lines in the Raman spectrum of the liquid form, and it is therefore suggested that both contain $P_4O_6$ as a molecular species.[23–4]

### LIQUID STATE

Measurements of the freezing point depression in molten naphthalene at 80°C. show the molecular formula to be $P_4O_6$,[25] and this conclusion is supported by the Raman spectroscopic data,[23–4] which do not, however, provide sufficient evidence for a complete vibrational analysis. The $^{31}P$ nuclear magnetic resonance spectrum of the liquid exhibits, as expected, a single very narrow and intense line (chemical shift $-112{\cdot}5 \pm 0{\cdot}1$ p.p.m. from 85% $H_3PO_4$), and for this reason phosphorus trioxide has been suggested as a reference standard in $^{31}P$ nuclear magnetic resonance.[54]

## Properties

### PHYSICAL PROPERTIES

Phosphorus trioxide forms soft, colourless, monoclinic crystals which melt at 23·8°C.[26–7] and boil without change at 175·4°C. at 1 atm.[27] It is soluble in carbon disulphide,[26] from which it can be recrystallized and dissolves also in benzene, naphthalene, carbon tetrachloride, chloroform, methylene dichloride, diethyl ether, dimethyl sulphide, dioxan and tetramethyl silane.[10, 25, 38] White phosphorus is soluble in it to the extent of 1·7 g./100 g. of trioxide at 25°C.[26] The density of the solid, $d_4^{21}$, is 2·135 and of the super-cooled liquid 1·943 g./c.c.[28]

The vapour pressure of phosphorus trioxide,[27, 29] between its melting and boiling points, is given in Table I, and can be calculated for other temperatures from the equation:

$$\log_{10} p_{\text{mm.}} = 11{\cdot}0510 - 0{\cdot}0040T - 2860T^{-1}$$

in which $T$ is the absolute temperature in °K.

Refs. p. 385

*Table I.—Vapour Pressure of Phosphorus Trioxide*

| °C. | $p_{\text{mm. Hg}}$ | °C. | $p_{\text{mm. Hg}}$ |
|---|---|---|---|
| 23·8 m.p. | 1·71 | 110 | 113 |
| 25 | 1·85 | 120 | 160 |
| 50 | 8·10 | 130 | 221 |
| 60 | 13·6 | 140 | 299 |
| 70 | 22·1 | 150 | 398 |
| 80 | 34·7 | 160 | 520 |
| 90 | 52·9 | 170 | 668 |
| 100 | 78·4 | 175·4 b.p. | 760 |

The equation for the heat of vaporization[29] derived from the vapour pressure relationship is:

$$\Delta H_0 = 13{,}082 - 0{\cdot}0183T^2 \text{ g.-cal./mole } P_4O_6$$

from which the calculated heat of vaporization at the b.p. and 1 atm. is 9·4 kcal./mole $P_4O_6$, and the entropy of vaporization $P_4O_6(\text{liq.}) \rightleftharpoons P_4O_6(\text{g.})$ is $\Delta S^\circ_{448{\cdot}56} = 21{\cdot}0$ g.-cal./mole/deg. A somewhat higher value, 13·4 ± 1·0 kcal./mole $P_4O_6$, was found for the heat of vaporization at 1 atm. and the boiling point by differential thermal analysis.[46] This technique also indicated a heat of fusion of 3·0 kcal./mole $P_4O_6$, in agreement with 2·9 kcal./mole $P_4O_6$ observed by direct calorimetry.[46] These data imply a heat of sublimation of 16–17 kcal./mole $P_4O_6$ at 25°C.[47]

Heats of formation $\Delta H^\circ_f$ $P_4O_6$(c.) of $-540$ kcal./mole from white phosphorus and of $-524 \pm 8$ kcal./mole from red phosphorus were obtained by an indirect route from measurements of the heat of combustion of red phosphorus in nitric oxide, but identification of the products of combustion was not necessarily definitive.[30] More direct determinations of the heat of combustion of a well-defined sample of phosphorus trioxide give an enthalpy of formation $\Delta H^\circ_f$ $P_4O_6$(c.) of $-392$ kcal./mole.[48] In the latter experiments it was established by *X*-ray analysis, that the combustion product was substantially the hexagonal form of phosphoric oxide. Small amounts of water-insoluble residue, possibly red phosphorus, and of a compound containing trivalent phosphorus, which were also present, were thought to have arisen from the pyrolysis reaction[10]:

$$4P_4O_6 \rightarrow 3P_4O_8 + 4P_{\text{red}}$$

The thermodynamic functions $C^\circ_p$, $-(G_0 - H^\circ_0)/T$, $H_0 - H^\circ_0$, $S^\circ$ and $S_{\text{vib.}}$ for $P_4O_6$ gas at 1 atm. pressure in Table II have been calculated on the basis of the most likely available frequency assignments[45] which are also given in the same table.

The surface tension of liquid phosphorus trioxide has been given as 36·6 dynes/cm.[2] at 34·3°C. and 27·8 dynes/cm.[2] at 109·4°C., the dielectric constant 3·2 at 22°C., and the specific conductivity $1{\cdot}2 \times 10^{-7}$ at 25°C.[31]

## CHEMICAL PROPERTIES

Phosphorus trioxide is thermally stable only up to about 200°C., above which temperature the following reaction takes place[10]:

$$nP_4O_6 \rightarrow 3(PO_2)_n + nP_{\text{red}}$$

In air phosphorus trioxide ignites and burns; much study has been devoted to the mechanism of the oxidation process, especially at room temperature. Unfortunately, most of the early work appears to have been conducted with preparations contaminated with elemental phosphorus and the observations are confusing. However, Miller[26] has shown that when phosphorus trioxide is very carefully purified by recrystallization at low temperature from carbon disulphide, followed by exposure to light and volatilization, it neither glows, oxidizes in moist or dry oxygen, nor reddens when exposed to sunlight at ordinary temperatures. By addition of pure elemental white phosphorus to the pure oxide, properties previously regarded as characteristic of the trioxide, such as white opaque appearance, glowing in air and ignition on cloth, are restored. However, phosphorus trioxide apparently exerts an inhibitory effect on the glow of phosphorus itself, for it has been shown[32] that the vapour of the oxide containing phosphorus luminesces only in the presence of substances, such as ozone or moisture, sufficient in amount to destroy the trioxide completely. This inhibitory effect of phosphorus trioxide, on a molar basis, is three times as great as that of ethylene.

When dry, ozonized oxygen is passed over phosphorus-free trioxide at 25°C., the reaction products include phosphorus tetroxide and phosphoric oxide.[33] Oxygen as well as ozone participates in this reaction, which from the experimental evidence may be written:

$$8P_4O_6+4O_3+5O_2 = 5P_4O_8+3P_4O_{10}$$

When phosphorus trioxide saturated with white phosphorus is oxidized in oxygen at 25°C. in the presence of a little water vapour, about 5 moles of the trioxide per mole of phosphorus are oxidized.[33] From this and other information, it appears that phosphorus trioxide is formed as an intermediate product in the oxidation of phosphorus by dry oxygen. However, as the inhibitory action of the trioxide on the glow of phosphorus is not observed, it has also been concluded that any trioxide formed is immediately oxidized further by active oxygen (or ozone) formed in the reaction at the same time, with the result that the final low-temperature oxidation product is a mixture of the tetroxide and the pentoxide. A detailed reaction mechanism has been proposed for the oxidation of phosphorus via the trioxide to the pentoxide.[55]

If a finely-divided suspension of phosphorus in carbon tetrachloride solution is oxidized by the passage of dry air,[34] a voluminous precipitate forms which has the empirical composition $P_2O_3$; as it possesses none of the normal properties of the trioxide $P_4O_6$, for example does not melt but decomposes when heated to above 100°C. *in vacuo*, it has been suggested[35] that this reported modification might be a sheet polymer, similar to the orthorhombic forms of phosphoric oxide (q.v.). Polymeric forms of the trioxide are also possibly formed in the reaction between phosphorus and sulphur trioxide in carbon disulphide solution.[36]

With cold water phosphorus trioxide behaves as the anhydride of phosphorous acid, and when shaken rapidly with excess of water forms this acid exclusively.[37–8] Without shaking, two liquid layers are formed, which are said to react to give phosphoric acid, possibly other lower oxides and perhaps phosphine. In hot water the reaction is violent and disproportionation occurs giving rise to hydrogen phosphides, sub-oxides of phosphorus, phosphoric acid and a red product of unknown nature.

Careful addition of water to phosphorous oxide in the proportions $3H_2O:P_2O_3$ to $2H_2O:P_2O_3$ yields a mixture of phosphorous and pyrophosphorous acids. The addition of less than two moles of water per mole of phosphorous trioxide, or the careful reaction of the oxide with phosphorous or pyrophosphorous acids, gives viscous liquid mixtures. The nuclear magnetic resonance spectra of these give evidence for the presence of unstable polyphosphorous acids, $H_2(P_nH_nO_{2n+1})$. They decompose by auto-oxidation–reduction reactions, giving orthophosphoric acid and a yellow solid containing P(III).

The reaction of liquid phosphorus trioxide with dimethylformamide, dimethyl sulphoxide, dimethyl sulphite, methanol or arsenic fluoride is very violent and often accompanied by charring. However, the reaction of the oxide at room temperature with trimethyl phosphite, phosphorous tris-dimethylamide, acetic anhydride, or at elevated temperatures with phosphorus trichloride or methyltrichlorosilane can be smooth and rapid. No unique products can be isolated from these reactions which probably involve exchange, simultaneous oxidation and reduction, and in some cases rearrangements of the Michaelis–Arbuzov type (see Section XXXII).

The yellow or white solids which often result from the reactions of phosphorus trioxide are claimed to be complex network polymers containing varying proportions of P–P and P–O–P linkages, and end-stopped with terminal groups depending on the original reactants.[38]

Phosphorus trioxide is insoluble in liquid sulphur dioxide below $-60$°C., but dissolves readily at higher temperatures. The solution reacts with tetramethylammonium sulphite, $[(CH_3)_4N]_2SO_3$, to form a pale yellow compound thought to be either $[(CH_3)_4N]PO_2,SO_2$ or $[(CH_3)_4N]PO,SO_3$, which dissolves in water with the separation of sulphur.[18]

Phosphorus trioxide has been shown to act as a donor compound. So far only a few cases are clearly established, but many more are obviously possible. Thus the trioxide reacts with excess nickel tetracarbonyl displacing carbon monoxide[56]:

$$P_4O_6 + xNi(CO)_4 \rightarrow P_4O_6.(Ni(CO)_3)_x + xCO \qquad (x = 1\text{–}4)$$

$P_4O_6(Ni(CO)_3)_4$ has been isolated as a crystalline solid.[57] When the phosphorus trioxide is in excess the species $(P_4O_6)_2Ni(CO)_2$ and $(P_4O_6)_3NiCO$ can be detected, while if the reagents are present in roughly equivalent amounts polymeric structures are formed in which nickel atoms and $P_4O_6$ molecules are connected together in a three dimensional network. The nuclear magnetic resonance spectra of these adducts accord with the above formulations. Iron carbonyls appear to undergo similar reactions.[56]

Similarly $P_4O_6$ reacts with diborane giving adducts of the formulæ $P_4O_6,nBH_3$ ($n = 1$–3).[58] $P_4O_6,2BH_3$ is a white, crystalline, very hygroscopic solid, which inflames on treatment with small quantities of water. The nuclear magnetic resonance spectrum is in accord with a structure $BH_3,P_4O_6,BH_3$, formed by symmetrical cleavage of $B_2H_6$.[59] $P_4O_6,3BH_3$, isolated as well-formed crystals from chloroform, rapidly decomposes at room temperature to an equilibrium mixture of 64% $P_4O_6,2BH_3$ and 36% $P_4O_6,3BH_3$. The borane adducts react with nickel tetracarbonyl, first by substitution on the unco-ordinated phosphorus atoms, and then by displacement of $BH_3$ groups, to yield $P_4O_6[Ni(CO)_3]_4$ as the final product.[58]

Phosphorus trioxide also reacts with boron trifluoride etherate to give ether, phosphorus trifluoride and diphosphorus oxytetrafluoride, $PF_2OPF_2$ (see Section XIII). There are also indications of complexes of unknown structure with other Group III halides.[58]

## PHOSPHORUS P(III/V) OXIDES

Phosphorus trioxide dissociates on heating in a sealed tube at 200–400°C., forming a red involatile residue and a sublimate of large colourless, transparent, very hygroscopic, cubic crystals. Various workers[39] had shown that these had an empirical formula close to $PO_2$, and a measurement of vapour density[40] gave values of molecular weight ranging from 293 to 721, i.e. $n = 5$–12 in the empirical formula $(PO_2)_n$. The structure of this so-called 'diphosphorus tetroxide' has now been clarified by a study of its hydrolysis products,[60] and by *X*-ray crystal structure determinations.[61–2] It has been shown to contain at least two mixed P(III/V) oxides of different composition and crystal structures and unique *X*-ray patterns. These are a rhombohedral $\alpha$ form with the variable composition $P_4O_{8\cdot1}$–$P_4O_{9\cdot2}$, and a monoclinic $\beta$ form ($P_4O_{8\cdot0}$–$P_4O_{7\cdot7}$).[60]

$\alpha$ P(III/V) oxide forms a series of mixed crystals of the two molecules $P_4O_9$ and $P_4O_8$. The space group is $R\bar{3}c$ with unit-cell dimensions $a = 10{\cdot}05$ A. and $\alpha = 57{\cdot}0°$. The four P atoms of the molecule are located at the corners of a trigonal pyramid and linked by six oxygen atoms at the edges. The remaining two or three O atoms are terminal (apical) oxygen atoms with respect to P.[61] The density falls regularly from a maximum of 2·658 g./c.c. at $P_4O_9$ to 2·518 g./c.c. at $P_4O_{8\cdot1}$ but the lattice constants do not vary in the same regular manner. The hydrolysis products are those which would be expected from the formula, i.e. predominantly salts of phosphorous, trimeta- and triphosphoric acids from $P_4O_9$ compositions, and pyrophosphorous ($P^3$–O–$P^3$) and diphosphoric ($P^5$–O–$P^5$) acids from $P_4O_8$ compositions.

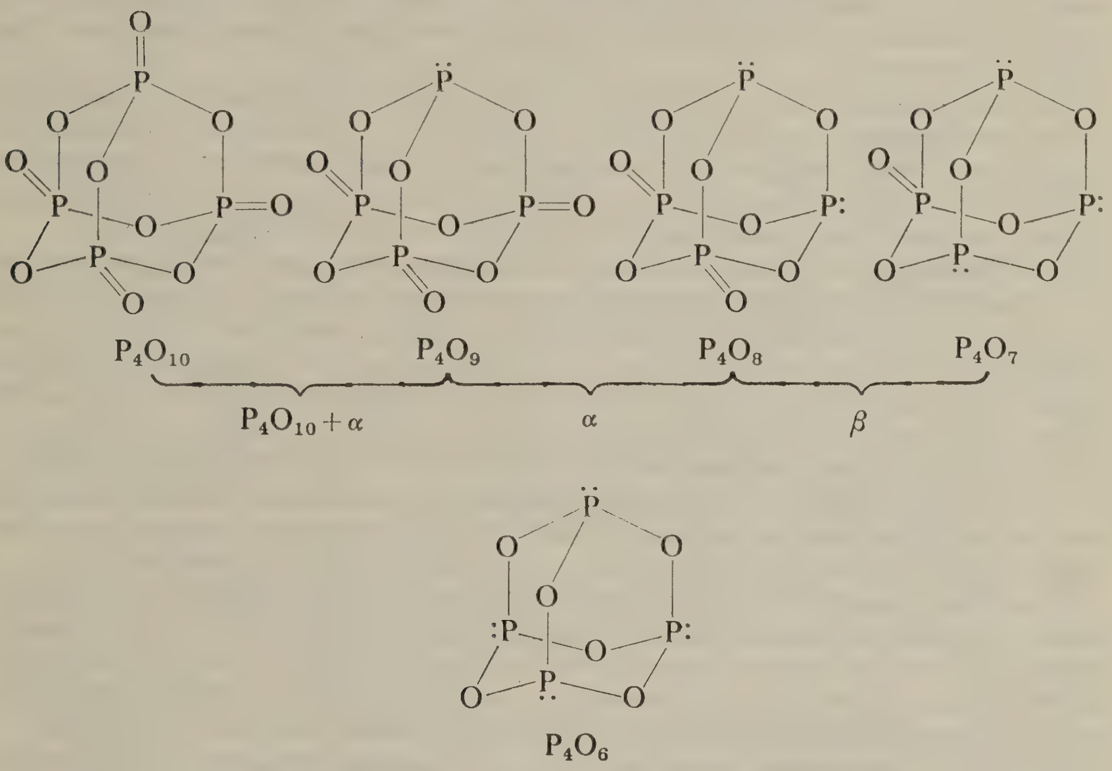

FIG. 2.—Relation of the phosphorus oxides

Similarly, $\beta$ P(III/V) oxides are mixed crystals of the two molecules $P_4O_8$ and $P_4O_7$. The composition range is narrower ($P_4O_{8\cdot0}$–$P_4O_{7\cdot7}$), products of lower oxygen content being thermally unstable. The $\beta$-oxide lattice is monoclinic with $a = 9{\cdot}66$, $b = 10{\cdot}10$, $c = 6{\cdot}93$ A. and $\beta = 96{\cdot}8°$. The $P_4O_7$ molecule has a structure similar to that of $P_4O_8$, but with one less apical oxygen atom.[62] The $\beta$-oxide on hydrolysis yields pyrophosphite, ortho- and diphosphate but no trimetaphosphate.

To summarize therefore, these P(III/V) oxides appear to be composed of varying proportions of $P_4O_7$, $P_4O_8$ and $P_4O_9$ molecules, which can, like $P_4O_{10}$, be supposed to result from the successive insertion of oxygen atoms at the four apical phosphorus positions[22] of the $P_4O_6$ molecule (Fig. 2).

None of these intermediate molecular species has yet been isolated in a pure state and free from the others. $P_4O_7$ and $P_4O_8$ molecules together form the β-oxide, $P_4O_8$ and $P_4O_9$ molecules the α-oxide. $P_4O_{10}$ and $P_4O_9$ do not form mixed crystals, and compositions in this range show the joint diffraction patterns of $P_4O_{10}$ and α P(III/V) oxide. Besides arising from the pyrolysis of phosphorus trioxide, the P(III/V) oxides are also formed by the reaction of phosphorus pentoxide with red phosphorus. Products in the α-oxide region are made at high temperatures, or using small proportions of phosphorus. The β-oxide results from the further reduction of α-oxide with phosphorus, the products being separated by fractional sublimation.[60]

## OTHER LOWER OXIDES OF PHOSPHORUS

Two oxides have been reported with the empirical formulæ $P_4O$ and $P_2O$,[41] but the evidence available is insufficient to show that they are not mixtures of phosphorus, solid phosphorus hydrides and oxyacids of phosphorus. However, it has been pointed out[35] that early workers had assigned formulations such as $P_4HO$, $P_4H_2O$, $P_5H_3O$ and $P_5H_3O_2$ to these and similar materials. A sample of $P_4O$ studied by *X*-ray diffraction showed a greater ordering of phosphorus atoms than red phosphorus, but a similar structure.[63]

The large number of red to yellow products reported in the literature (see reference 35 for bibliography), some of which, in addition to a substantial proportion of phosphorus, contain oxygen and hydrogen, are probably mixtures of a number of bodies with complex structures containing P–P, P–H, P–O and P–OH bonds. Most of them are insoluble in water, alcohol and ether, but can be burned in air.

It has been reported[42] that an orange-yellow substance is formed when phosphorus is oxidized with air in an atmosphere of water; it has an average composition phosphorus 89·0%, oxygen 10%, and hydrogen 0·8%, which corresponds to an empirical formula of $P_4OH$. Its insolubility in all common solvents and chemical behaviour suggest that it consists of a polymeric network of phosphorus atoms to which–OH groups are attached, i.e. $(P_4OH)_n$. On heating this substance in an inert atmosphere to 250–300°C., a little phosphine and products similar to red phosphorus are formed; in a normal atmosphere, the compound oxidizes to a mixture of phosphoric, phosphorous and hypophosphorous acids. Phosphine and hydrogen are evolved when the yellow substance is treated with cold normal sodium hydroxide solution.

It has been suggested[42] that the body described above, Schenck's scarlet phosphorus, so-called solid phosphine and other similar yellow materials are all the same compound. The available evidence favours attachment of OH groups to the phosphorus atoms, rather than the presence of separate P–O and P–H bonds; it is possible to neutralize the compound and obtain the sodium derivative, $(P_4ONa)_n$.

A polymeric phosphorus monoxide, $(PO)_n$, of unknown structure, has also been described. It can be prepared by two methods; in the first[43] by the electrolysis of anhydrous phosphorus oxychloride at 0°C. in the presence of triethylamine hydrochloride to increase the conductivity. Chlorine is evolved at the anode and a solid brown substance, with the empirical formula $(PO)_n$, separates at the cathode according to the equations:

$$POCl_3 \rightleftharpoons POCl_2^+ + Cl^-$$
$$3nPOCl_2^+ \rightleftharpoons (PO)_n + 2nPOCl_3$$

The polymeric monoxide is insoluble but stable in water, and generates phosphine in alkaline solutions. Its structure and molecular weight are not known. In the second method[44] it is formed in the reaction between anhydrous phosphorus oxybromide, $POBr_3$, and magnesium in absolute ether at the boiling point:

$$2nPOBr_3 + 3n\,Mg = 2(PO)_n + 3nMgBr_2$$

The product, although similar in composition, differs slightly in properties from that obtained by the previous method of preparation, being completely amorphous by *X*-ray examination and decomposing in moist air.

## SECTION X

# PHOSPHORIC OXIDE AND HIGHER PHOSPHORUS OXIDES

BY J. E. SUCH

## PHOSPHORIC OXIDE

### Preparation

Phosphoric oxide, also known as phosphorus pentoxide, phosphoric anhydride or phosphoric acid anhydride, is obtained when phosphorus is burnt in excess of dry air or oxygen.

The formation of phosphoric oxide by reactions other than the oxidation of phosphorus has been reported but the products are probably not entirely anhydrous phosphoric oxide. For example, the action of dinitrogen trioxide, $N_2O_3$, on phosphorous acid, $H_3PO_3$ or phosphorus trichloride; the reaction between phosphorus oxychloride, $POCl_3$, and potassium chlorate, $KClO_3$; reactions occurring during the distillation of pyrophosphoryl chloride, and by heating bone-ash with charcoal in a current of chlorine[1]; also by the displacement of phosphoric oxide from anhydrous tripotassium orthophosphate, $K_3PO_4$, tetrapotassium pyrophosphate, $K_4P_2O_7$, or potassium metaphosphate (Kurrol salt) when these salts are heated with an excess of sulphur trioxide.[2] It has also been claimed that phosphoric oxide is liberated at the anode during the electrolysis of fused sodium phosphate.[3]

On the commercial scale, phosphorus is burnt in a specially designed burner in a current of air which has been dried by refrigeration or other methods. The phosphoric oxide vapour so formed passes into a cooling chamber where it condenses to the familiar white powder. When produced under proper combustion conditions, such commercial phosphoric oxide contains only traces of the lower oxides but, according to the conditions of storage, small proportions of condensed phosphoric acids may also be present, owing to absorption of moisture. Further purification may be carried out by sublimation at atmospheric pressure[1, 4] or *in vacuo*.[5] Alternatively the vapour may be condensed in a bed of fluidized phosphoric oxide, yielding a free-flowing dustless product in the form of small spheres or beads.[126]

The oxidation of phosphorus to phosphoric oxide is believed to proceed by a chain mechanism,[6] described more fully in Section V (page 241).

### Polymorphic Modifications

Several polymorphic modifications of phosphoric oxide are known, their presence and proportions in any sample depending on its thermal history. Whilst such polymorphs had been postulated to explain apparent inconsistencies in vapour pressure and other data, the nature of the modifications was not known until the system had been studied by optical and *X*-ray methods.[4, 16, 25] Correlated with published vapour pressure measurements,[7–13] this study indicated a one-component system with three triple-points and at least two liquids.

The known solid crystalline modifications of phosphoric oxide are:

#### 1. HEXAGONAL (H), VOLATILE LOW-TEMPERATURE OR METASTABLE FORM

Commercial phosphoric oxide consists mainly of this variety in the form of a soft fine white powder and it is always produced when the vapour of phosphoric oxide condenses on a cool surface. A powdery amorphous modification designated as the $\beta$-form is said to be present occasionally in commercial phosphoric oxide,[14] but has not been described elsewhere.

The rhombohedral crystals normally encountered belong to the hexagonal system and usually occur as small hexagonal plates.[4] Larger crystals, obtained by vacuum sublimation, are uniaxial positive and give, on optical resolution, the following refractive indices in sodium light:

$$n_\omega = 1{\cdot}469 \pm 0{\cdot}002$$
$$n_\varepsilon = 1{\cdot}471 \pm 0{\cdot}002$$

### 2. ORTHORHOMBIC (O) FORM

This second, metastable modification, consisting of aggregates of small orthorhombic crystals is obtained when the (H) form is heated for about 2 hr. at 400°C. in a closed system.[4] It is claimed that polymerization of the (H) form can also be conveniently carried out at atmospheric pressure, without excessive loss of vapour, by heating a mixture of one part of the (H) form with four parts of the (O) or (O′) form for a short time at 400°C.[15] Large crystals obtained by slow deposition from the vapour phase are bi-refringent, bi-axial negative, with refractive indices in sodium light as follow:

$$n_\alpha = 1{\cdot}545 \pm 0{\cdot}002$$
$$n_\beta = 1{\cdot}578 \pm 0{\cdot}002$$
$$n_\gamma = 1{\cdot}589 \pm 0{\cdot}002$$

### 3. ORTHORHOMBIC (O′) FORM

The (O′) form is thermodynamically stable and can be obtained as horny aggregates of relatively large and twinned crystals by heating the (H) form for about 24 hr. at 450°C., again in a closed system.[4] The indices of refraction in sodium light are reported as:

$$n_\omega = 1{\cdot}599$$
$$n_\varepsilon = 1{\cdot}624$$

and the crystals were first thought to belong to the tetragonal system.[4] Further examination, however, has shown them to be orthorhombic.[16]

### 4. HIGH-PRESSURE CRYSTALLINE FORM

The hexagonal crystalline variety of phosphoric oxide can be transformed under high pressure into a new modification which reverts to the original form when the pressure is relieved.[17] The transformation exhibits marked hysteresis, the extent of which diminishes as the temperature increases and it is believed that the transition should be truly reversible at about 500°C., whilst the new modification should persist as a metastable form at 1 atm. and *ca.* −80°C.

The pressure required for half conversion to the new form in the forward, $P_f$, and the reverse, $P_r$, directions, and the volume change $\Delta_r$ for 13·0 g. of phosphoric anhydride, (H) form, are given in Table I.

The density of the high pressure form has been calculated to be 2·53 g. cm.$^{-3}$, but the crystal structure is not known.

### Liquid Forms

Three liquid forms of phosphoric oxide have been described:

(1) The metastable (H) form melts on rapid heating (m.p. 420°C., triple-point pressure 3600 mm. Hg) to a metastable mobile liquid with high vapour pressure, which quickly polymerizes to a glass containing crystals of the (O) form, with an accompanying fall in pressure.

(2) At about 562°C. and a triple point pressure of 437 mm. Hg, the metastable (O) form slowly melts to a viscous liquid; at a slightly higher temperature, 571°C., the fusion is more rapid and it has been suggested that the two liquid phases may be structurally different.[4]

(3) The stable (O′) form melts extremely slowly (m.p. 580 ± 5°C., triple-point pressure 555 mm. Hg); superheating of the crystals readily occurs and the liquid formed on melting is very viscous.[8–9, 121] This behaviour is said to be consistent with the reorganization of a polymeric structure during fusion.[18]

Besides the three solid modifications already mentioned, melts of phosphoric oxide have, on rapid cooling, a strong tendency to form glasses, which so far have received but little attention.

### Structure

#### 1. VAPOUR

The vapour of phosphoric oxide consists substantially of $P_4O_{10}$ molecules in the temperature range 700–1400°C. according to vapour density measurements.[19–20] That there is some association, at least below 1100°C., is shown by the fact that the observed vapour densities correspond to a molecular weight of 302, compared with the formula weight of 284.

The structure of the individual $P_4O_{10}$ molecule in the vapour state, consistent with electron diffraction measurements,[21, 122] is shown in Fig. 1.

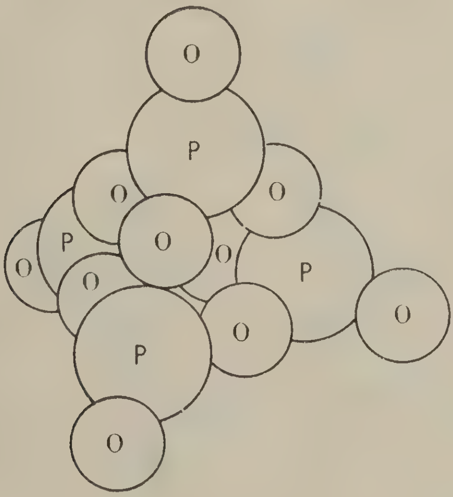

FIG. 1.—$P_4O_{10}$ molecule

The phosphorus atoms form a regular tetrahedron, and to each one is attached a closely bound oxygen atom, not otherwise connected. Each of the other six oxygen atoms is attached to two phosphorus atoms, resulting in a tetrahedral configuration of oxygen atoms around each phosphorus atom. (For bond lengths and angles see page 1160.)

## 2. SOLID FORMS

(i) The metastable solid (H) form of phosphoric oxide consists of $P_4O_{10}$ molecules with the same structure as in the vapour state, according to *X*-ray diffraction patterns,[22, 127] infra-red[128] and Raman spectra.[23–4] Since it is only the van der Waals' forces between the discrete $P_4O_{10}$ molecules of the soft crystalline (H) form which are broken during vaporization, this variety is readily volatile and also reacts violently with water.

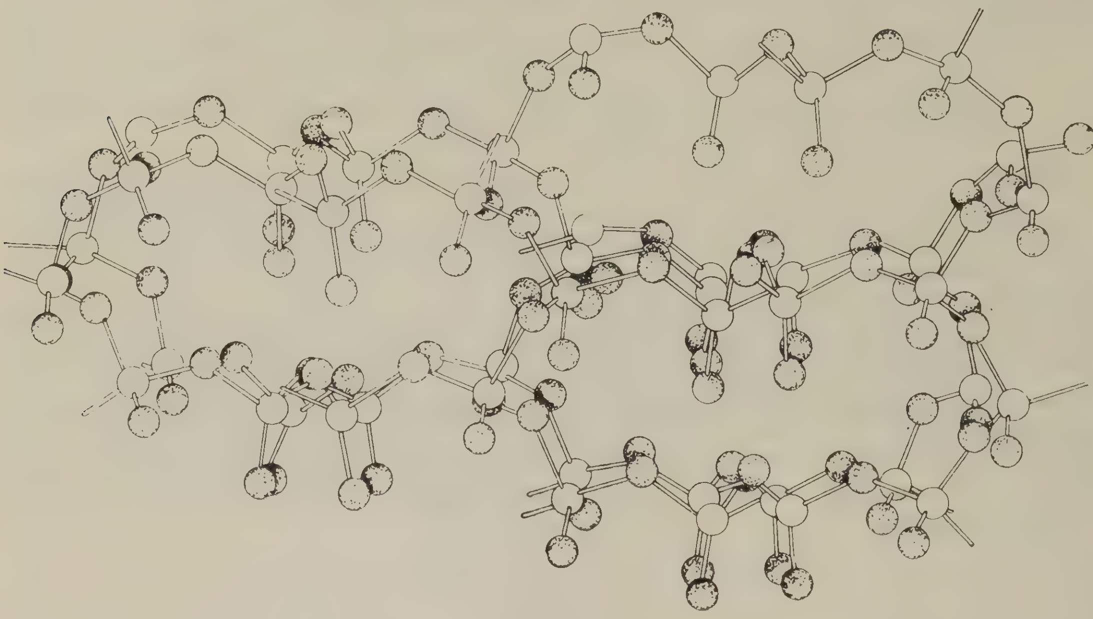

FIG. 2.—The (O) form of phosphoric oxide

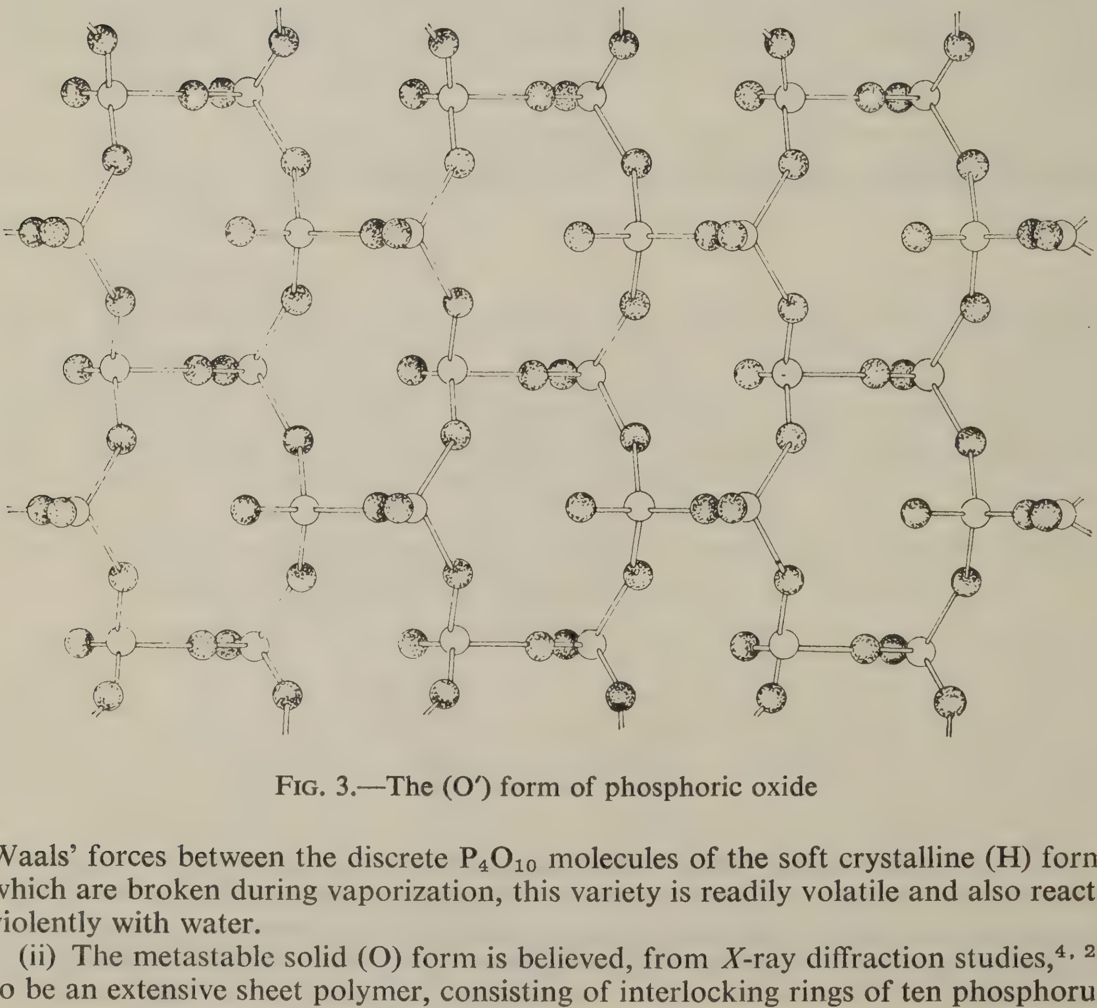

FIG. 3.—The (O′) form of phosphoric oxide

(ii) The metastable solid (O) form is believed, from *X*-ray diffraction studies,[4, 25] to be an extensive sheet polymer, consisting of interlocking rings of ten phosphorus and ten oxygen atoms; each phosphorus atom is surrounded tetrahedrally by four oxygen atoms, the atom spacings being near to those for $P_4O_{10}$ (see Fig. 2).

The crystals are hard and brittle and since covalent bonds are broken during vaporization or hydration, the solid is much less volatile and less readily attacked by water than the metastable (H) form.

(iii) The stable (O′) form is also thought to consist of an extensive corrugated sheet polymer,[16, 127] but in this modification the interlocking rings contain only four phosphorus and four oxygen atoms (see Fig. 3).

(iv) Phosphoric oxide glasses probably consist of a three-dimensional network of linked $PO_4$ tetrahedra; any discussion of their structure is usually based on the assumption that phosphoric oxide is the limiting case for phosphate glasses of the general composition $x\text{H}_2\text{O}.y\text{P}_2\text{O}_5$.[26]

(v) The structure of the liquid forms of phosphoric oxide has not been studied; it is likely that the limpid liquid obtained by heating the (H) form contains $P_4O_{10}$ molecules, which rapidly polymerize to layer or three-dimensional polymeric forms.

## Physical Properties

DENSITY (g. cm.$^{-3}$)

| | Observed | Calculated from unit cell dimensions | Calculated from refractive index |
|---|---|---|---|
| (H) form | 2·283–2·317[4] | 2·30[22] | |
| (O) form | | 2·72[25] | |
| (O′) form | 2·737–3·05[4] | | 2·89[4] |

VAPOUR PRESSURE

Vapour pressure data for the crystalline and liquid modifications of phosphoric oxide, set out in Table III and shown graphically in Fig. 4, were calculated from the

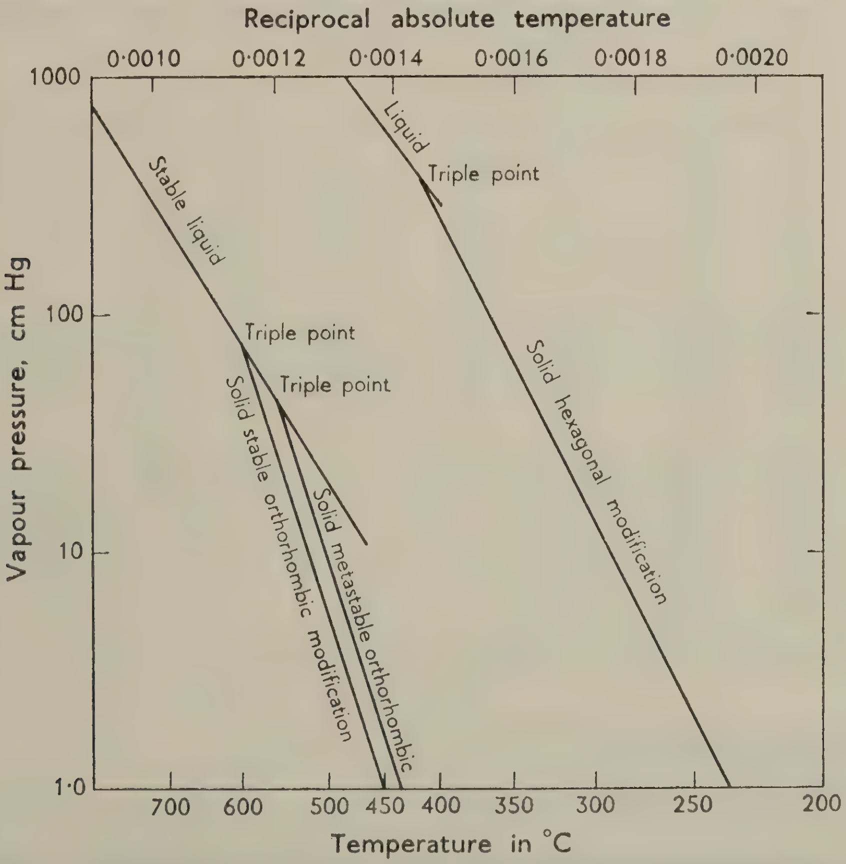

FIG. 4.—Vapour pressure of the three crystalline and two liquid forms of phosphoric oxide

equations given in Table II,[27] which in turn were derived from selected values of the triple points and heats of sublimation and vaporization of the various forms. The data were obtained from a critical survey of extensive earlier pressure–temperature relations.[4, 7, 9, 11–3]

*Table II.—Vapour Pressure Equations for Phosphoric Oxide*[27]
*($T$ = Absolute Temperature in °K.)*

| Modification | Vapour pressure equation ($p$ in cm. of mercury) | Temperature range °C. |
|---|---|---|
| Solid (H) form | $\log_{10} p = -4963/T + 9{\cdot}7163$ | 250–420 |
| Solid (O) form | ,, $= -7958/T + 11{\cdot}698$ | 440–562 |
| Solid (O′) form | ,, $= -7411{\cdot}5/T + 10{\cdot}4314$ | 480–580 |
| Liquid (H) form | ,, $= -3542/T + 7{\cdot}6663$ | 420–485 |
| Liquid (O′) form | ,, $= -4088/T + 6{\cdot}5359$ | 480–655 |

Nothing is known about the complexity of the species $(P_2O_5)_n$ which result from the depolymerizing of the crystalline modifications during conversion into the vapour, but it appears that the vapour rapidly adjusts itself to an equilibrium in which the predominant species is $P_4O_{10}$.[28]

### THERMODYNAMIC PROPERTIES

### Heats of Vaporization, Sublimation and Fusion

The heats of vaporization, sublimation and fusion of the three modifications of phosphoric oxide, calculated from the vapour pressure equations given in Table II, are contained in Table IV.

The values in parenthesis for the (O) form are based on the assumption that the vapour pressure equation for the liquid (O′) form in Table II applies equally to the liquid phases formed from both (O) and (O′) forms. In view of the uncertainty about the nature of the transformations occurring in these liquids, the data concerning them should be regarded as only tentative.

*Table IV.—Heats of Vaporization, Sublimation and Fusion of Phosphoric Oxide*

| Modification | Latent heat of vaporization of liquid $P_4O_{10}$ kcal. mole$^{-1}$ | Latent heat of sublimation of solid $P_4O_{10}$ kcal. mole$^{-1}$ | Latent heat of fusion of solid $P_4O_{10}$ kcal. mole$^{-1}$ |
|---|---|---|---|
| (H) form $P_4O_{10}$ | 16·2 | 22·7 | 6·5 |
| (O) form $(P_2O_5)_n$ | (18·7) | 36·4 | (17·7) |
| (O′) form $(P_2O_5)_n$ | 18·7 | 33·9 | 15·2 |

A value of 17·6 kcal. mole$^{-1}$ of $P_4O_{10}$ for the heat of sublimation of the (H) form, based on calorimetric measurements, has been reported,[29] but some doubt has been expressed about the homogeneity of the sample used,[27] and the value quoted in Table IV is preferred.

## Heats of Formation, Free Energy and Entropy and Heat Capacity

After correcting the early data of Giran[30] and Thomson[31] to modern atomic weights and using revised values for the heat of combustion of naphthalene, the enthalpy of formation of crystalline (H) form phosphoric oxide has been reported to be −720 kcal. mole$^{-1}$.[32]

More accurate recent values, derived from measurements of the heat of combustion of various forms of phosphorus,[33] have been found to be:

| | $\Delta H^\circ_{f298}$ $P_4O_{10}$(H) form |
|---|---|
| From yellow phosphorus | $-713·2 \pm 1·0$ kcal. mole$^{-1}$ |
| red phosphorus (*X*-ray amorphous) | $-706·2 \pm 0·5$ ,, ,, |
| red phosphorus (form IV[34]) | $-700·7 \pm 0·4$ ,, ,, |

The free energy and entropy of phosphoric oxide ($P_4O_{10}$), considered as an ideal gas at 1 atm. pressure, have been approximately calculated over the temperature range 298–1400°K., assuming the standard entropy of this form to be 51 g.-cal.deg.$^{-1}$mole$^{-1}$ at 25°C.[35]

Using the recent value of −713·2 kcal. mole$^{-1}$ for $\Delta H^\circ_{f298}$ for the $P_4O_{10}$(H) form, the complete set of frequency assignments for the expected vibrations of the $P_4O_{10}$ molecule and the contributions to entropy from rotational and translational motion, the values for the heat content, $H_0 - E^\circ_0$, the free energy function $-(G_0 - E^\circ_0)/T$, the standard entropy $S_0$ and the heat capacity at constant pressure, $C^\circ_p$, have been re-calculated for $P_4O_{10}$ gas at 1 atm. pressure[36] and are given in Table V.

Earlier work[29] on gaseous $P_4O_{10}$ yielded a value for $C^\circ_p$ of $73·6 \pm 2·0$ g.-cal. deg.$^{-1}$ mole$^{-1}$ between 110 and 320°C.

The heat capacity of hexagonal $P_4O_{10}$ has been determined from 12 to 324°K. in an adiabatic calorimeter, and values of $C_p$, $S$, $(H - H^\circ_0)$, $(H - H^\circ_0)/T$ and $-(G - H^\circ_0)/T$ have been listed over this range. The standard entropy $S_{298·15}P_4O_{10(\text{hex})}$ is given as $54·68 \pm 0·1$ g.-cal./deg./mole, and the standard free energy of formation, $\Delta G_{298}$ as −644·8 kcal./mole.[129] The values given by these authors for the heat capacity of hexagonal $P_4O_{10}$ are lower by 2% at 100°K. and 6% at 300°K. than earlier values.[130]

*Table V.—Values of* $-\frac{G_0-E_0^\circ}{T}$, $H_0-E_0^\circ$, $S^\circ$ *and* $C_p^\circ$ *for* $P_4O_{10}$ *Gas at* 1 *atm.*

| Temperature (°K.) | Free energy function, $-\frac{G_0-E_0^\circ}{T}$ g.-cal. deg.$^{-1}$ mole$^{-1}$ | Heat content, $H_0-E_0^\circ$ g.-cal. mole$^{-1}$ | Standard entropy, $S^\circ$ g.-cal. deg.$^{-1}$ mole$^{-1}$ | Heat capacity, $C_p^\circ$ g.-cal. deg.$^{-1}$ mole$^{-1}$ |
|---|---|---|---|---|
| 298·15 | 71·9 | 6,350 | 93·2 | 43·5 |
| 400 | 79·7 | 11,100 | 107·4 | 53·1 |
| 631 | 95·7 | 24,500 | 134·5 | 64·2 |
| 900 | 111·7 | 42,500 | 159·0 | 71·7 |
| 1000 | 117·0 | 49,600 | 166·6 | 73·0 |
| 1100 | 122·5 | 57,000 | 174·3 | 74·1 |
| 1300 | 131·3 | 71,300 | 186·1 | 75·5 |
| 1500 | 139·6 | 86,100 | 197·0 | 76·4 |

Some values have also been quoted for the heats of formation and hydration of the orthorhombic (O) form of phosphoric oxide; the accuracy claimed is not high[37]

(a) $4P_{(\text{yellow})}+5O_{2(\text{gas})} = P_4O_{10(\text{orthorhombic})}$
$\Delta H^\circ_{f298} = -736{\cdot}8 \pm 14$ kcal. mole$^{-1}$

(b) $P_4O_{10(\text{orthorhombic})}+6H_2O_{(\text{liquid})} = 4H_3PO_{4(\text{solution})}$
$\Delta H^\circ_{f298} = -102{\cdot}50 \pm 0{\cdot}84$ kcal. mole$^{-1}$

Using the values for the heats of formation of the (H) form[33] and the heats of sublimation for the (H) and (O) forms respectively (Table IV), the calculated $\Delta H^\circ_{f298}$ for $P_4O_{10}$(O) form is $-727{\cdot}1$ kcal. mole$^{-1}$, a value which lies within the limits of $-736{\cdot}8 \pm 14$ kcal. mole$^{-1}$ quoted in reference 37. As part of a study of the heats of solution of crystalline and glassy phosphates, the heat of solution of sublimed phosphoric oxide (presumably the H form) in 6N HCl solution at 35°C. was found to be $-50{\cdot}15$ kcal./mole.[123]

### SURFACE TENSION

The surface tension of liquid phosphoric oxide has been measured by the pendant drop method[38]; the reported values of 60 dynes cm.$^{-1}$ at 100°C. and 50 dynes cm.$^{-1}$ at 400°C. possibly refer to highly supercooled or to partially hydrated oxide, since published melting points for all forms of phosphoric oxide are higher than the temperatures used in these determinations.

### SOLUBILITY

Phosphoric oxide (H) form is sparingly soluble in anhydrous liquid hydrogen chloride, giving a solution of low conductivity. The oxide did not react with tetramethylammonium chloride in this medium.[124]

## Chemical Properties

### THE HYDRATION OF PHOSPHORIC OXIDE

Phosphoric oxide of commerce (the low temperature, volatile (H) form) is exceedingly hygroscopic, attracting and retaining water, with which it reacts to form various oxyacids of phosphorus. For this reason it is one of the most effective drying agents, at least below 100°C.,[39] but it must be correctly distributed, e.g., on glass wool, otherwise its absorptive capacity is diminished by the formation of a crust of hydration products which have appreciable water vapour pressure. The high temperature modifications, (O) and (O′) forms, are much less effective in this respect.

Uncontrolled high temperature hydration of all varieties of phosphoric oxide with an excess of water leads, finally, to orthophosphoric acid which is almost free from other more complex phosphoric acids.

On the other hand the reactions involved and the compounds formed in controlled low temperature hydration have been the source of much speculation for many years. As early as 1884[40] marked differences were reported in the rate of solution in water of the then known forms of phosphoric oxide, and during the thirty years following the low temperature studies of Sabatier in 1888[41] much conflicting evidence emerged. It was, at that time, supposed that the reaction between phosphoric oxide and ice-cold water could be represented by:

$$n/2\ P_2O_5 + n/2\ H_2O = (HPO_3)_n$$

The value of $n$ was certainly not unity, and conductivity measurements[42] and freezing point data[43] showed it to be much greater than one.

Between 1910 and 1916 Balareff[44] studied the course of the low temperature hydration process and claimed that metaphosphoric acid was formed first and that further hydration probably proceeded *via* pyrophosphoric to orthophosphoric acid. However, as adequate analytical procedures were not then available, these observations were not conclusive.

Boratyński and his co-workers[45–8] extended earlier work[42] on the conductivities of solutions prepared by dissolving the high and low temperature forms of phosphoric oxide in ice-cold water, and concluded that the acid derived from the 'amorphous' high temperature variety was, like the oxide, strongly polymerized. This conclusion was supported by *X*-ray data on the oxides, which also indicated that the commercial product consisted substantially of the 'crystalline', or low-temperature modification. Hydration of commercial phosphoric oxide, in which the temperature was kept as low as possible in order to avoid local overheating,[45] gave a solution containing 89% of unhydrolyzed metaphosphoric acid, on the basis of a differential titration technique used by Sabatier.[41] This quantity diminished with higher initial concentrations of oxide. The observed alteration in conductivity of such solutions with time was attributed to two processes: (i) a decrease, due to formation of orthophosphate, and (ii) an increase, due to de-polymerization of the first-formed metaphosphoric acid to a simpler molecule. The former was favoured by high initial concentrations in the preparation of the solution and the latter by high temperature. With reference to the second process, the authors claimed support from Sabatier,[41] Balareff,[44] Pessel,[49] Prideaux[42] and others, and suggested that the intermediate compound of high conductivity might be the hitherto unknown monometaphosphoric acid, $HPO_3$, or the dimetaphosphoric acid, $(HPO_3)_2$, reported by Rechid[50] and Travers and Chu.[51] For the first time in this field, it was also suggested that polyphosphoric acids might be involved in the changes which metaphosphoric acid undergoes in solution.

A species believed to be dimetaphosphoric acid, $(HPO_3)_2$, was reported to have been prepared by the dehydration of orthophosphoric or pyrophosphoric acid.[50] The product was a syrupy liquid, soluble in water, which readily hydrolyzed to pyrophosphoric acid; this reaction distinguished it from other possibly more highly polymerized forms, $(HPO_3)_n$. It was also claimed that ordinary phosphoric oxide on hydration occasionally gave a solution containing a large proportion of the dimeric acid, and only in such instances was pyrophosphoric acid observed as a hydration intermediate before the final state of orthophosphoric acid was reached.

Working with phosphoric oxide freed from lower oxides by heating *in vacuo* at 70°C., Travers and Chu[51] claimed that the first hydration product of phosphoric oxide was $H_2P_2O_6$ or $(HPO_3)_2$ and that the formation of this body ought to be a normal occurrence and not to be observed only infrequently. Demonstration of the presence of the dimer was, however, claimed to be possible only if special precautions were taken to avoid local over-heating. For example, this could be done by adding the oxide in small portions either to ether saturated with water, or to pure orthophosphoric acid in dry ether, whilst agitating under slightly reduced pressure. However, evidence for the presence of dimetaphosphoric acid was not conclusive. Ideally the hydration sequence could be represented by the equations:

(1) $P_2O_5 + H_2O \rightarrow (HPO_3)_2$
(2) $(HPO_3)_2 + H_2O \rightarrow H_4P_2O_7$
(3) $H_4P_2O_7 + H_2O \rightarrow 2H_3PO_4$

and it was argued that the usual absence of pyrophosphoric acid in the progressive hydration of phosphoric oxide was explicable on the grounds that the $(HPO_3)_2$ first produced was polymerized by local heating effects and that unknown substances formed during uncontrolled hydration were derived from this hypothetical polymer. It is now believed that the dimetaphosphoric acid described could have been tetrametaphosphoric acid.[52]

Further investigations by Glixelli *et al.*[46–8] showed that solutions of the low temperature (H) form of phosphoric oxide in ice-cold water contained orthophosphoric and pyrophosphoric acids (which were estimated by independent methods). In addition, other polyphosphoric acids contributed to the differential titration of the solution between the change points of methyl orange and phenolphthalein indicators. Calculations of the heat of solution of phosphoric oxide in water[29] at 29°C., based on the assumption that orthophosphoric acid is substantially the only product of the reaction, are therefore not valid.

No clear picture of the hydration process had therefore emerged prior to the establishment of the structural arrangements of the polymorphic modifications of phosphoric oxide and to the availability of suitable procedures, such as chromatography, to analyse hydrolysates.

Possible hydration mechanisms, arising from the known molecular structures of phosphoric oxide, are believed to be as follows:

### 1. *The hydration of the hexagonal (H) form*

This polymorph exists, both in the crystalline and gaseous states in the form of individual $P_4O_{10}$ molecules, and is in fact always formed when the gas condenses on a cool surface. The molecule, idealized in Fig. 5, has four phosphorus atoms at the corners of a tetrahedron, each bonded to three oxygen atoms along the edges, with an additional oxygen atom attached to each phosphorus atom (cf. Mellor, II, Suppl. II, 1324).

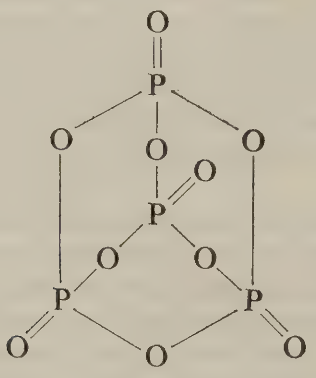

FIG. 5.—Phosphoric oxide (H) form, $P_4O_{10}$

*Stage 1.* The first stage in the hydration of phosphoric oxide (H) form can, theoretically, consist in the fission by water of any one of the six equal P–O–P bonds along the edges of the tetrahedron, with the formation of the structure shown in Fig. 6, drawn in planar configuration for the sake of clarity.

*Stage 2.* The five P–O–P bonds remaining are no longer identical in character, but assuming that the next attack by a water molecule is at the most anhydride-like—i.e. the presumably most reactive P–O–P bond, namely the oxygen bridge shown in Fig. 6—this leads directly to cyclic tetrametaphosphoric acid shown in Fig. 7.

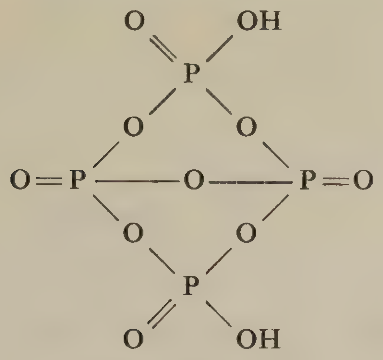

FIG. 6.—$H_2P_4O_{11}$

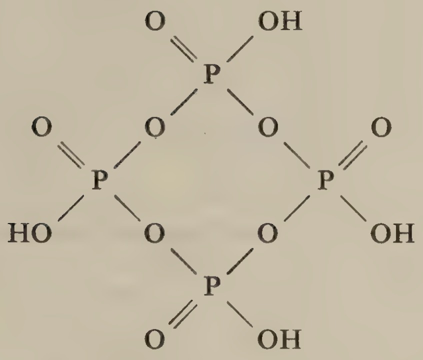

FIG. 7.—Tetrametaphosphoric acid, $H_4P_4O_{12}$ or $(HPO_3)_4$

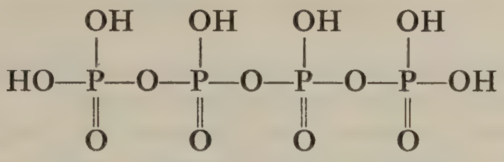
*Stage 3.* In tetrametaphosphoric acid the P–O–P bonds are again identical in character and, irrespective of which is next attacked by water, the ring splits and tetraphosphoric acid results, as shown in Fig. 8.



$$\mathrm{HO{-}\underset{\underset{\displaystyle O}{\Vert}}{\overset{\overset{\displaystyle OH}{|}}{P}}{-}O{-}\underset{\underset{\displaystyle O}{\Vert}}{\overset{\overset{\displaystyle OH}{|}}{P}}{-}O{-}\underset{\underset{\displaystyle O}{\Vert}}{\overset{\overset{\displaystyle OH}{|}}{P}}{-}O{-}\underset{\underset{\displaystyle O}{\Vert}}{\overset{\overset{\displaystyle OH}{|}}{P}}{-}OH}$$

FIG. 8.—Tetraphosphoric acid, $H_6P_4O_{13}$

*Stage 4.* The hydration of tetraphosphoric acid could, in principle, proceed to orthophosphoric acid by the two routes, designated I and II, shown in Fig. 9.

From the available evidence[53, 60] it appears that hydration under acid conditions proceeds predominantly, and probably exclusively, by Route II, that is by attack on the end oxygen–phosphorus bridges.

Rupture of a P–O–P bond, other than that in the oxygen bridge of the molecule shown in Fig. 6, would lead to an isomeric form of tetrametaphosphoric acid, which theoretically could hydrate by three routes, designated III, IV and V, according to attack by water at any of the three types of bonds *a*, *b* (of which there are two) and *c*. These routes are shown in Fig. 10.

It is therefore apparent that, even starting with phosphoric oxide of unitary character, a hydration mechanism based on structural considerations could lead to complex mixtures of hydration products according to the conditions under which the hydration is performed. This scheme indicates the reasons which have led to confusion in the interpretation of the results obtained by many investigators in this field.

The hydration mechanism outlined above has been verified partially by the isolation in good yield (60–70%) of the sodium salt of tetrametaphosphoric acid from the hydrolysate formed by slowly adding phosphoric oxide (H) form to well stirred ice-water, first reported in 1949,[54–7] confirmed in 1950,[58] and described in greater

detail in 1952.[59] A similar study has been made on the effect of hydrolysis temperature on the yield of tetra-ammonium tetrametaphosphate.[131]

The application of paper chromatography enabled the composition of hydrolysates of the low-temperature hydration of phosphoric oxide to be determined more satisfactorily[60] and the results of one experiment at 0°C. are given in Table VI.

*Table VI.—Products of Hydration of Phosphoric Oxide (H) form in Ice-water*

| Form | Percentage of total phosphorus present |
|---|---|
| Tetrametaphosphoric acid | 77·0 |
| Tetraphosphoric (and higher polyphosphoric) acids | 3·0 |
| Trimetaphosphoric acid | 2·0 |
| Triphosphoric acid | 15·0 |
| Orthophosphoric acid | 3·0 |

Calculations[18] of the composition of the hydrolysate, based on the assumption that the scission of P–O–P linkages is completely independent of their position in the molecule, was not in accord with the experimental values quoted in Table VI; better agreement was obtained if the probability of obtaining *iso*tetrametaphosphoric acid, in Stage 2 of the hydration, was increased by a factor of about four and, in addition, if decomposition of this body at bond (*a*) to give *iso*tetraphosphoric acid, was enhanced by a factor of about 3·5.

FIG. 10.—The hydration routes for *iso*tetrametaphosphoric acid, (HPO$_4$)$_4$

Although tetrametaphosphoric acid is the principal product of the ice-cold hydrolysis of commercial or freshly sublimed phosphoric oxide, trimetaphosphoric acid has been reported (Table VI). It has been suggested[60] that this does not arise from the hydrolysis of the hypothetical *iso*tetrametaphosphoric acid (Route IV, Fig. 10), but mainly by decomposition of a small amount (about 6%) of what are believed to be cross-linked high molecular-weight polyphosphoric acids. These appear as gelatinous flocks during the initial reaction between the oxide and water and dissolve only slowly.[60, 62] If the flocks are filtered before they decompose, then the trimetaphosphoric acid content of the hydrolysate is lower.[60] Further, if the anhydride is dissolved in boiling water, kept just alkaline, the cloudy flocks dissolve more slowly than in water alone and the solution finally contains 28% of its phosphorus content in the form of high molecular weight polyphosphoric acid species and 5% as trimetaphosphoric acid; this proportion rises to 20% on further boiling.[60] The mechanism of the reactions leading to the formation of high molecular-weight cross-linked ultraphosphates under these conditions is not completely understood, but a process similar to that advanced for the formation of linear polyphosphates with high molecular weight from those with lower degrees of polymerization is possible.[61, 63]

On the other hand, slowly dissolving gelatinous flocks are not observed when freshly sublimed phosphoric oxide is dissolved in ice-cold water, but are observed when the commercial oxide is similarly treated; this could be ascribed to the presence in the latter of modifications other than the (H) form.[4, 62]

*iso*Tetraphosphoric acid, $H_2P_4O_{11}$, and *iso*tetrametaphosphoric acid and their salts have not yet been isolated from hydrolysates obtained by the low-temperature hydration of phosphoric oxide (H) form. However, the products obtained by solvolysis with ethyl ether[64–5] and *iso*propyl ether[66] are stated to contain about 70% of the *iso*tetrametaphosphoric ester and 30% of the normal ester based on an examination of the nature and composition of their hydrolysis products. The high yield of tetrametaphosphoric acid obtained in the aqueous hydration of phosphoric oxide at low temperature has been ascribed[60] to the repulsive effect of the two ionized P–OH groups in $H_2P_4O_{11}$ (see Fig. 6) which causes the second water molecule to react with the P–O–P group of the oxygen bridge rather than with a P–O–P bonding adjacent to either of the $PO^-$ groups. In non-aqueous media the POH (or POR, $R = C_2H_5$ or $C_3H_7$) group does not tend to ionize, and there is no inductive effect to prevent the five P–O–P bonds being equally reactive. According to probability considerations, four times as much *iso*tetrametaphosphoric ester as normal ester should then be formed. Nuclear magnetic resonance data[67] have, however, been interpreted to show that only a minor proportion (3%) of the total phosphorus in the product of the reaction between ethyl ether and phosphoric oxide is present in the form of branching points[18] ($PO_4$ groups in which three oxygen atoms are shared by neighbouring $PO_4$ groups) characteristic of an *iso*tetrametaphosphoric ester.

### 2. *The hydration of the orthorhombic (O) form*

Whereas the soft crystalline (H) modification of phosphoric oxide reacts violently with water, dissolving with a hiss and usually giving off a puff of vapour or mist, the hard crystalline (O) form has a very slow rate of dissolution indeed even at steam-bath temperatures.[4, 60, 62] Dissolution proceeds by fragmentation of the crystals along cleavage cracks and often a gelatinous stage is observed, and the gel disappears but slowly on standing.

The (O) form exists in the crystalline state as an extensive array of interlocking $PO_4$ tetrahedra in a continuous structure and the theoretical consequences of the step-wise hydration of this variety have not been explored as fully as for the (H) form. However, the initial attack by water on such a sheet polymer would inevitably lead to polyphosphoric acids of high molecular weight, possibly cross-linked, which would account for the formation of gel-like bodies.

Cyclic tetrametaphosphoric acid has not been observed in the hydrolysates of this modification[60, 62]; small amounts of orthophosphoric, pyrophosphoric and trimetaphosphoric acids have been reported from chromatographic analysis, but the principal products are high molecular weight acids of which the sodium salts have an Na:P atom ratio of 0·8:1, indicating the presence of cross-linked anions.[60]

### 3. *The hydration of the (O′) form*

The rate of hydration of the (O′) modification, another sheet polymer, is also slow; with a limited amount of water it is converted into a stiff gel with the evolution of considerable heat.[4] Preferential hydration at branching or cross-linking points soon degrades the gelatinous structure, and the solution becomes more limpid. Hydrolysates are similar in composition to those reported for the (O) modification,[60] but a detailed study of the hydration process is lacking.

### ABSORPTION OF WATER VAPOUR

The three crystalline modifications of phosphoric oxide absorb water vapour from the atmosphere initially at about the same rate when samples are spread out in thin layers; eventually the rate of absorption by the (O) and (O′) forms decreases, whilst that of the (H) form continues undiminished,[4] as shown in Fig. 11.

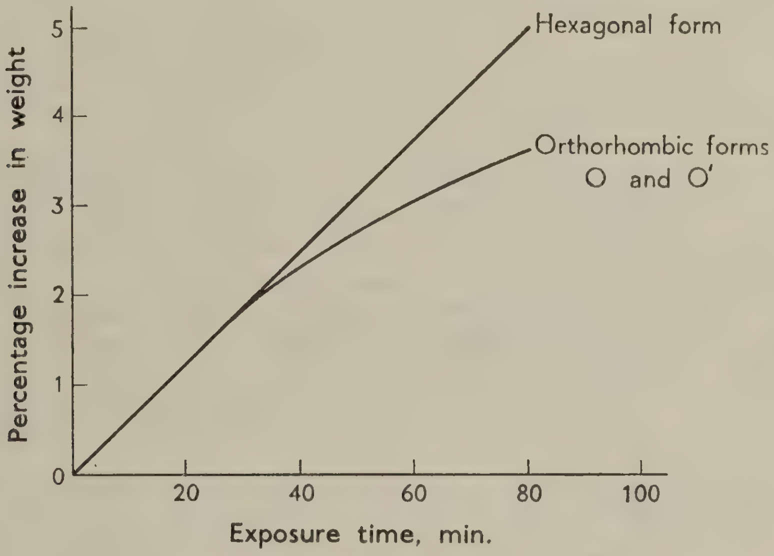

FIG. 11.—Absorption of atmospheric moisture by crystalline phosphoric oxide at room temperature

The properties and hydration characteristics of the various glassy forms of phosphoric oxide have not been reported.

Besides its avidity for free water, the (H) form of phosphoric oxide can also remove water of composition from many inorganic and organic compounds.[68] For example, it converts ethanol to ethylene and sulphuric acid to sulphur trioxide. It can also dehydrate amides to nitriles and methylarylcarbinols to the respective styrenes.[69]

Hydrogen peroxide reacts with phosphoric oxide, and these processes are described in Section XXIX.

### REACTIONS BETWEEN PHOSPHORIC OXIDE AND ORGANIC COMPOUNDS

Commercial phosphoric oxide reacts with alcohols; provided the reactions are controlled by cooling to restrict the tendency towards dehydration and the consequent formation of olefines, organic phosphates are formed, the exact composition of which depends on the proportions and moisture contents of the reagents employed.[70–2] It also combines with phosphate esters, for example triethyl phosphate,[70] and ethers,[64–6, 72] and the mechanism of the solvolysis can be regarded as being similar in many respects to that described for water.[70] The aminolysis of phosphoric oxide by various amines such as triethylamine, $(C_2H_5)_3N$, aniline, $C_6H_5NH_2$, and *p*-chloroaniline, *p*-$ClC_6H_4NH_2$, also occurs,[70, 73] the effect being the more complete the weaker is the base.[70] Phosphoric oxide also reacts with urea when the two are heated together[74] to form a non-hygroscopic water-soluble product with water-softening properties and of uncertain and possibly complex composition.

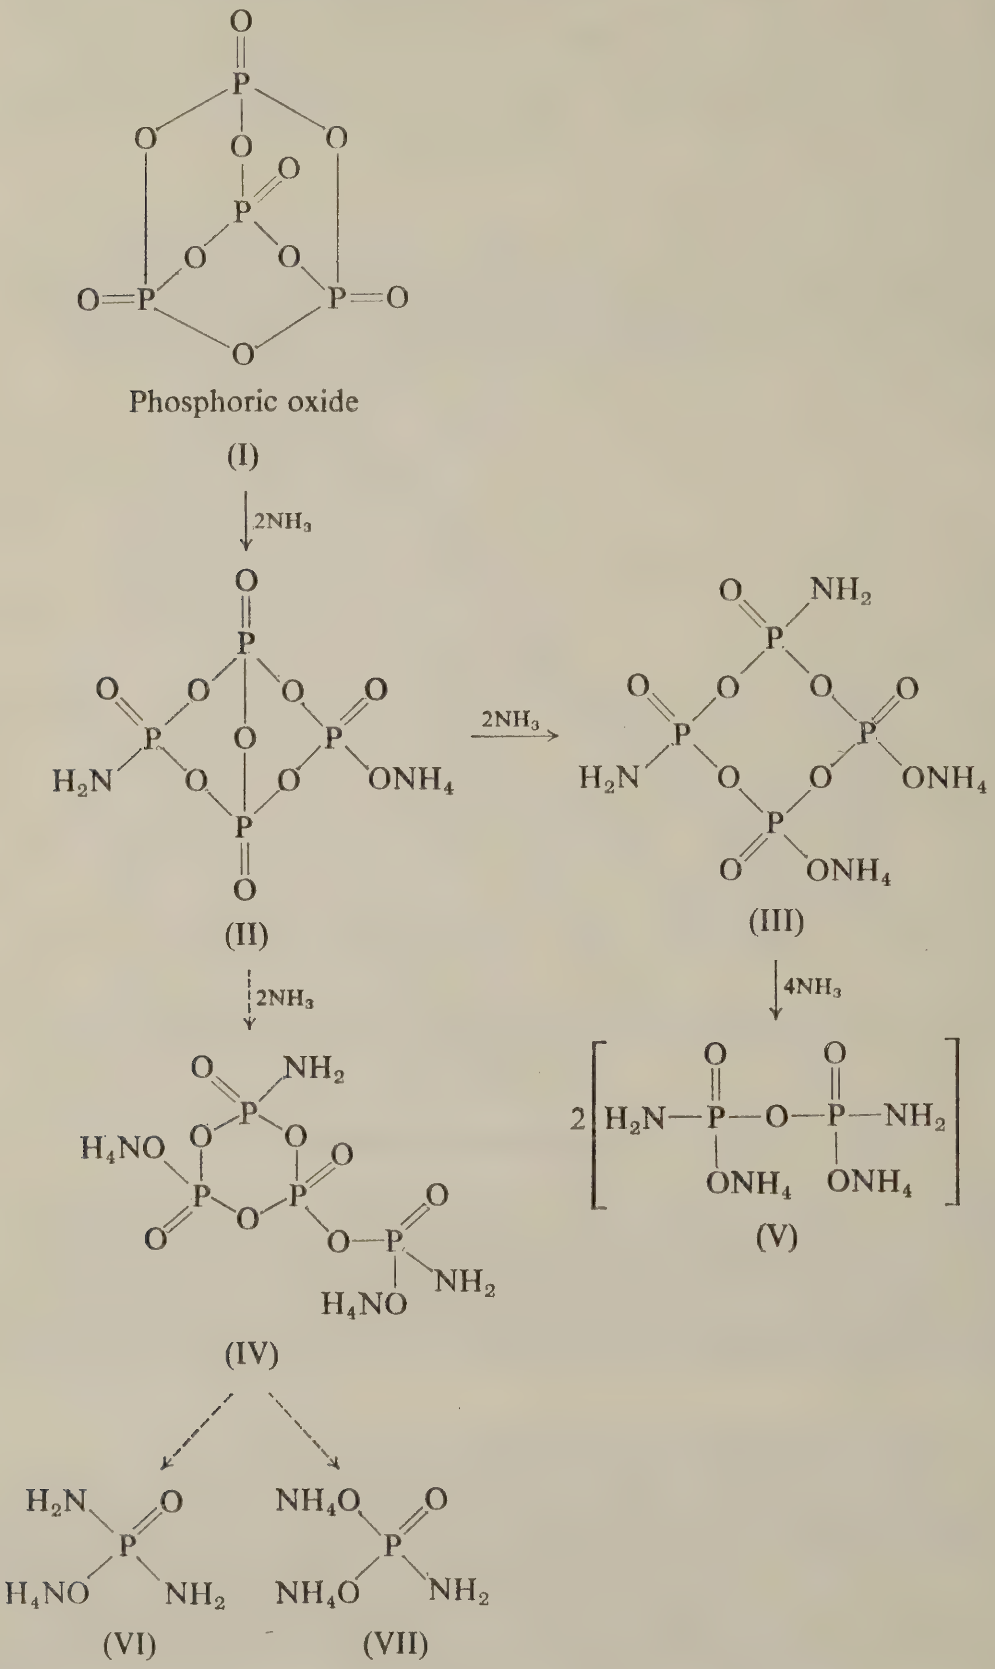

FIG. 12.—Low temperature ammonolysis of phosphoric oxide (H) form

## THE REACTION BETWEEN PHOSPHORIC OXIDE AND AMMONIA

Phosphoric oxide reacts vigorously with dry or wet ammonia to form amorphous powders,[68, 75] which are mixtures of ammonium salts of condensed phosphates containing P–$NH_2$, P–NH and P–NH–P linkages.

Incomplete reaction between very dry ammonia and purified phosphoric oxide has been claimed to be due to the encrustation of particles of the oxide by reaction products[76] and it has even been reported that no reaction occurs at all.[77] However, when the course of the reaction is followed by the changes in pressure in an ammonia-charged vessel containing resublimed phosphoric oxide, neither hypothesis is confirmed; the product has a glassy appearance.[78–9]

When gaseous or liquid ammonia is passed into phosphoric oxide, either alone or suspended in mineral oil, and the temperature kept below 150°C., further heat treatment of the solid formed is said to induce condensation or polymerization which enhances the calcium ion sequestering properties of the product. During the heat treatment, ammonia is believed to be lost by the condensation of adjacent P–$NH_2$ groups[80] and only 60–80% of the total nitrogen present is in the form of ammonium ion. If phosphoric oxide, sublimed in a current of air at 270°C., is allowed to react with ammonia gas, it is claimed that pure amidophosphoric acids are obtained[81]; these observations were verified[82] but it was not possible to propose a mechanism for the reaction on the evidence then available.

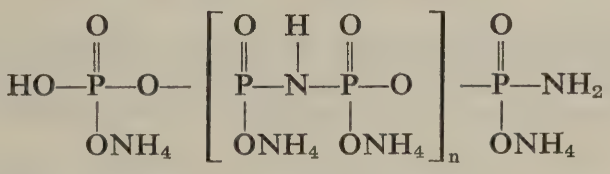
In order to avoid the difficulty of slow reactivity due to crust formation when using gaseous ammonia, the reaction between freshly sublimed phosphoric oxide and an excess of liquid ammonia has been investigated[83] by allowing the reagents to stand for a long time in sealed tubes at room temperature, or for a shorter time at 40–50°C. The products contain $P:N_{Total}:N_{Ammonium}$ in the approximate ratio 1:1·79:1·16, and paper chromatography shows the presence of several compounds. At 180–220°C. in an autoclave liquid ammonia reacts rapidly with phosphoric oxide, giving a melt. The reaction is complete at 400°C. under a pressure of 12–50 kg./cm.$^2$ The product is a colourless transparent glass, similar to those described above.[125] The course of the low-temperature ammonolysis of the (H) form of phosphoric oxide is probably similar to that already described for hydration with water, and is illustrated[83] in Fig. 12.

Since only a trace of diamidophosphate (VI) is formed under the prescribed low temperature conditions, ammonolysis is thought to proceed mainly by the route which leads to diammonium diamidodiphosphate (V), after which further ammonolysis is unlikely.[84]

At 50°C. the reaction mixture largely consists of diammonium diamidotetrametaphosphate (III) and diammonium diamidodiphosphate (V) and on further heating undergoes condensation, with loss of ammonia, to give a composition

$$P:N_{Total}:N_{Ammonium} = 1:1{\cdot}5:1$$

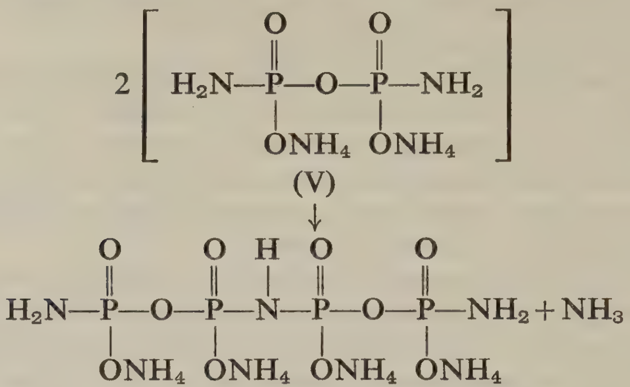
Ammonia can be lost from (V) either intra- or inter-molecularly; in the first instance it is thought[83] that the monoammonium salt of diamidophosphoric acid is first formed by loss of ammonia, and that by analogy with the behaviour of amidophosphoric acid[85] further polymerization can yield compounds of general formula:



$$HO-\underset{ONH_4}{\overset{O}{\overset{\|}{\underset{|}{P}}}}-O-\left[\underset{ONH_4}{\overset{O}{\overset{\|}{\underset{|}{P}}}}-\overset{H}{\overset{|}{N}}-\underset{ONH_4}{\overset{O}{\overset{\|}{\underset{|}{P}}}}-O\right]_n-\underset{ONH_4}{\overset{O}{\overset{\|}{\underset{|}{P}}}}-NH_2$$

(VIII)

When condensation occurs inter-molecularly, so that ammonia is lost from two molecules of (V), the primary product would be a derivative of an imidotetraphosphoric acid (IX), which is capable of still further condensation:



$$2\left[H_2N-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle ONH_4}{|}}{P}}-O-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle ONH_4}{|}}{P}}-NH_2\right]$$

(V)

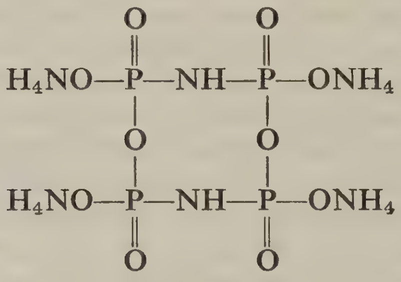
$$\downarrow$$

$$H_2N-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle ONH_4}{|}}{P}}-O-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle ONH_4}{|}}{P}}-\overset{\overset{\displaystyle H}{|}}{N}-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle ONH_4}{|}}{P}}-O-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle ONH_4}{|}}{P}}-NH_2+NH_3$$

(IX)

In both instances, therefore, ammonium salts of polyphosphoric acids containing P–NH–P as well as P–O–P bridges can result. From the calcium sequestering power of these condensed materials it is believed that they consist mainly of compounds of the type illustrated by formula (VIII).

In addition to linear polymers, the formation of cyclic polymers of type (X) has been suggested



(X)

when the primary reaction products of phosphoric oxide and ammonia are heated further.[80] But, so far, compounds of this class have not been isolated.

Another method for the preparation on a commercial scale of materials such as those described above, is the controlled reaction between ammonia and phosphoric oxide (produced by burning phosphorus in the same apparatus); water vapour is often introduced with the ammonia[86–9] and sometimes the initial product of a dry reaction is subsequently subjected to steam treatment to modify its properties.[90]

Similar products are also said to be formed when monoammonium dihydrogen orthophosphate is heated with ammonia and phosphoric oxide, under pressure, at 200°C. or above.[91]

### THE REACTION BETWEEN PHOSPHORIC OXIDE AND HALIDES OR OXYHALIDES

When phosphoric oxide reacts on heating with any halide, some phosphoryl halide is formed according to the equation

$$(1) \qquad 3MX+P_4O_{10} = 3MPO_3+POX_3$$

In the presence of a little water, condensation of the phosphoryl chloride, for example, to mixtures of polyphosphoryl chlorides, can occur with the formation of equivalent quantities of hydrogen chloride. When sufficient water is available the reaction may be idealized as:

$$(2) \qquad 4MX+P_4O_{10}+2H_2O = 4MPO_3+4HX$$

but it is extremely likely that the glassy solid remaining at the end of the reaction, if sodium chloride is used, consists of a mixture of polyphosphates of the type

$Na_nH_2P_nO_{3n+1}$. When phosphorus is burned with excess of oxygen in the presence of finely divided chlorides, glassy phosphates and chlorine, instead of hydrogen chloride, are produced according to the equation:

$$4MCl + P_4O_{10} + O_2 = 4MPO_3 + 2Cl_2 \tag{3}$$

The reaction expressed by equation (1) can be used for the preparation of phosphoryl chloride from sodium chloride,[92] and of phosphoryl fluoride from cryolite[92] or calcium fluoride.[93–4] The products are impure, often containing some phosphorus trihalide and/or pentahalide. For example, when a mixture of sodium chloride, calcium fluoride and phosphoric oxide is heated to 350°C. or above, a mixture of phosphorus trifluoride, $PF_3$, phosphoryl fluorides, $POF_3$, $POF_2Cl$ and $POFCl_2$, and phosphoryl chloride is formed.[95]

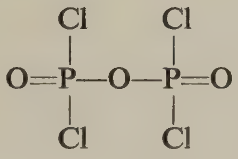
It has been claimed that the reaction represented by equation (2) can be realized in practice by burning elemental white phosphorus with air in the presence of water vapour and finely divided or volatilized alkali or alkaline earth halides[96–9]; the technical difficulties in achieving a satisfactory commercial process by this reaction are considerable.

The reaction in which chlorine is evolved, equation (3), first described in 1928,[96] has since been the subject of several other patents,[98, 100] in one of which[100] it is claimed that by spraying finely divided sodium chloride into a phosphorus flame at 2000°C., a good yield of chlorine gas can be obtained.

Phosphoric oxide also reacts with phosphorus pentahalides[101] thus:

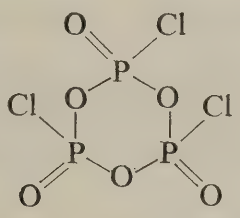
$$P_4O_{10} + 6PX_5 = 10POX_3 \tag{4}$$

and with phosphoryl chloride (in excess) in sealed tubes at 200°C. to give a viscous mixture of hygroscopic polyphosphoryl chlorides, containing chiefly pyrophosphoryl chloride, $P_2O_3Cl_4$,



$$O{=}\underset{\underset{\textstyle Cl}{|}}{\overset{\overset{\textstyle Cl}{|}}{P}}{-}O{-}\underset{\underset{\textstyle Cl}{|}}{\overset{\overset{\textstyle Cl}{|}}{P}}{=}O$$

and cyclic trimetaphosphoryl chloride, $P_3O_6Cl_3$,



with smaller amounts of linear polyphosphoryl chlorides $P_nO_{3n+1}Cl_n$ ($n = 4$–6).

Dropwise addition of fluorosulphonic acid, $HSO_3F$, to an excess of phosphoric oxide gives phosphoryl fluoride in good yield[102] according to the equation:

$$P_4O_{10} + 6HSO_3F = 2POF_3 + 2HPO_3 + 4SO_3 + 2H_2SO_4$$

The autocatalytic absorption of hydrogen chloride gas by phosphoric oxide is thought to proceed *via* intermediates such as $PO_2Cl$ or $P_2O_3Cl_4$; under extremely dry conditions the absorption is long delayed.[103]

### THE REACTION BETWEEN PHOSPHORIC OXIDE AND NITROGEN OXIDES

Phosphoric oxide does not react with nitrogen,[68] but when heated with dry dinitrogen tetroxide at 250°C. it undergoes a reaction thought[104] to be:

$$P_4O_{10} + 2N_2O_4 = P_4O_{10},4NO + 2O_2$$

or alternatively[132]:

$$N_2O_4 + 2P_4O_{10} \rightarrow (NO)_2P_8O_{21} + \tfrac{1}{2}O_2$$

The glassy white solid of unknown structure which is formed is rather less deliquescent than phosphoric oxide itself, and is also produced by the direct combination of the oxide with nitric oxide. It decomposes when treated with water to give nitric oxide and condensed phosphoric acids.[104] A similar reaction occurs at room temperature, but very much more slowly.[105] Thus the changes in properties of dinitrogen tetroxide on intensive drying with phosphoric oxide are due to chemical action and not to a shift in the equilibrium $N_2O_4 \rightleftharpoons 2NO_2$.[105]

With dinitrogen trioxide, $N_2O_3$, at room temperature for 15 months, reaction is thought to occur according to the equation[105]:

$$P_4O_{10} + 4N_2O_3 = P_4O_{10},4NO + 2N_2O_4$$

the conversion of $N_2O_3$ to $N_2O_4$ accounting for the observed increase in vapour density.

### THE REACTION BETWEEN PHOSPHORIC OXIDE AND OXIDES, HYDROXIDES, CARBONATES AND OTHER INORGANIC SALTS

The low-temperature (H) forms of phosphoric oxide reacts with most basic and other oxides to form phosphates of various kinds. When the reaction mixture is quite dry, combination does not usually take place till heat is applied, as for example, with alumina,[62] silica,[106] boric oxide[107] or ferric oxide.[108] But if the oxides are hydrated, or if a few drops of water are added to initiate the reaction by the heat evolved during the hydration of the phosphoric oxide, then the mixtures often combine with the evolution of considerable heat and some volatilization of the phosphoric oxide.[62, 18]

Similar reactions occur with metal hydroxides, carbonates,[109–10] bicarbonates and sulphates, hydrated or otherwise, the nature of the products depending on the relative proportions of the metal to phosphorus, the amount of water available during the reaction process and the temperature attained. For example,[62] if anhydrous sodium carbonate is mixed with phosphoric oxide in the molar ratio of 2:1 and the reaction initiated by local heating, the product consists mainly of cyclic sodium trimetaphosphate, $(NaPO_3)_3$, owing to the relatively high temperature reached by the reaction mass:

$$3P_4O_{10} + 6Na_2CO_3 = 4(NaPO_3)_3 + 6CO_2$$

If, however, hydrated sodium carbonate, sodium sesquicarbonate or sodium bicarbonate is used, the reaction proceeds at a lower temperature and long chain polyphosphates in addition to orthophosphate are present in the final products; for example,

$$3P_4O_{10} + 4(NaHCO_3,Na_2CO_3,2H_2O) = 3Na_4H_2P_4O_{13} + 8CO_2 + 7H_2O$$

The reaction between phosphoric oxide and lime[92] or solid sodium hydroxide[62] is extremely violent when initiated, the product from the latter having a glassy appearance.

Calcium orthophosphate (fluoroapatite) absorbs phosphoric oxide vapour at 1000°C. to form a melt, which on chilling forms a glass consisting substantially of so-called calcium metaphosphate.[111]

### OTHER REACTIONS OF PHOSPHORIC OXIDE

#### *Phosphorus*

The reduction of phosphoric oxide by red phosphorus yields α(PIII/V) oxide with a composition in the range $P_4O_{8 \cdot 1}$ to $P_4O_{9 \cdot 2}$ (Section IX). Mixtures of phosphoric oxide and tetraphosphorus decasulphide in the appropriate proportion yield phosphorus hexaoxide tetrasulphide, $P_4O_6S_4$ (Section XII) when heated. By the evaporation of mixtures of arsenic and phosphoric acids mixed crystals of $(AsP)_2O_5$ are formed containing up to 50 mol. % of $P_2O_5$, and isostructural with $As_2O_5$.[133]

### Uses of Phosphoric Oxide

The main commercial use of phosphoric oxide is its conversion by hydration into orthophosphoric and polyphosphoric acids and in the preparation of phosphoryl chloride.

Owing to its extreme hygroscopicity it is also widely employed as a drying agent, for it is a convenient means of removing traces of moisture from vacuum systems such as those used in the production of electric light bulbs and radio valves. It is also useful for drying those gases and liquids with which it does not combine.

Phosphoric oxide is used as an intermediate in the synthesis of drugs and in the manufacture of phosphate esters of long-chain alcohols employed for uranium extraction[112] and as flotation agents.

When incorporated into air-blown asphalt[113] it stabilizes the product, both against softening at relatively high temperatures and against embrittlement at low temperatures.

## HIGHER PHOSPHORIC OXIDES

### Phosphorus Peroxide

When dry electrolytic oxygen, freed from traces of hydrogen and saturated with phosphoric oxide vapour, is passed through a heated discharge tube at low pressure, a blue-violet solid condenses in the cool section of the apparatus immediately after the discharge.[114–5] The best yields of products are said to be obtained using a silent discharge from aluminium–lead electrodes, at 3 kilovolts and 150 milliamps, at a pressure of 1 mm. Hg and a temperature of 150–220°C.

If it is assumed that phosphorus peroxide has the empirical formula $P_2O_6$,[115] then the violet compound produced under the conditions described above contains about 5% of this substance. This proportion is deduced from (*a*) determination of its oxidizing activity in liberating iodine from potassium iodide solution, or (*b*) by heating it to 130°C. (*in vacuo*), when the compound loses its colour and decomposes, liberating oxygen, the volume of which can be measured.

If phosphoric oxide vapour is passed through the heated discharge tube in the absence of oxygen, a very small amount of the violet compound is observed to condense, together with some phosphorus, or one of its lower oxides, which causes the product to inflame on exposure to the atmosphere when removed from the apparatus.[115] When cylinder argon is the carrier gas for phosphoric oxide, the condensate has the same outward appearance as when oxygen is used, but although it has a high peroxide content, based on the oxidizing activity of its solution, the latter exhibits none of the typical reactions for peroxophosphoric acids (see below). It has therefore been suggested that substances derived from the nitrogen content of the argon may be present.[115]

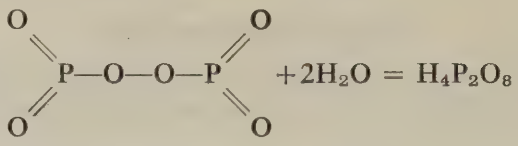
The violet solid is stable, if dry, and is soluble in water to give an aqueous solution which behaves like a peroxophosphoric acid. For example, the solution liberates iodine from potassium iodide, gives a yellow colour with titanyl sulphate solution and oxidizes aniline in cold hydrochloric acid solution, first to nitrosobenzene and then, after long standing, to nitrobenzene. Also, if the excess of phosphoric acid in the hydrolysate is removed by precipitation with ammoniacal magnesia mixture, the solution, when neutralized, gives with aqueous silver nitrate first a dark-coloured precipitate which rapidly turns white and then yellow.

In contrast to phosphoric oxide, the violet compound is insoluble in chloroform, so that by extraction with this solvent a product with an equivalent content of 11% $P_2O_6$ can be obtained.[115]

On the basis of the similarity of the properties of its aqueous solution with those of the peroxophosphoric acids obtained by the reaction between hydrogen peroxide and orthophosphoric or pyrophosphoric acids,[116–9] it was first suggested that the violet

Refs. p. 408

compound might be regarded as the anhydride corresponding to the acid $H_4P_2O_8$, peroxodiphosphoric acid:



Another suggestion,[120] however, is that the substance formed in the discharge tube consists of an unstable violet compound, possibly a free radical, and a colourless compound with the formula $P_4O_{11}$. The latter is thought to react with water according to the equation:

$$P_4O_{11}+4H_2O = H_4P_2O_8+H_4P_2O_7$$

to produce peroxodiphosphoric and pyrophosphoric acids, but neither peroxomonophosphoric acid nor hydrogen peroxide. The same authors have shown that if the peroxide is prepared in the presence of a little nitrogen, a nitroso compound, $P_4O_{11}.2P_4O_{10}.3NO$ is formed, which can be hydrolyzed to a nitroso tetrametaphosphate, probably $HN(PO_3)_4$.

The structure proposed[120] for $P_4O_{11}$, shown in Fig. 13, accounts for the observed hydrolysis products, assuming that all the –POP– bonds in the neighbourhood of the –POOP– group are polarized and more easily attacked by water.

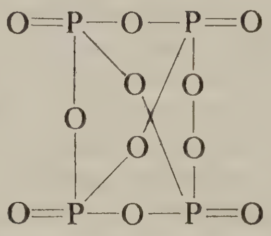


FIG. 13.—Structure of phosphorus peroxide

The anhydride corresponding to peroxomonophosphoric acid, $H_3PO_5$, which is said to exist in equilibrium with peroxodiphosphoric acid, $H_4P_2O_8$, in aqueous solution according to the equilibrium:

$$H_4P_2O_8+H_2O \rightleftharpoons H_3PO_5+H_3PO_4$$

has not been described.

The true nature and structure of oxides of phosphorus higher than phosphoric oxide therefore, await more detailed investigations by physico-chemical techniques.

## SECTION XI

# THE PHOSPHORUS SULPHIDES

BY A. F. CHILDS

The existence of four sulphides of phosphorus has been well authenticated. Three of these, viz., tetraphosphorus trisulphide, $P_4S_3$, tetraphosphorus heptasulphide, $P_4S_7$, and tetraphosphorus decasulphide, $P_4S_{10}$, were identified by Stock (Mellor, VIII, 1048) from the melting point–composition diagram of the phosphorus–sulphur system. The fourth, tetraphosphorus pentasulphide, $P_4S_5$, first prepared by Bouloch by the interaction of $P_4S_3$ and iodine in carbon disulphide, and regarded as a solid solution both by him and Stock, has been shown[1, 3] to be a definite compound with a unique and unexpected structure. The molecular structures of these four sulphides have been determined by *X*-ray single crystal techniques[2–5] and are supported by a variety of physical and chemical data which will be discussed in detail for each sulphide individually. For comparative purposes, however, the structural data for these compounds are brought together in Tables I and II and the structures illustrated in Fig. 1. More accurate data, in general agreement with those in Fig. 1, have been reported.[115]

*Table I.—X-Ray Crystallographic Data for the Phosphorus Sulphides*

| | $P_4S_3$ | $P_4S_5$ | $P_4S_7$ | $P_4S_{10}$ |
|---|---|---|---|---|
| Crystal System | Orthorhombic | Monoclinic | Monoclinic | Triclinic |
| *a* (A.) | 10·63 | 6·41 | 8·87 | 9·07 |
| *b* (A.) | 9·69 | 10·94 | 17·35 | 9·18 |
| *c* (A.) | 13·72 | 6·69 | 6·83 | 9·19 |
| $\alpha°$ | | | | 92·4 |
| $\beta°$ | | 111·7 | 92·7 | 101·2 |
| $\gamma°$ | | | | 110·5 |
| Space group | $D_h^{16}-Pnmb$ | $P2_1$ | $P2_1/n$ | $P\bar{1}$ |
| No. of molecules | 8 | 2 | 4 | 2 |
| Observed density | 2·03 | 2·17 | 2·19 | 2·09 |
| Calculated density | 2·06 | 2·15 | 2·19 | 2·10 |
| Reference | 2 | 3 | 4 | 4 |

*Table II.—Interatomic Distances in the Phosphorus Sulphides*

| | $P_4S_3$ | $P_4S_5$ | $P_4S_7$ | $P_4S_{10}$ |
|---|---|---|---|---|
| P—S (A.) | 2·235 | 2·08–2·19 | 2·08 | $2{\cdot}08_5$ |
| P=S (A.) | — | 1·94 | 1·95 | $1{\cdot}95_5$ |
| P—P (A.) | 2·090 | 2·21 | 2·35 | — |
| Reference | 2 | 3 | 4, 5 | 4 |

It will be seen that each of these sulphides contains four phosphorus atoms arranged roughly tetrahedrally. The structures are regular and, except in the case of $P_4S_5$, the observed interatomic bond distances show little variation from the mean. There appear to be no analogies for the unusually long P–P bond distance observed in $P_4S_7$.

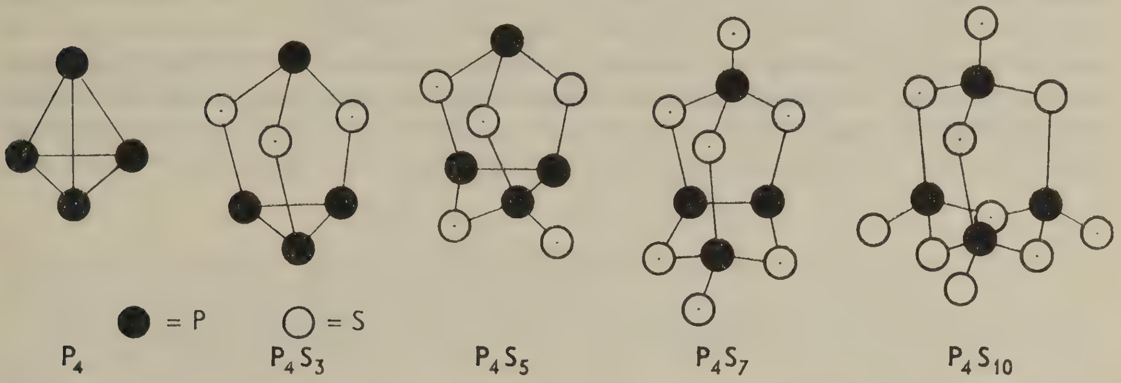

FIG. 1.—The structures of the $P_4$ molecule and of molecules of the phosphorus sulphides

The bond angles in $P_4S_{10}$ do not differ significantly from the tetrahedral values of 109° 28′, and most of the bond angles in $P_4S_7$ are also near this value. In $P_4S_3$ the P–P–P bond angles are 60°, as in $P_4$, while the P–S–P bond angles are 102°. Variation in bond angles is again at its highest in the irregular molecule $P_4S_5$.

While, therefore, there seems little doubt of the existence of these four sulphides,

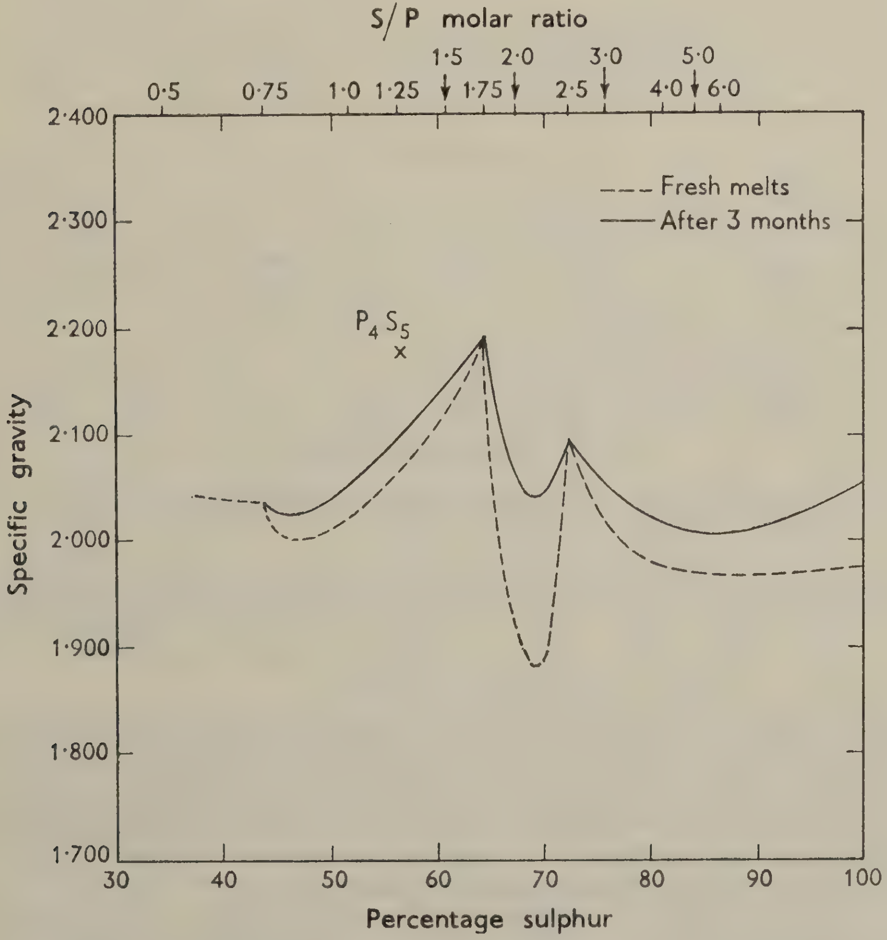

FIG. 2.—Specific gravity of phosphorus–sulphur compositions

evidence for others is more debatable. A study of the variation of density with composition in phosphorus sulphide melts[1] shows only three maxima corresponding to $P_4S_3$, $P_4S_7$ and $P_4S_{10}$, respectively (Fig. 2). On the other hand, repetition of the work of Giran (Mellor, VIII, 1049), on the melting point of red phosphorus–sulphur compositions which had been refluxed under nitrogen, shows well-defined maxima corresponding to $P_4S_3$, $P_4S_7$, $P_4S_{10}$ and $P_4S_{24}$.[6] The curve (Fig. 3) is of the same form as that of Giran, differing only in that a maximum at 308·5°, corresponding to the composition $P_4S_7$, is observed in place of Giran's maximum of 296° for $P_4S_6$. Later workers detected four maxima in the liquidus line corresponding to the percentage compositions by weight 27·9% P (=$P_4S_{10}$) m.p. 288 ± 1°C., 35·6% P (=$P_4S_7$) m.p. 308 ± 1°C., 56·3% P (=$P_4S_3$) m.p. 174 ± 1°C., and 66% P (=$P_4S_2$) m.p. 46 ± 2°C., as

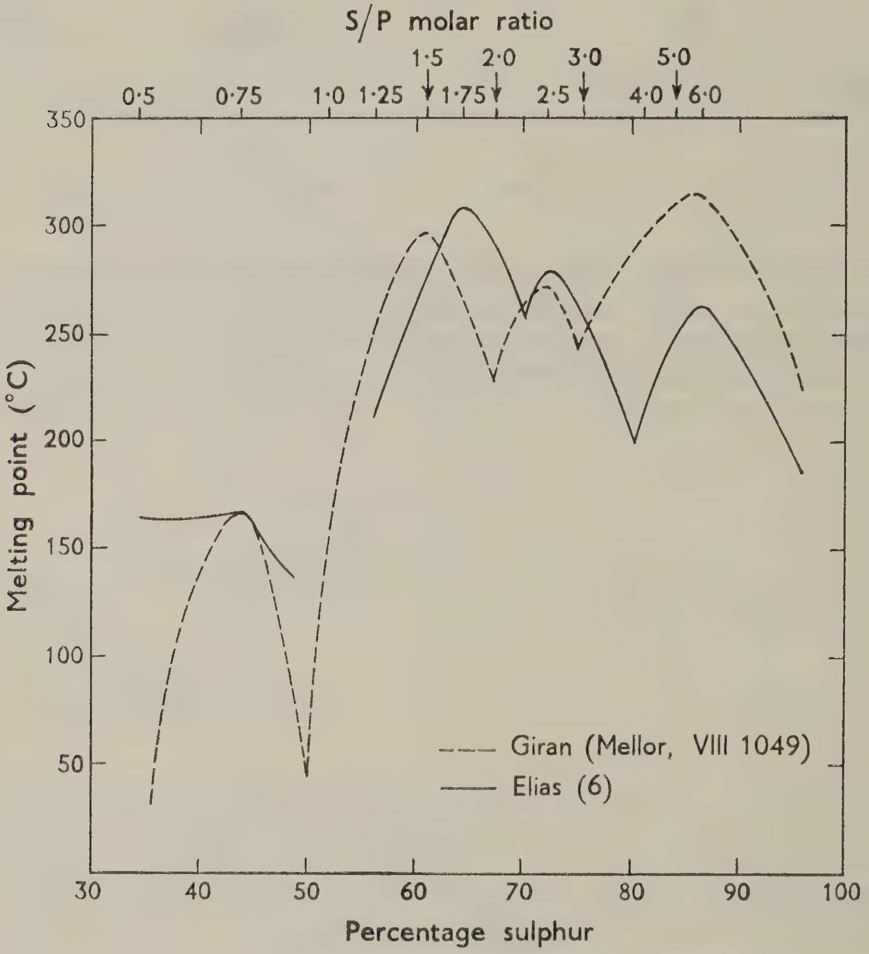

FIG. 3.—Fusion curve of phosphorus–sulphur compositions

well as the compounds $P_4S_6$ with a peritectic at 232°C. and $P_4S_5$ (peritectic 162°C.). $P_4S_{24}$ was not detected in this study. Eutectics were observed as follows: $P_4S_{10}$–S, 1·5% P, 112°C.; $P_4S_7$–$P_4S_{10}$, 31·0% P, 251°C.; $P_4S_3$–$P_4S_5$, 53·0% P, 106°C.; $P_4S_2$–$P_4S_3$, 18°C.; $P_4$–$P_4S_2$, 77 ± 2% P, −65 ± 5°C.[106]

After considerable controversy[1, 7–10] the existence of tetraphosphorus hexasulphide seemed to be established by its identification as a phase of variable composition, stable within narrow temperature limits, and having a unique *X*-ray diffraction pattern.[11] The same pattern is exhibited by the thiohydrolysis product of phosphorus trichloride. However, an *X*-ray diffraction study of this product shows it to be a defect form of tetraphosphorus heptasulphide.[108] Evidence[8, 9] for the existence of tetraphosphorus pentasulphide in this material can be explained by assuming its decomposition on dissolution in carbon disulphide. On the other hand, there seems little doubt that the sulphides $P_2S_4$ and $P_8S_{11}$, described by Dervin

(Mellor, VIII, 1047), were in reality impure $P_4S_7$ and $P_4S_5$.[8–9] Phosphorus monosulphide, $(PS)_n$, hitherto known only in the monomeric state as a spectroscopic entity,[12–3] has been prepared[14] by the action of magnesium on thiophosphoryl bromide:

$$2PSBr_3 + 3Mg \rightarrow \frac{2}{n}(PS)_n + 3MgBr_2$$

Ill-defined phosphorus sulphides are also formed by the interaction of phosphine with sulphur or hydrogen sulphide,[15] their composition depending on the initial proportions of reactants:

$$2PH_3 + nS \rightarrow 3H_2S + P_2S_{n-3}$$
$$2PH_3 + nH_2S \rightarrow (3+n)H_2 + P_2S_n$$

The former reaction goes rapidly to completion at 450°C.; the latter is slower, although more rapid than the decomposition of either reactant alone.

Nuclear magnetic resonance, viscosity and reactivity studies of a range of phosphorus sulphide melts of varying composition[78, 83] have led to the conclusion that the simple 'cage' molecules described above, and based essentially on $P_4$, predominate in melts of low sulphur content. Using S/P mole ratios greater than about 0·9, however, amorphous phosphorus sulphides of infinitely variable composition can be obtained. These, while having some 'cage' structures, contain also a considerable amount of random network polymer, the proportion and detailed structure of which depend on the S/P molar ratio. At very high S/P ratios, for example, the system can be regarded as a network of elastomeric plastic sulphur $(S\mu)_n$ cross-linked by phosphorus.[84–5] Two good reviews of this subject have appeared[78, 99] which draw on earlier work.[8, 10] Commercial aspects have also been discussed.[41]

## TETRAPHOSPHORUS TRISULPHIDE (PHOSPHORUS TETRITATRISULPHIDE; PHOSPHORUS SESQUISULPHIDE), $P_4S_3$

### Preparation

A typical plant for the commercial manufacture of this substance has been described.[16] The process involves batch reaction of molten sulphur and phosphorus at 350°C. followed by distillation of the product at 410°C. and 760 mm. Hg. Alternative continuous procedures, in which the heat of reaction is absorbed in a 'heel' of product or used to effect its distillation, have been suggested.[17–8] The introduction of small amounts of oxygen during the distillation has been claimed to improve the colour of the product[19] but this leads to the formation of oxysulphides, and an inert atmosphere is usually employed, the distillate being cast into blocks or flaked. The technical product can be purified by boiling with water for 2 hr. to hydrolyse other sulphides, drying, and dissolving in carbon disulphide. The solution is further dried over phosphorus pentoxide, filtered and evaporated. If well-formed crystals are required, the sulphide can be recrystallised by slowly cooling an almost saturated benzene solution from a temperature not exceeding 40°C., air being excluded by a blanket of inert gas.[20]

### Physical Properties

Tetraphosphorus trisulphide forms brick-shaped yellow crystals, showing full orthorhombic symmetry with right angles clearly displayed. Often the crystals are six-sided and columnar along the [*b*] axis with [100] the well-developed face. Sometimes poorly formed pyramidal faces develop at the ends.[6, 8] When warmed this solid undergoes a transition at 313·90°K.,[107] which has been detected by adiabatic calorimetry,[107] microscopy, dilatometry and differential thermal analysis.[2, 20–1] The entropy of transition $\Delta S_t$ is $7{\cdot}85 \pm 0{\cdot}03$ g.-cal./(mole °K.), and the enthalpy of transition $2{\cdot}464 \pm 0{\cdot}01$ kg.-cal./mole, in close agreement with earlier estimates of $+3{\cdot}4$[20]

and $+2{\cdot}5 \pm 0{\cdot}3$ kg.-cal./mole,[21] obtained by differential thermal analysis. The entropy of $P_4S_3$ at 298·15°K. is 48·60 g.-cal./(mole °K.).[107] Nothing is known of the crystal structure of the high temperature form, which melts at 172·6–173°C.[22] to a brownish-yellow liquid. The heat and entropy of fusion have been determined by differential thermal analysis to be $+1{\cdot}2$ kcal./mole and 2·8 e.u./mole, respectively, while the heat of vaporization is $+12{\cdot}2$ kcal./mole,[21] $+15{\cdot}2 \pm 0{\cdot}4$ kcal./mole, giving an entropy of vaporization of $22{\cdot}4 \pm 0{\cdot}7$ e.u./mole.[106] Values for the b.p. (408°C.,[23, 8] $407 \pm 2$°C.[10, 6]) agree with earlier determinations. The density of the low-temperature crystalline form, calculated from $X$-ray diffraction data (2·06 g./c.c.),[24] is also in good agreement with the earlier experimental value given by Stock (2·03 g./c.c. at 17°C.) and confirmed by later workers.[1] The apparent linear coefficients of expansion of the two forms, as determined by $X$-ray diffraction, are $2{\cdot}5 \pm 0{\cdot}6 \times 10^{-6}$°K.$^{-1}$ (295–308°K.) for the low-temperature form and $3{\cdot}2 \pm 1{\cdot}7 \times 10^{-6}$°K.$^{-1}$ (319–337°K.) for the high temperature form.[107] The density and surface tension of liquid tetraphosphorus trisulphide at 172·2°C. are 1·7935 g./c.c. and 22·86 ergs/cm.$^2$, respectively.[25]

The parachor calculated from these data accords better with the accepted structure for $P_4S_3$ (Fig. 1) than with previously proposed structures. The value of 0·81$D$ for the dipole moment of $P_4S_3$ in benzene solution, and the molar refractivity 57·8 (calc. 59·3),[26] are also in harmony with the general outlines of the structure given in Fig. 1 and Tables I and II, which has been established both by electron diffraction in the vapour phase[27–8] and $X$-ray diffraction on the solid.[2, 24, 29] The high-resolution phosphorus nuclear magnetic resonance spectrum[30–1] of $P_4S_3$ shows two absorptions, corresponding to the presence of phosphorus atoms in two distinct environments. One peak, a quadruplet of chemical shift $-71 \pm 1$ p.p.m., corresponds to a single phosphorus atom connected through sulphur atoms to three other phosphorus atoms. The other, a doublet of chemical shift $+120 \pm 1$ p.p.m., is attributed to three identical phosphorus atoms, presumably those in the $P_3$ ring. The high absolute values of the chemical shifts, as in the $P_4$ molecule, can probably be explained by the effect on bond hybridisation of the high degree of strain in the molecule. They are confirmed by independent measurements on the solid sulphide, using a rapidly rotating specimen technique, which gave values of $+103$ and $-72$ p.p.m. relative to 85% phosphoric acid.[111]

The Raman spectrum of tetraphosphorus trisulphide[22] shows absorption frequencies of 442, 420, 290 and 87 cm.$^{-1}$ (symmetrical, polarized) and 486, 384, 341, 221 and 154 cm.$^{-1}$ (degenerate, depolarized). Force constants calculated from these data on the basis of the accepted structure gave the values $f_1$ ($P_4S_1$) $16{\cdot}3 \times 10^4$, $f_2$ ($P_1S_1$) $16{\cdot}7 \times 10^4$, and $f_3$ (P–P) $10{\cdot}7 \times 10^4$ dynes/cm., respectively, in reasonable agreement with values calculated by the empirical rules of Badger and Gordy. The compound shows broad infra-red absorption maxima at 430 and 473 cm.$^{-1}$.[22] Other workers have found absorptions at 427, 440, 447 and 486 cm.$^{-1}$ in carbon disulphide solution.[6]

As would be expected in a molecule having no centre of symmetry, solid tetraphosphorus trisulphide shows no pyro- or piezoelectric effects.[20] An estimated value of 32 kcal./mole for the enthalpy of formation of tetraphosphorus trisulphide[21] was obtained by a study of the reaction:

$$4P_{\text{red}} + 3S_{\text{liq.}} \xrightarrow{200\text{–}260°} P_4S_{3\ \text{liq.}}$$

using differential thermal analysis. The observed heat of reaction was corrected for heat of fusion and phase change.

## Chemical Properties

Solutions of tetraphosphorus trisulphide in organic solvents absorb oxygen from the air, with precipitation of a yellowish-white amorphous solid having the empirical formula $P_4S_3O_4$, which is discussed in more detail on page 435.[32]

The trisulphide shows the lowest reactivity towards water of all the phosphorus sulphides, a fact which may be used in its purification. The conductivity of a suspension of the sulphide in water at 60°C. is almost zero and increases only very slowly with time, unlike $P_4S_7$ and $P_4S_{10}$ which both show a great increase in conductivity over 3 hr.[33, 99] Hydrolysis is reasonably rapid in boiling dilute sodium hydroxide solution, giving hydrogen sulphide, phosphine and varying amounts of phosphorus oxyacids (see Table III).

*Table III.—Alkaline Hydrolysis Products of Tetraphosphorus Trisulphide*

| Reference | Atoms of P per mole $P_4S_3$ determined as: | | | | |
|---|---|---|---|---|---|
| | $PH_3$ | $H_3PO_2$ | $H_3PO_3$ | $H_3PO_4$ | unaccounted for |
| 1 | 0·2 | 0·6 | 3·0 | — | 0·2 |
| 10 | 0·1 | 1·5 | 2·0 | 0·2 | 0·2 |

In acid solution hydrolysis is much slower[1] but under paper chromatographic conditions using an acid solvent, a mixture of thiophosphates, thiophosphites and thiohypophosphites is formed from $P_4S_3$, as in the case of $P_4S_7$ (q.v.)[34]; alkaline oxidative hydrolysis leads to a mixture of phosphorus oxyanions, discussed more fully under the heptasulphide.[97, 109]

The primary product of the reaction between tetraphosphorus trisulphide and liquid ammonia at −33°C. is a hygroscopic brownish-orange compound of empirical formula $P_4S_3{,}4NH_3$.[23] When heated *in vacuo* this loses ammonia in stages to give $P_4S_3{,}3NH_3$ and $P_4S_3{,}2NH_3$, both of which revert to the original compound on solution in liquid ammonia. At higher temperatures the compound $P_4S_3{,}2NH_3$ gives $P_4S_3$, ammonia and a residue which, after repeated extraction with ammonia followed each time by heating at 180°C., is found to have the formula $P_4S_2NH{,}4NH_3$. $P_4S_2NH{,}4NH_3$ is a dark brown solid, non-hygroscopic and insoluble in liquid ammonia. It evolves between one and two moles of ammonia when heated to 180°C. *in vacuo*, giving a mixture of $P_4S_2NH{,}3NH_3$ and $P_4S_2NH{,}2NH_3$.

The compounds $P_4S_3{,}nNH_3$ and $P_4S_2NH{,}4NH_3$ are soluble with hydrolysis in water or alkalis, but insoluble in dilute non-oxidizing acids. When heated at even higher temperatures (275°C.) extensive decomposition sets in and $P_4S(NH)_2$ and $P_4(NH)_3$ are formed. The latter compound is deep orange, insoluble in $CS_2$ and is decomposed by hot alkalis with evolution of phosphine. If heated to 400°C. it evolves phosphorus vapour and ammonia, phosphorus pentanitride, $P_3N_5$, being formed:

$$5P_4(NH)_3 \rightarrow 2P_3N_5 + 5NH_3 + 14P$$

This extensive series of reactions can be explained completely on the basis of the accepted structure for the trisulphide as shown in Fig. 4.

Tetraphosphorus trisulphide reacts rapidly with iodine in carbon disulphide, 7·9–8·1 atoms of iodine being taken up per mole of sulphide. Besides the phosphorus tri-iodide previously reported (Mellor, VIII, 1051), tetraphosphorus heptasulphide can be isolated in 34% yield based on the equation:

$$7P_4S_3 + 24I_2 \rightarrow 16PI_3 + 3P_4S_7$$

An intermediate compound, $P_4S_3I_8$, was postulated,[1] but the reaction has more recently been shown to proceed via the known $P_4S_3I_2$,[35] an orange yellow solid, m.p. 120·5°C. A solution of the trisulphide in carbon disulphide also rapidly takes up 8·2–8·4 atoms of bromine per mole of sulphide, but no products have been recorded. The reaction between tetraphosphorus trisulphide and bromine in an aqueous acid medium has been followed potentiometrically. The results correspond to no simple mechanism, between 23 and 28 atoms of bromine being absorbed for every mole of the trisulphide, and sulphur is the only product observed.[1]

Because of its low reactivity, tetraphosphorus trisulphide is little used as an intermediate in organic chemistry. With alcohols, a melt of composition $P_4S_4$ (which was presumably composed mainly of $P_4S_3$ [83]) gave poor yields of dialkyl phosphorothioites, $(RO)_2PSH$, and di- and trialkyl phosphorodithioates, $(RO)_2PS(SH)$ and $(RO)_2PS(SR)$.[36] Ethylmagnesium bromide gives a mixture of di- and triethylphosphine, triethylphosphine sulphide and tetraethylphosphonium bromide in poor yields. With phenylmagnesium bromide the yield of phenylated products is rather better and diphenyldithiophosphinic acid, $(Ph)_2PS(SH)$, is formed as an additional product.[37] Unlike tetraphosphorus decasulphide the trisulphide does not react with anisole.[38]

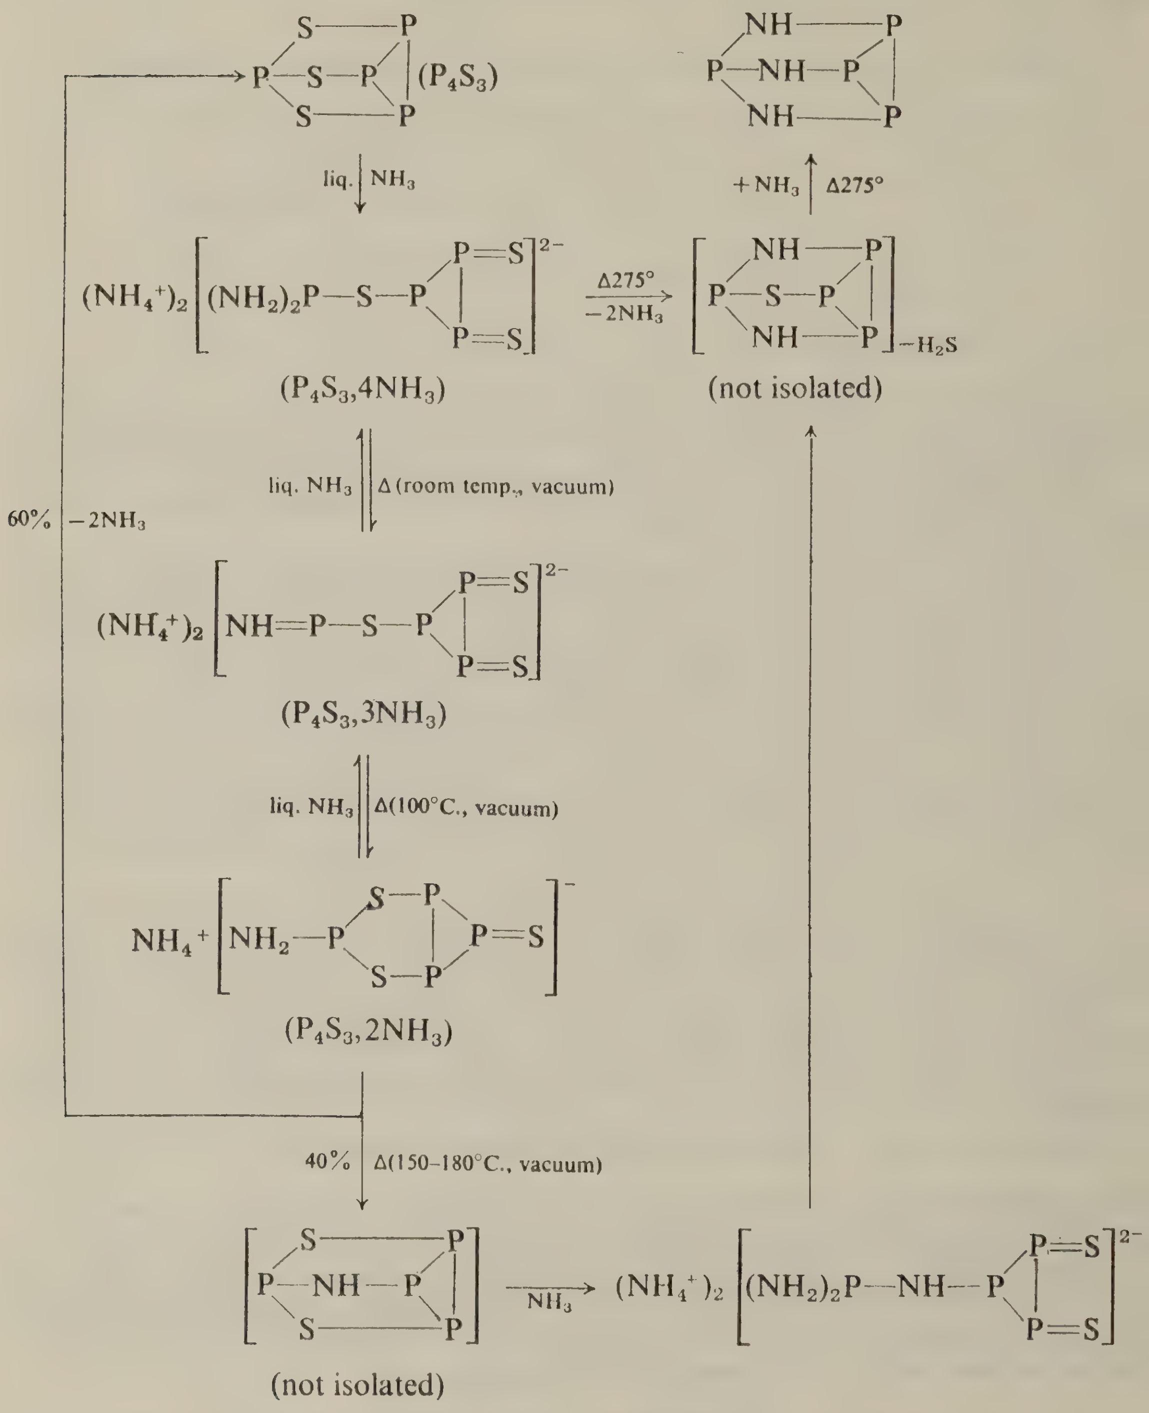

FIG. 4.—The ammonolysis of tetraphosphorus trisulphide

## PHOSPHORUS MONOSULPHIDE, PS

Two band systems can be detected in the ultraviolet emission spectrum of a helium discharge tube containing a small amount of tetraphosphorus trisulphide. One of these, which appears in the region 2700–3100 A. and shows a doublet splitting of 324 cm.$^{-1}$, is assigned to the species PS and the other, a singlet system in the region 2300–2750 A., to PS$^{+}$.[12–3] There is some evidence[14] that a compound of empirical formula PS is formed by the reaction of thiophosphoryl tribromide with magnesium in absolute ether:

$$2PSBr_3 + 3Mg \rightarrow (PS)_x + 3MgBr_2$$

It is described as a pale yellow powder, insoluble in the common organic solvents but containing small amounts of a crystalline material, $(PS)_n$, which forms lemon-yellow crystals from carbon disulphide. A gradual transformation from the amorphous to the crystalline form is claimed to occur on warming. The amorphous material decomposes at 135–140°C., the crystalline at 240°C. Both forms slowly hydrolyse in damp air, giving hydrogen sulphide and a mixture of hypophosphorous and phosphorous acids. Owing to its sparing solubility (80 mg./100 ml. at 23°C. in carbon disulphide) the mol. wt. of the crystalline form could not be determined, but in view of the ready interconversion of the phorphorus sulphides, even in solution, further confirmation of its structure and analysis is obviously desirable.

## TETRAPHOSPHORUS PENTASULPHIDE (PHOSPHORUS TETRITAPENTASULPHIDE), $P_4S_5$

### Preparation

Tetraphosphorus pentasulphide decomposes below its melting point[11]:

$$2P_4S_5 \rightleftharpoons P_4S_3 + P_4S_7$$

and hence cannot be obtained directly from a melt[1] although it results, together with the heptasulphide, from the extraction with carbon disulphide of a solidified melt of $P_4S_6$ composition.[33] It is best prepared following the method of Bouloch (Mellor, VIII, 1047), by irradiation of a solution of tetraphosphorus trisulphide and sulphur in carbon disulphide, using a trace of iodine as catalyst. The precipitated mass is washed with carbon disulphide, and recrystallized from the same solvent in a Soxhlet apparatus, all operations being conducted in an inert atmosphere.[8, 20]

### Physical Properties

Tetraphosphorus pentasulphide forms sulphur-yellow monoclinic crystals,[3] usually aggregated flat triangular plates, which are always twinned. The [*b*] axis is markedly uniterminal in appearance, showing that the crystals belong to the hemimorphic class of the monoclinic system.[6] A value of 10 g. per 100 g. $CS_2$ has been given for the solubility of the pentasulphide at 17°C.[39] This figure is possibly an estimate, since a solubility of 0·3–0·5 g. per 100 g. $CS_2$ has been independently determined by three other workers.[6, 11, 20] A solubility of 14·1 g. per 100 g. *o*-dichlorobenzene at 179°C. has also been recorded[8]; it was claimed that no decomposition was apparent from the infra-red spectrum of the recrystallized product.

The solid melts over the range 170–220°C.[1]: *X*-ray evidence shows that decomposition to $P_4S_3$ and $P_4S_7$ is already occurring in the solid at about 130°C.[11] Values of the density of the solid as determined directly[1] (2·17 g./c.c. at 25°C.) and from *X*-ray data[3] (2·15 g./c.c.) are in good agreement.

The unexpected and highly irregular structure of the tetraphosphorus pentasulphide molecule seems well established[3, 20] (see Fig. 1 and Tables I and II). Particularly interesting evidence is that given by the $^{31}P$ nuclear magnetic resonance spectrum of the solid, which shows three broad but well-spaced lines at $-200$, $-20$ and $+120$ p.p.m. relative to 85% orthophosphoric acid.[111] Optical activity, which would be expected in such a molecule, is not exhibited by solutions of the pentasulphide in carbon disulphide.[8] This could, however, be due to ready racemization or the existence of two racemic forms. The infra-red spectrum of the pentasulphide in carbon disulphide solution shows absorptions at 528 and 707 cm.$^{-1}$ [6] The '*d* values' of the three most intense lines in the *X*-ray diffraction pattern have been given as 4·76, 3·09, 1·78 A.[6] and 4·83, 3·09, 5·2 A.[8] An approximate value of $-50$ kcal./mole for the heat of formation has been estimated by differential thermal analysis[21] using the reaction:

$$P_4S_{5\text{cryst.}} + 2S_{\text{liq.}} \xrightarrow{155°\text{C.}} P_4S_{7\text{cryst.}}$$

### Chemical Properties

Although it is stable at room temperature, and can be recrystallised with suitable precautions, tetraphosphorus pentasulphide is the most reactive and unstable of the four authenticated phosphorus sulphides. In carbon disulphide solution at 170°C. it appears to exist in a mobile equilibrium with the tri- and hepta-sulphides.[11] The pentasulphide is also very readily hydrolysed and crystals of the compound decompose fairly quickly unless protected from moisture. As in the case of the tri- and hepta-sulphides, the products of hydrolysis include thio-phosphates, -phosphites and -hypophosphites.[34, 97, 109] The reaction with ammonia has been closely studied.[23] The sulphide dissolves readily in liquid ammonia and on evaporation of the solution at $-33$°C. a canary yellow hygroscopic solid of empirical formula $P_4S_5,6NH_3$ can be recovered. This product, which forms ammonia-insoluble salts with complex ammono-cations such as $[Cr(NH_3)_6]^{3+}$ or $[Ni(NH_3)_4]^{2+}$, contains the tribasic anion $[P_4S_5(NH_2)_3]^{3-}$, and probably has some such structure as

$$(NH_4)_3{}^+[(NH_2)_2P\text{–}S\text{–}P(S)\text{–}P(S)\text{–}P(S)NH_2]^{3-}$$

When heated *in vacuo* to +70°C., this compound decomposes with loss of ammonia giving a golden yellow solid of formula $P_4S_5,4NH_3$. At higher temperatures (140°C.) this loses hydrogen sulphide and more ammonia to give $P_4S_3(NH)_2$, presumably analogous to $P_4S_5$, which in its turn decomposes at 180°C. into tetraphosphorus trisulphide and a colourless involatile solid of empirical formula $P_4S_3(NH)_7$. The last compound, formally analogous to $P_4S_{10}$, is insoluble in carbon disulphide or liquid ammonia and is hydrolysed by water or dilute acids to phosphoric acid, hydrogen sulphide and ammonia. It is stable to alkalis even on boiling. Further treatment with ammonia gas at 750°C. converts it into triphosphorus pentanitride, $P_3N_5$. The decomposition of $P_4S_5,4NH_3$ gives rise also to minor quantities of tetraphosphorus decasulphide, heptasulphide and heptasulphide tri-imide (colourless and insoluble in carbon disulphide) which may be separated by taking advantage of their differing volatilities and solubilities. Little else is known of the reactions of tetraphosphorus pentasulphide. A study of its reaction with ethanol[36] gave no identifiable products, and was in any case probably carried out with a fusion product of phosphorus and sulphur analysing as $P_4S_5$. Such a product would be a mixture of tetraphosphorus tri- and heptasulphides with varying amounts of the metastable '$\beta$-heptasulphide' phase.

## TETRAPHOSPHORUS HEXASULPHIDE ($P_4S_6$)

### Preparation

Several early claims for the existence of a compound with an empirical formula $P_4S_6$ (or $P_2S_3$) were discounted by other authors (Mellor, VIII, 1052), since melts of this composition could readily be separated into tetraphosphorus trisulphide and heptasulphide by sublimation or crystallization. Beeli[33] showed that the products of solvent extraction of a sulphide sample of composition $P_4S_6$ were in fact tetraphosphorus pentasulphide and heptasulphide. This was later confirmed[8–9] and the same workers also showed that a sulphide of identical composition formed from phosphorus trichloride and liquid hydrogen sulphide at room temperature[7] could be resolved in the same way.

Fresh evidence is, however, provided by an *X*-ray study[11] of melts with compositions in the range $P_4S_5$ to $P_4S_{6\cdot9}$. If these are made up from tetraphosphorus trisulphide and sulphur or the heptasulphide, the product on cooling has a unique *X*-ray powder diagram, unlike that of any known sulphide. Melts made from red phosphorus and sulphur also contain this new phase, but are mixed with other sulphides unless catalytic amounts of iodine are added, when the new phase alone is formed. The reaction product of phosphorus trichloride and hydrogen sulphide also shows the same diffraction pattern, though there is some evidence of other material being present.

### Physical Properties

Tabular lemon-yellow crystals of the new phase can be obtained by slow cooling of melts with compositions near to $P_4S_6$. Such crystals sinter at 235°C. and melt with decomposition between 250° and 290°C. The strongest powder lines have *d* values 5·72(s), 3·62(ms), 2·95(ms) and 2·86(s) A. The mother liquor on solidification shows the same diffraction pattern, although its melting point is lower, and this evidence of segregation, together with the wide composition range over which the phase is formed, suggests that it may be of variable composition. This is supported by the observation that there is a regular increase in the *X*-ray powder line spacings, corresponding to a decrease in lattice dimensions, with decreasing sulphur content.

The crystals have an orthorhombic unit cell, of space group *Pbcn* with cell lengths $a = 8{\cdot}14 \pm 0{\cdot}04$, $b = 11{\cdot}43 \pm 0{\cdot}03$, $c = 11{\cdot}39 \pm 0{\cdot}03$ A. and density 2·09 g./c.c.[108] With 4 molecules per unit cell, the statistical composition would be $P_4S_{6\cdot6}$, and the *X*-ray data cannot be reconciled with any simple stoicheiometry. Analysis of specimen crystals is difficult because of their instability, but again suggests that they contain more sulphur than the $P_4S_6$ melt from which they are formed. The problem has been resolved by an *X*-ray investigation which shows that the new phase comprises molecules of $P_4S_7$ of the same type as those found in the stable ($\alpha$) phase of this composition. However, molecules of the new ($\beta$) phase, unlike $\alpha$-$P_4S_7$, have an exact crystallographic 2-fold symmetry axis, and there is crystallographic evidence for a deficiency of sulphur in the apical positions, which accounts for the peculiar composition. The molecular dimensions are those of $\alpha$-$P_4S_7$, except that the P–P bond has a more normal length of 2·26 A.[108]

### Chemical Properties

'$\beta$-Tetraphosphorus heptasulphide' is stable only over the narrow temperature range 200–250°C. Rapid chilling from 270°C. of a partly melted specimen shows $\alpha$-tetraphosphorus heptasulphide to be present, though normally such melts supercool sufficiently for the $\beta$-heptasulphide to separate. Below 200°C. the $\beta$-heptasulphide also decomposes to the trisulphide and $\alpha$-heptasulphide, but the process is sufficiently slow (about 1 day at 195°C.) for the $\beta$-heptasulphide to be cooled with little decomposition to room temperature, where it may be preserved for several months. Sublimation decomposes the sulphide into $\alpha$-tetraphosphorus heptasulphide and trisulphide, whilst treatment with carbon disulphide gives these two sulphides and, in addition, tetraphosphorus pentasulphide.[11] It is claimed that a melt of $P_4S_6$ composition is more effective in reducing phenols to hydrocarbons than trisulphide or $\alpha$-heptasulphide, either alone or in admixture.[102]

## TETRAPHOSPHORUS HEPTASULPHIDE (PHOSPHORUS TETRITAHEPTASULPHIDE), $P_4S_7$

### Preparation

Tetraphosphorus heptasulphide can be obtained from solidified melts of composition between $P_4S_6$ and $P_4S_8$ by extraction with carbon disulphide in a Soxhlet apparatus, when the sparingly soluble heptasulphide crystallizes in the flask.[33] The preparative procedure of Mai (Mellor, VIII, 1053) has been confirmed by later workers.[8–9] It involves heating appropriate mixtures of sulphur and phosphorus or phosphorus sesquisulphide in boiling xylene, in the presence of a trace of iodine, followed by recrystallization of the product from carbon disulphide. Tetraphosphorus heptasulphide is also formed by the action of sulphur on diphosphorus tetraiodide, or phosphorus with a trace of iodine, in cold carbon disulphide solution.[100] Several procedures have been described for the commercial production of this sulphide, both from the elements[17–8] and by reaction of mixtures of sulphur and ferrophosphorus.[40] However, it is not widely used commercially, probably because of its ready hydrolysis and the poorly defined character of its organic reaction products.[10, 41]

## Physical Properties

Crystals of tetraphosphorus heptasulphide are usually very small and often fragmentary. They are squat and columnar along the [*c*] axis, with poorly developed end faces. The refractive indices are $\alpha = 1{\cdot}465$ (along the crystal [*b*] axis), $\beta = 1{\cdot}48$, $\gamma = 1{\cdot}49$, with $\gamma \wedge [c] = 10°$.[6] They are almost white with a faint yellowish tinge.[8] The sulphide melts at 310°C. and boils at 523°C.[23] (cf. m.p. 308 ± 1°C., b.p. 529 ± 2°C.[106]). Values of +17·5 kcal./mole for the heat of fusion, and +20·0 kcal./mole for the heat of vaporisation, have been estimated by differential thermal analysis.[21] Later values of 22·4 ± 0·6 kg.-cal./mole and 27·9 ± 1·0 e.u./mole have been recorded for the heat and entropy of vaporization respectively.[106] The density, 2·19 g./c.c., calculated from *X*-ray diffraction data[4] agrees exactly with an earlier experimental value.[42]

The structure of the tetraphosphorus heptasulphide molecule has been established by *X*-ray diffraction[4] (see Fig. 1 and Tables I and II). The lengths of the P–S and P═S bonds agree well with the corresponding bonds in the $P_4S_{10}$ molecule but, as previously pointed out, there is no analogy for the unusually long P–P bond.

The infra-red spectrum of the heptasulphide in carbon disulphide solution shows absorptions at 452, 480, 509, 538, 698 and 708 cm.$^{-1}$ [6]

The '*d* values' of the strongest lines in the *X*-ray powder photograph are given as 2·92, 3·10, 6·21[8]; 2·90, 6·30, 6·40[6]; 2·92, 3·09, 6·19 A.[11] Tetraphosphorus heptasulphide is very sparingly soluble in carbon disulphide (Mellor, VIII, 1054) and even in *o*-dichlorobenzene at 179°C. only 1·32 g. of sulphide dissolves in 100 g. of solvent.[8]

By the differential thermal analysis of heated mixtures of $P_4S_{3\text{cryst.}} + 4S_{\text{liq.}}$ and $4P_{\text{red}} + 7S_{\text{liq.}}$ it was established that between 160° and 275°C. formation of heptasulphide is almost complete. Values of the enthalpy of formation derived from the observed heats of reaction are in good agreement, the mean value being 71 ± 10 kcal./mole.[21]

## Chemical Properties

Cold water attacks tetraphosphorus heptasulphide slowly, with evolution of hydrogen sulphide. In hot water the reaction is rapid, and phosphine and hydrogen occur among the products.[41] The electrical conductivity of a slurry of tetraphosphorus heptasulphide in water increases very rapidly with time, eventually reaching a constant value which is nearly twice as great as that given by the same amount of the decasulphide.[33] The sulphide also hydrolyses rapidly in dilute acids or alkalis, the final products being hydrogen sulphide, phosphine and phosphorus oxyacids (see Table IV).

*Table IV.—Alkaline Hydrolysis Products of Tetraphosphorus Heptasulphide*

| Reference | Atoms of P per mole $P_4S_7$ determined as: | | | | |
|---|---|---|---|---|---|
| | $PH_3$ | $H_3PO_2$ | $H_3PO_3$ | $H_3PO_4$ | Unaccounted for |
| 1 | 0·1 | 0·1 | 1·5 | 2·3 | — |
| 10 | — | 0·95 | 0·87 | 2·03 | 0·15 |

Under milder conditions intermediate hydrolysis products can be isolated. Thus on a paper chromatogram, using the alcoholic trichloroacetic acid solvent of Ebel, tetraphosphorus heptasulphide gave a number of spots, which by their chemical behaviour and by comparison with standards, were identified with fair certainty as mono- and di-thiohypophosphite, monothiophosphite and monothiophosphate.[34] The mechanism proposed for their formation is shown in Fig. 5.

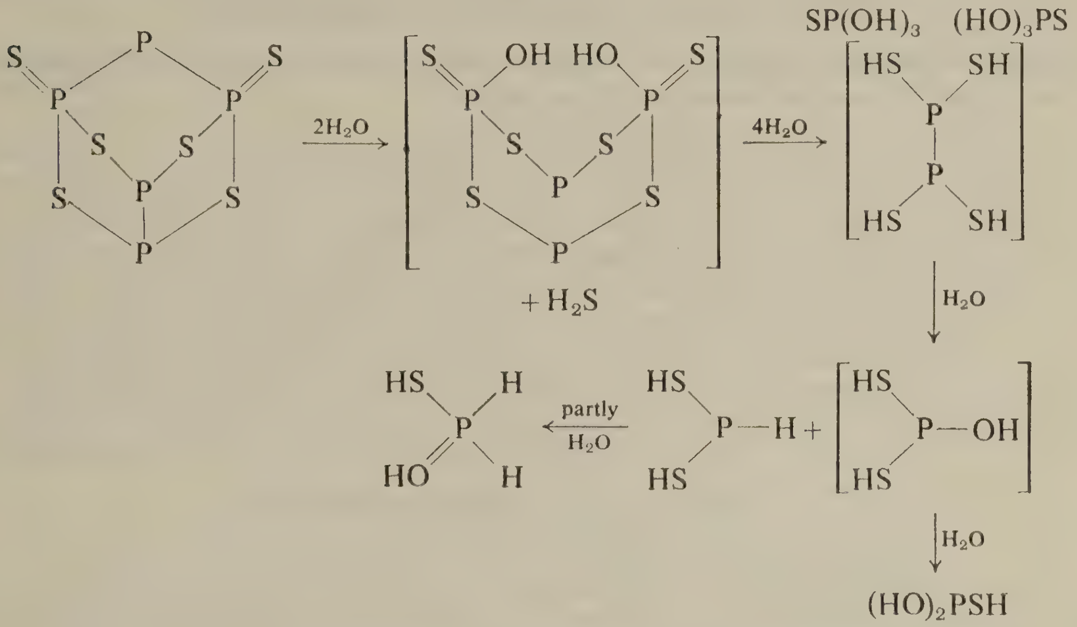

FIG. 5.—The hydrolysis of tetraphosphorus heptasulphide

Alkaline hydrolysis of the lower phosphorus sulphides in the presence of hydrogen peroxide, on the other hand, gives a number of oxyacids.[97, 109] Some of these retain P–P bonds present in the parent sulphides. The anions may be detected and determined by paper chromatography, and are present in the proportions shown in Table V.

*Table V.—Oxidative Hydrolysis Products of Lower Phosphorus Sulphides*

| Sulphide | Anion (Percentage based on initial P added) | | | | | |
|---|---|---|---|---|---|---|
| | $(HPO_3)^2$ | $(PO_4)^{3-}$ | $(P_2O_7)^{4-}$ | $(P_2O_6)^{4-}$ | $(PO_3.PO_2.PO_3)^{5-}$ | $(PO_3.O.PO_2.PO_3)^5$ |

The products of ammonolysis can also be explained by reference to the structure of the sulphide.[43] One mole of the sulphide reacts with 8·5 moles of liquid ammonia at −33°C. according to the equation:

$$2P_4S_7 + 17NH_3 \rightarrow (NH_4)_3PS_4 + 2(NH_4)_2PS_3NH_2 + (NH_4)_3(P_3S_3(NH)_3) + NH_4P_2SN$$

The mechanism was established by quantitative isolation of $(NH_4)_3PS_4$ and $(NH_4)_2PS_3NH_2$, which differ in their solubility in liquid ammonia. The highly soluble $(NH_4)_3(P_3S_3(NH)_3)$ was isolated as the double salt $Ni(NH_3)_4NH_4(P_3S_3(NH)_3)$, in almost theoretical yield. The results accord with the roughly equal participation of the two routes of ammonolysis shown in Fig. 6.

Tetraphosphorus heptasulphide does not react with bromine or iodine in carbon disulphide solution. In an aqueous medium reaction is rapid, roughly 30 atoms of bromine being taken up per mole of sulphide. Sulphur was the only product identified.[1]

As with the other lower sulphides, the organic reactions of the heptasulphide have been little studied. The lower alcohols yield a variety of products, including di- and trialkyl phosphorodithioates, $(RO)_2PSSH$ and $(RO)_2PS(SR)$, and dialkyl phosphorothioites, $(RO)_2PSH$.[36, 83] Grignard reagents alkylate the phosphorus, largely according to the equation:

$$P_4S_7 + 12RMgX \rightarrow 3R_3P + R_3PS + 6MgS + 6MgX_2$$

although dialkylphosphinodithioic acids, $R_2PS_2H$, and alkylphosphonotrithioic acids, $RPS_2SH$, may be formed as by-products.[37]

FIG. 6.—The ammonolysis of tetraphosphorus heptasulphide

## TETRAPHOSPHORUS DECASULPHIDE (PHOSPHORUS TETRITADECASULPHIDE, PHOSPHORUS PENTASULPHIDE), $P_4S_{10}$

### Preparation

Tetraphosphorus decasulphide is commercially the most important of all the phosphorus sulphides, and for this reason it has been extensively studied, but certain aspects of its chemistry remain to be explained. Of the two forms reported by Stock to occur in the commercial sulphide (Mellor, VIII, 1055) only that with the lower solubility in carbon disulphide has been characterized.

A laboratory preparation of the sulphide by reaction between white phosphorus and sulphur in an organic solvent has been described[44] but the preferred method is still that of Stock,[45] involving the recrystallization of a solidified melt. Purification is assisted if the crude sulphide is caused to react with ethanol until half is dissolved. The residue requires little recrystallization to give pure tetraphosphorus decasulphide.[46] Isotopically labelled tetraphosphorus decasulphide has been obtained by exchange reaction of the inactive sulphide with carrier free $H_3{}^{32}PO_4$. The product retained its specific activity through repeated recrystallizations from carbon disulphide.[47]

A continuous process for the manufacture of the decasulphide has been described.[17, 41, 112] Liquid white phosphorus and sulphur in the correct proportions are fed continuously to a stirred heel of molten sulphide. The product overflows to a mixer-finisher for final adjustment of composition, and thence to a water-cooled drum flaker. In another process the heat of reaction is used to assist the distillation of the sulphide.[18] A product of improved colour obtained by introduction of oxidizing agents during this distillation[19] probably contains oxysulphides. The use of purified phosphorus is also claimed to give a product of good colour.[113]

Processes have been described for the manufacture of tetraphosphorus decasulphide from ferrophosphorus, a by-product of the electric furnace manufacture of phosphorus.[40, 48] The reactions concerned are:

$$4Fe_2P + 18FeS_2 \rightarrow P_4S_{10} + 26FeS$$
$$4Fe_2P + 18S \rightarrow P_4S_{10} + 8FeS$$

The manufacture of phosphorus sulphides, including the pentasulphide, by carbon reduction of phosphates in the presence of sulphur has also been claimed.[49] Finally it has been reported that tetraphosphorus decasulphide is formed by reaction of thiophosphoryl chloride with hydrogen sulphide in the presence of a tertiary base at 120–130°.[114]

### Physical Properties

Pure tetraphosphorus decasulphide forms well developed triclinic crystals. The most common habit is a combination of prismatic and pyramidal forms. Some crystals are lath- or needle-shaped and a very few rhomboidal, but all give the same *X*-ray unit cell measurements, showing that only one crystalline form is present. All the principal refractive indices seem to be less than 1·50, and the optical sign is positive. The crystals are weakly birefringent, as would be expected from the crystal structure, in which highly symmetrical molecules are arranged in a near-cubic lattice.[4, 6] A density of 2·11 g./c.c. deduced from *X*-ray diffraction data[4] is in good agreement with the experimental value of 2·09 g./c.c.[45] Tetraphosphorus decasulphide melts at 288 ± 1°C. and boils at 514 ± 2°C. Its enthalpy and entropy of vaporization are 21·3 ± 0·6 kcal./mole and 27·2 ± 1·2 e.u./mole, respectively.[106]

The structure of the tetraphosphorus decasulphide molecule[6] is entirely analogous to that of the H form of phosphoric oxide, $P_4O_{10}$[50] (see Fig. 1 and Tables I and II). The molecule is symmetrical, within the limits of experimental error. The infra-red spectrum[6] shows absorptions at 535 and 695 cm.$^{-1}$ The $^{31}P$ nuclear magnetic resonance spectrum of the solid sulphide, measured by a rapidly rotating specimen technique, shows a single line at −45 p.p.m. relative to 85% orthophosphoric acid (cf. −16 p.p.m. for $P_4O_6S_4$ and +48 p.p.m. for $P_4O_{10}$).[111] The '*d* values' of the strongest lines in the *X*-ray powder diagram are given as 2·86, 2·92, 4·04 A.[8]; 2·86, 2·88, 2·95 A.[6]

The variation of heat capacity with temperature between 30 and 350°K. is smooth, and shows no anomalies characteristic of a transition to a plastically crystalline phase, such as are observed with tetraphosphorus trisulphide. The entropy of $P_4S_{10}$ at 298·15°K. is 91·24 g.-cal./(mole °K.) and the molal heat capacity 70·74 g.-cal./°K.[107]

The solubility of tetraphosphorus decasulphide in both carbon disulphide and *o*-dichlorobenzene, is intermediate between that of the heptasulphide and of the trisulphide. The latter solvent dissolves 6·03 g. of decasulphide/100 g. of solvent at

179°C.[8] The decasulphide is also slightly soluble in chloronaphthalene and trichlorobenzene.[41]

### Other Forms of 'Phosphorus Pentasulphide'

The form of phosphorus decasulphide of which the properties have been described above is obtained in greatest yield by slow cooling of melts having a composition in the $P_4S_{10}$ region. It is highly crystalline, with a characteristic infra-red spectrum, and low solubility in carbon disulphide (0·22% at 17°C.). Its mol. wt. as determined by cryoscopy is in good agreement with the formula $P_4S_{10}$ (=444). Quick cooling of $P_4S_{10}$, from either melts or the vapour, gives a product which appears to be a mixture of this normal $\alpha$ form with other crystalline and amorphous forms. These have a much higher solubility in carbon disulphide (up to 4%), their infra-red spectra exhibit satellite absorptions around the main maxima at 535 and 695 cm.$^{-1}$ and mol. wt. determinations give values below 400. An *X*-ray study also reveals differences. Thus the *X*-ray powder diagram of pure $\alpha$-decasulphide exhibits a doublet (6·04 and 5·87 A.) and a singlet (3·67 A.), which in very quickly cooled 'pentasulphide' are replaced by a singlet (5·91 A.) and a doublet (3·81 and 3·76 A.), respectively. Intermediate cooling rates give intermediate values for the splitting.[6, 41, 51]

The pure $\alpha$-decasulphide gives a pale yellow solution in carbon disulphide, but that of the 'quickly-cooled' material is intensely yellow. The solid recovered from the latter solution is yellowish white and melts at about 250°C.[6] It reacts more rapidly and exothermically with aliphatic alcohols than does the $\alpha$ form and, remarkably, the products appear to be fewer in number.[83] The proportion of the reactive form can be raised by increasing the rate of cooling of the melt through the temperature range around the melting point, i.e. 280–260°C.[51–2] The reactivity of a quickly-cooled melt can also be reduced, and the proportion of $\alpha$-decasulphide correspondingly increased by reheating the solid for various times at temperatures between 150° and 270°C.[53, 105] In view of their high solubility and reactivity, these reactive forms of the decasulphide are not likely to be highly polymeric in character, though there is no evidence for the suggestion[41] that they contain diphosphorus pentasulphide, $P_2S_5$.

### Chemical Properties

The hydrolysis of tetraphosphorus decasulphide, if allowed to go to completion, results in the formation of phosphoric acid and hydrogen sulphide with only traces of other phosphorus compounds (see Table VI and more recent results[81] in Fig. 7).

*Table VI.—Alkaline Hydrolysis Products of Tetraphosphorus Decasulphide*

| Reference | Atoms of P per mole $P_4S_{10}$ expressed as: | | | | |
|---|---|---|---|---|---|
| | $PH_3$ | $H_3PO_2$ | $H_3PO_3$ | $H_3PO_4$ | Unaccounted for |
| 1 | — | 0·4 | — | 3·2 | 0·4 |
| 10 | — | — | — | 4 | — |

The polythiophosphoric acids, $H_3PS_4$, $H_3PS_3O$, $H_3PS_2O_2$ and $H_3PSO_3$, are probably involved as intermediates. These acids are all unstable, and can exist only in dilute solution, but their alkali metal salts are more stable, the stability decreasing with increasing sulphur content.[54] Only phosphorothioate could be identified in the hydrolysis products of the sulphide on a paper chromatogram under acid conditions.[34]

The decasulphide reacts with liquid ammonia at −33°C. to give a mixture of diammonium phosphoramidotrithioate, $(NH_4)_2PS_3NH_2$, and diammonium phosphoronitridodithioate, $(NH_4)_2PS_2N$, which can be separated using their differing solubilities

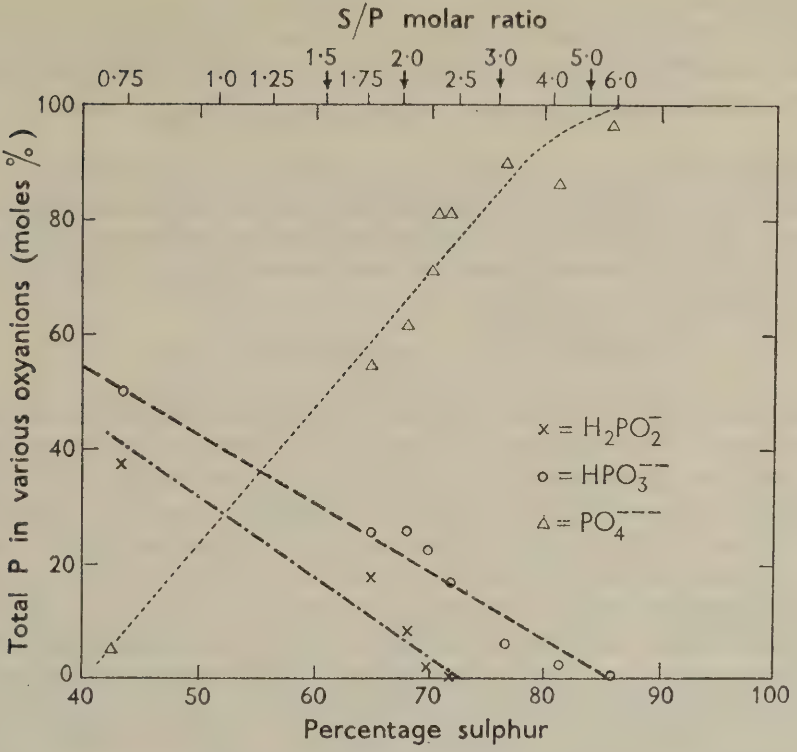

FIG. 7.—Hydrolysis products of phosphorus–sulphur compositions

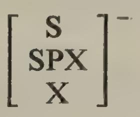
in liquid ammonia, the former being sparingly, and the latter readily, soluble at −78°C.[43] This contrasts with the findings of Stock[55] who, working at room temperature, obtained in addition to $(NH_4)_2PS_2N$, triammonium phosphorimidotrithioate, $(NH_4)_3PS_3NH$, and tetra-ammonium diimidopentathiopyrophosphate,

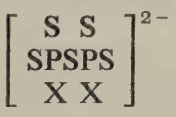
$$((NH_4S)_2P(NH))_2S$$

Tetraphosphorus decasulphide does not react with iodine in carbon disulphide, and gives only a slight reaction with bromine under similar conditions.[1] Phosphoric oxide reacts with the decasulphide giving oxysulphides (see page 406). The interaction of certain metal salts with tetraphosphorus decasulphide in polar media yields anionic substituted thiophosphates of types 1–3



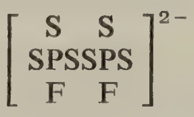
$$\left[\begin{matrix} \mathrm{S} \\ \mathrm{SPX} \\ \mathrm{X} \end{matrix}\right]^-$$

1



$$\left[\begin{matrix} \mathrm{S\ S} \\ \mathrm{SPSPS} \\ \mathrm{X\ X} \end{matrix}\right]^{2-}$$

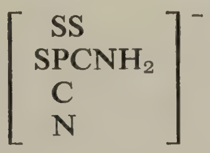
2



$$\left[\begin{matrix} \mathrm{S\ \ \ S} \\ \mathrm{SPSSPS} \\ \mathrm{F\ \ \ F} \end{matrix}\right]^{2-}$$

3

The type of anion formed depends on the solvent employed and the isolation procedure. Thus sodium fluoride or azide in water yield divalent anions of type 2, while in acetonitrile the products are predominantly of type 1. Sodium cyanide under these conditions appears to yield the species



$$\left[\begin{matrix} \mathrm{SS} \\ \mathrm{SPCNH_2} \\ \mathrm{C} \\ \mathrm{N} \end{matrix}\right]^-$$

These anions, the structures of which are not yet rigorously established, show fairly good stability towards acids and bases. Hydronium salts have been prepared in several cases, and those of the $S_2P(N_3)_2$ and $S_2PF_2$ anions can be distilled *in vacuo* with little decomposition.[116]

ORGANIC REACTIONS

The organic reactions of tetraphosphorus decasulphide have been extensively studied. With alcohols[56] the corresponding dialkyl phosphorodithioates are formed:

$$P_4S_{10} + 8ROH \rightarrow 4(RO)_2PSSH + 2H_2S$$

Dialkyl sulphides, mercaptans, sulphur, 'phosphorus polysulphides',[57] tetra-alkyl trithiopyrophosphates[46] and other organic compounds containing phosphorus and sulphur[83] occur as by-products either from the reaction or from the decomposition of the primary products. Phenols also give phosphorodithioates[58] while tetrathioates result from thiophenols or mercaptans[59]:

$$8RSH + P_4S_{10} \rightarrow 4(RS)_2PSSH + 2H_2S$$

Orthoformates and trithio-orthoformates give phosphorodithioates and phosphorotetrathioates respectively.[60] Primary and secondary amines yield a variety of phosphorothioic amides, dealkylation occurring in some instances.[61–2] Carboxylic amides, on the other hand, form complexes of unknown structure, which decompose on heating to give the corresponding thioamides. Tetraphosphorus decasulphide reacts with aromatic hydrocarbons to give a variety of products in which both phosphorus and sulphur may be attached to the aromatic nucleus. Under controlled temperature conditions, unstable derivatives of the empirical formula $ArPS_2$ can be isolated. These normally exist in the dimeric form, and polymerize further on heating, while on hydrolysis they yield the corresponding phosphonic acids, $ArPO(OH)_2$.[38, 63] In the presence of aluminium chloride the reaction takes a different course, and diarylphosphinodithioic acids are formed in good yield[64]:

$$8ArH + P_4S_{10} \rightarrow 4Ar_2PSSH + 2H_2S$$

Less well-defined products, which result from the action of the decasulphide on a variety of aliphatic and alicyclic hydrocarbons, find application as lubricant additives.[65]

Tetraphosphorus decasulphide has been widely used for the replacement of oxygen by sulphur in organic oxygen-containing compounds. Examples of such reactions include the preparation of thioamides from amides,[66] thioketones from aliphatic ketones,[67] and thioaldehydes from aldehydes.[68] Thiocholesterol,[69] thiopyran,[70] thiouracils,[71] mercaptopurines[103] and thiopyridones[72] have been made in a similar way. One, two or three of the oxygen atoms in barbituric acids can be replaced by sulphur using tetraphosphorus decasulphide under varying conditions.[73] Some alcohols or ketones, such as $C_6H_5CH_2NHCH_2CH_2OH$,[74] $RCOCHR'COOR''$[75] and $C_6H_5COCH_3$[68] undergo somewhat more complex thiation reactions leading to cyclic derivatives.

Tetraphosphorus decasulphide reacts with Grignard reagents in anhydrous ether. Hydrolysis of the product yields a mixture of compounds in which alkylphosphonodithioic acids, $RPS(OH)(SH)$, dialkylphosphinodithioic acids, $R_2PSSH$, and trialkylphosphine sulphides, $R_3PS$, predominate successively as the proportion of Grignard reagent to sulphide is increased in the original reaction.[76–7]

## HIGHER SULPHIDES OF PHOSPHORUS

Tetraphosphorus decasulphide is the highest authenticated sulphide of phosphorus. However, the physical properties of melts having an S/P molar ratio higher than 2·5 do not alter monotonically with the proportions of the elements present,[78–9, 104] and this suggests that some type of combination is occurring between the decasulphide and sulphur when these are heated together. Several pieces of evidence support this hypothesis. A clearly defined maximum in the melting point–composition diagram for the phosphorus sulphides (Fig. 3) occurs at a sulphur content of 84–86% (see above, page 414). The solubility of phosphorus sulphide melts in carbon disulphide goes through a minimum at a similar sulphur content. A series of mixtures of tetraphosphorus decasulphide and sulphur was heated to 400°C. in an inert atmosphere, cooled, kept for one week and ground. A 25 g. sample of each was agitated twice at room temperature for 30 min. with two separate 200 ml. portions of carbon disulphide; the weights of sulphide extracted are shown in Table VII.[80]

*Table VII.—Solubility of Phosphorus Sulphide Melts in Carbon Disulphide*

| Sulphur content of melt (%) | Solubility in 400 ml. $CS_2$ (g.) |
|---|---|
| 72·18 | 4·3 |
| 75·0 | 3·3 |
| 79·13 | 2·0 |
| 86·10 | 0·7 |
| 93·04 | 10·6 |

Experiments at higher sulphur contents are in general agreement, showing a decreasing solubility from 100 to 93% S.[79]

A study of the hydrolysis of a similar series of phosphorus sulphide melts has given supporting evidence. Melts of S/P ratio around 0·75 give hypophosphite, phosphite and phosphate on hydrolysis. As the S/P ratio increases, the proportion of hypophosphite and phosphite decreases, until at $S/P \simeq 2{\cdot}5$ hypophosphite is no longer observed. Phosphite is still formed, however, and can be detected in the hydrolysates of melts up to $S/P = 5$–$6$ (see Fig. 7).[81]

Unlike mechanical mixtures of sulphur and decasulphide, melts with S/P ratios higher than 2·5 (72·7% S) cannot be completely separated by extraction with benzene or carbon disulphide. Melts containing from 72 to 84% sulphur give a solution containing phosphorus decasulphide; between 85 and 89% the solution contains almost pure sulphur. In both cases the residue from repeated extraction[6] has a composition nearer to $PS_6$; similar shifts in composition have been observed by later workers.[79]

Material having a composition in the range 85·5–87·5% S is non-crystalline (by *X*-ray examination) and is almost insoluble in benzene or carbon disulphide. Unsuccessful attempts have been made to anneal it into a crystalline form by cooling it slowly from various temperatures below its melting point. It melts to a viscous liquid, from which threads can be drawn by touching it with a glass rod and pulling away. The *X*-ray diffraction diagrams of these threads are typical of glasses or unoriented polymers. The diffraction rings which they exhibit show no orientation effects from which a repeat distance along the axis of the thread might be inferred. Spacings of 3·03, 5·45 and possibly 11·47 A. can be calculated from the diffraction rings,[6] but these do not correspond to spacings observed in the known phosphorus sulphides, nor to those in plastic sulphur.[82] There is no evidence of crystallization in threads which have been aged for periods of up to 35 days.[6]

It may be assumed that the polymeric sulphides $(PS_{5\cdot5})_x$ and $(PS_7)_x$, obtained by the reaction of tetrathiophosphoric acid with sulphur dichloride and disulphur dichloride, respectively, are of similar nature. These are described as plastic yellow products, stable at room temperature but decomposing above 200°C. They are insoluble in water or organic solvents, and are decomposed by alkalis.[98, 110]

This evidence, though circumstantial, suggests the existence of a phase of variable composition with an empirical formula approximating to $PS_6$. There is, however, no reason to suppose that such a phase, even if it exists, would have a simple molecular structure. Indeed its properties are just those which would be expected if it were a random network polymer of the type discussed by Van Wazer.[78, 83] The clearest evidence for such polymer formation is afforded by the viscosity–temperature curves of phosphorus sulphide melts[83] as shown in Fig. 8. Pure liquid white phosphorus has a low viscosity which increases only slightly with decreasing temperature. Similar behaviour is shown by sulphide melts of S/P ratio 1·00 and 1·25, though their viscosity reaches very much higher values, suggesting a degree of cross-linking. However, melts with an S/P ratio above about 2 show a maximum in their viscosity–temperature curves similar to that observed in the case of liquid sulphur, where such behaviour has been ascribed to the presence of polymeric molecules of high mol. wt. It is found that minor variations in composition exert a marked effect on the viscosity of phosphorus sulphide melts. The maximum value of the viscosity increases with increasing sulphur content over the S/P range 2–3, while the temperature of the viscosity maximum falls. The viscosity of such melts is little affected by additives which reduce the viscosity of pure sulphur, and their flow behaviour is Newtonian at temperatures between 300 and 500°C., suggesting that the rate of molecular reorganization under these conditions is rapid compared with the mean relaxation time. Nuclear magnetic resonance spectroscopy shows that even in melts of S/P ratio as low as 1·00 or 1·25, only 59 and 33%, respectively, of the total phosphorus is present in the form of discrete $P_4S_3$ molecules. Several other resonance peaks seen in the spectra evince the presence of phosphorus atoms in a number of unidentified environments. It is evident from consideration of this evidence that amorphous phosphorus sulphides, particularly those of S/P ratio ⩽ 1·8, contain not only small 'cage molecules' of the type already described, but also chains both straight and branched, and rings of sulphur atoms all cross-linked through phosphorus. A complementary study of the kinetics of alcoholysis of phosphorus sulphide melts of varying composition, and the varying nature of the products obtained therein, was in broad general agreement with this picture.[83]

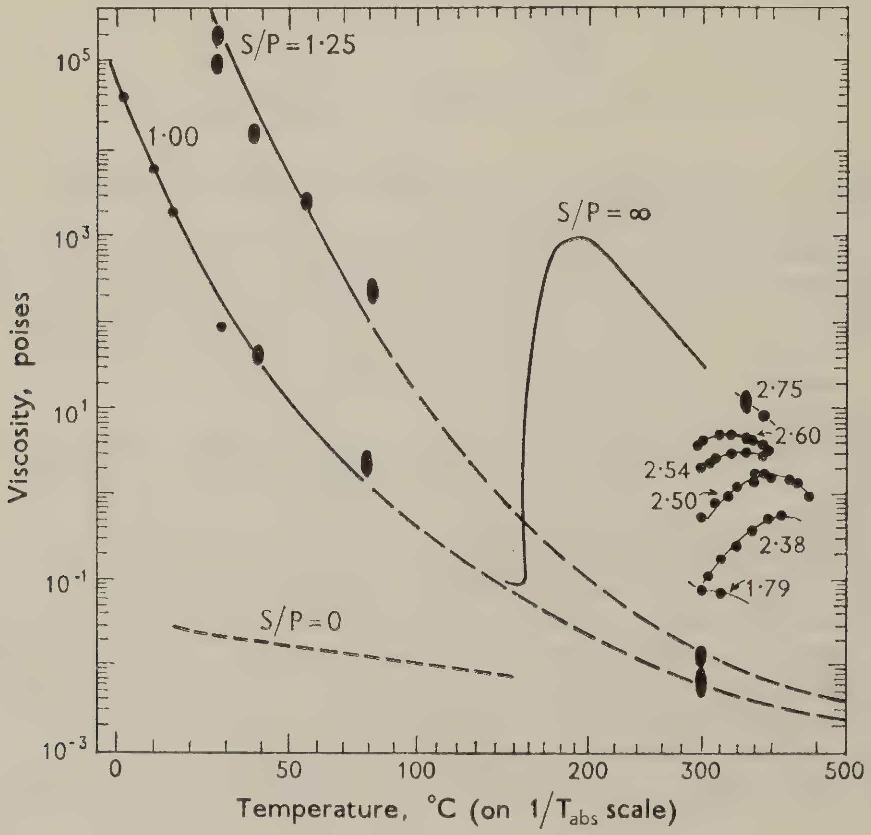


FIG. 8.—Viscosity of various phosphorus sulphides

Further evidence of the polymeric nature of phosphorus sulphide melts has been obtained from a study of their elasticity. Pure plastic sulphur (S$\mu$) yields relatively weak fibres, but the addition of a few per cent of phosphorus greatly increases its elastic modulus, as shown in Fig. 9. The process appears to be analogous to the

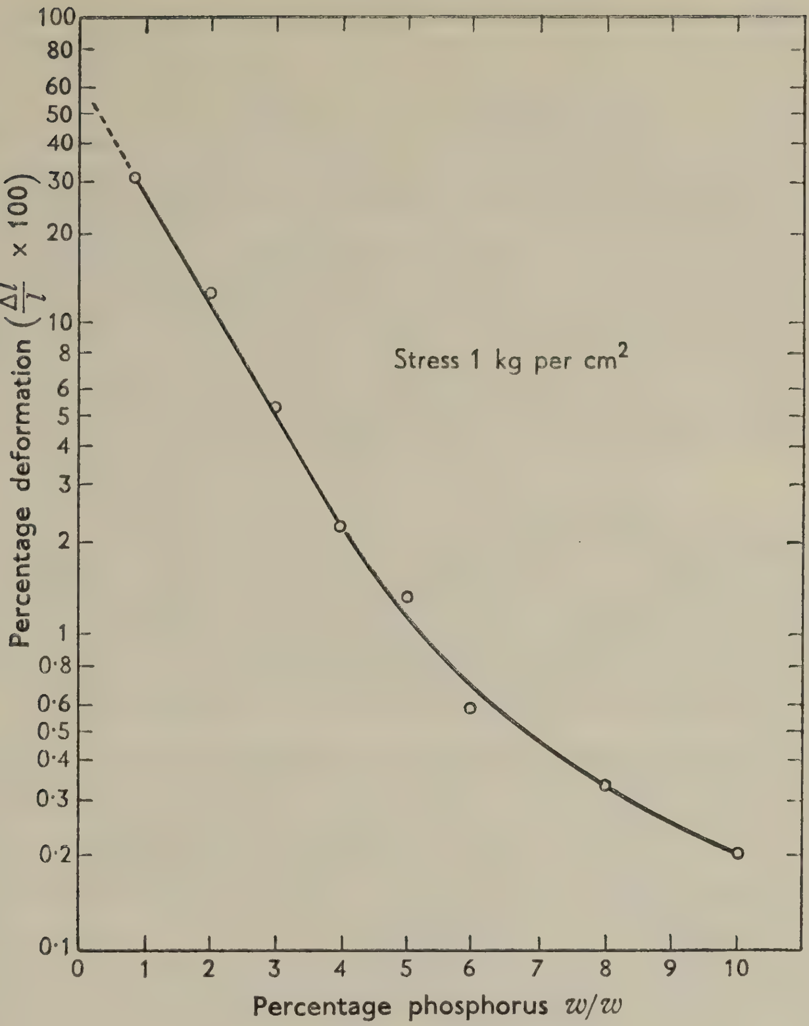

FIG. 9.—The effect of phosphorus on the elastic deformation of $\mu$ sulphur

vulcanization of natural rubber by sulphur, involving the progressive cross-linking of long polymer chains.[84] At low phosphorus contents ($< 5\%$) the variation of elastic deformation with temperature is typical of an elastomer, while when the composition approaches 10% P, the structure becomes highly cross-linked, and essentially vitreous.[85]

## COMMERCIAL APPLICATIONS OF PHOSPHORUS SULPHIDES

Commercial applications of the phosphorus sulphides have been reviewed.[41, 86] The chief outlet for tetraphosphorus trisulphide is still in the manufacture of matches (cf. Mellor, VIII, 1058), though it has been suggested as a heat transfer fluid because of its compatibility with stainless steel.[101] Nevertheless this sulphide has been surpassed in importance by tetraphosphorus decasulphide (phosphorus pentasulphide), which in the form of its organic derivatives is widely employed in the manufacture of lubricant additives of all kinds. The complex patent literature has been reviewed.[65, 87–8] It is mainly concerned with two classes of compounds:

(1) Metal salts of the organic phosphorodithioates formed by the reaction of alcohols or phenols with phosphorus pentasulphide.
(2) The reaction products of phosphorus pentasulphide with unsaturated organic compounds (polyolefines, terpenes, etc.).

These materials, and their decomposition products, adhere to metal bearing surfaces, so that oils which contain them, besides having good lubricating properties under extreme pressures, may inhibit corrosion of certain alloy metals.[89] Similar products act as antioxidants, and impart detergent properties to the base lubricant. Greases[90] and cutting oils containing such additives have also been described. The effect of additive structure on lubricant properties has been discussed.[91]

Many organophosphorus insecticides are based on phosphorus pentasulphide. The dialkyl phosphorodithioates can be converted directly into the phosphorodithioate insecticides such as malathion, while on chlorination they yield the dialkyl phosphorochloridothionates used in the manufacture of phosphorothioate insecticides like parathion, systox or diazinon.[92] Dicresyl phosphorodithioate and the sodium or ammonium salts of certain dialkylphosphorodithioic acids (especially the ethyl, *iso*propyl and *sec.*-butyl derivatives), are widely used in the flotation of sulphide minerals, where they function as 'collectors' in the same way as the alkyl xanthates.[86, 93] Other derivatives have been recommended as catalysts for the blowing of asphalts[94] and as antioxidants or colour improvers in rubber[95] and polyethylene.[96]

### SECTION XII

# PHOSPHORUS OXYSULPHIDES

BY A. F. CHILDS

## General

Diphosphorus dioxytrisulphide, $P_2O_2S_3$, reported by Besson (Mellor, VIII, 1061) to result from the action of hydrogen sulphide on phosphoryl chloride, has not been subsequently investigated, although a substance of this composition is said to be formed by the action of hexamethyldisilthiane on phosphoryl chloride.[11] Tetraphosphorus hexaoxytetrasulphide, $P_4O_6S_4$, is now well authenticated, however, and two other oxysulphides have been reported. Tetraphosphorus tetraoxytrisulphide, $P_4O_4S_3$, is made by the action of oxygen on tetraphosphorus trisulphide. Although its formula suggests a formal analogy to tetraphosphorus heptasulphide, nothing certain is known of its structure. The nature of hexaphosphorus decaoxide pentasulphide, prepared by distillation of $P_4O_6S_4$ with excess of phosphorus pentoxide, is equally obscure.

## TETRAPHOSPHORUS TETRAOXYTRISULPHIDE, $P_4O_4S_3$

### PREPARATION

Solutions of tetraphosphorus trisulphide in benzene, carbon disulphide, carbon tetrachloride[1] or *o*-dichlorobenzene[2] react rapidly with dry air or oxygen with the formation of a voluminous precipitate. Analysis of the solvent-free material[1] as well as consideration of the quantity of oxygen absorbed[2] has established the empirical formula as $P_4O_4S_3$.

### PROPERTIES

Tetraphosphorus tetraoxytrisulphide is a fluffy, yellowish-white, apparently amorphous powder, insoluble in the usual solvents, and has a density of 1·96 at room temperature. On heating it softens at 150°C. and melts at 250°C. to a yellow liquid containing a suspended white solid. Sublimation *in vacuo* at 400°C. yields a volatile portion, which probably contains $P_4S_3$ and $P_4O_6S_4$, and leaves a residue (about 10% by weight of the original) which is decomposed by water with evolution of phosphine and hydrogen sulphide.

Phosphorus tetraoxytrisulphide deliquesces rapidly in the air, and inflames if moistened with a little water. When added carefully to a large volume of water it dissolves, giving a milky suspension of sulphur and a yellow residue of indeterminate composition. It reacts rapidly with aqueous sodium hydroxide forming a yellowish solution, which is decolorized on heating with evolution of phosphine and hydrogen.[1]

The only organic reaction of this oxysulphide described is that with olefins to give polymeric products of the empirical formula $(C_nH_{2n})_3,P_4S_3O_4$. These substances react further with alcohols or phenols[2] yielding polymeric esters which are claimed to have the formula $(C_nH_{2n})_3,P_4S_3O_4.(OX)_3$.

## TETRAPHOSPHORUS HEXAOXYTETRASULPHIDE, $P_4O_6S_4$

### PREPARATION

The formation of this substance by the interaction of tetraphosphorus hexaoxide and sulphur (Mellor, VIII, 1061) has been confirmed.[3, 4] The reaction is violent, and should be carried out only on a small scale to avoid the danger of an explosion. An alternative method is to heat a suitable mixture of phosphorus pentoxide and tetraphosphorus decasulphide, when the oxysulphide is formed according to the equation:

$$3P_4O_{10}+2P_4S_{10} \rightarrow 5P_4O_6S_4$$

If the reaction is carried out at 400–500°C. the oxysulphide distils off and condenses as a clear pale yellow liquid which rapidly solidifies. Redistillation under reduced pressure gives a purer product, which nevertheless has been claimed[9] to be less pure than that made by the original procedure. However, if the paste-like reaction product

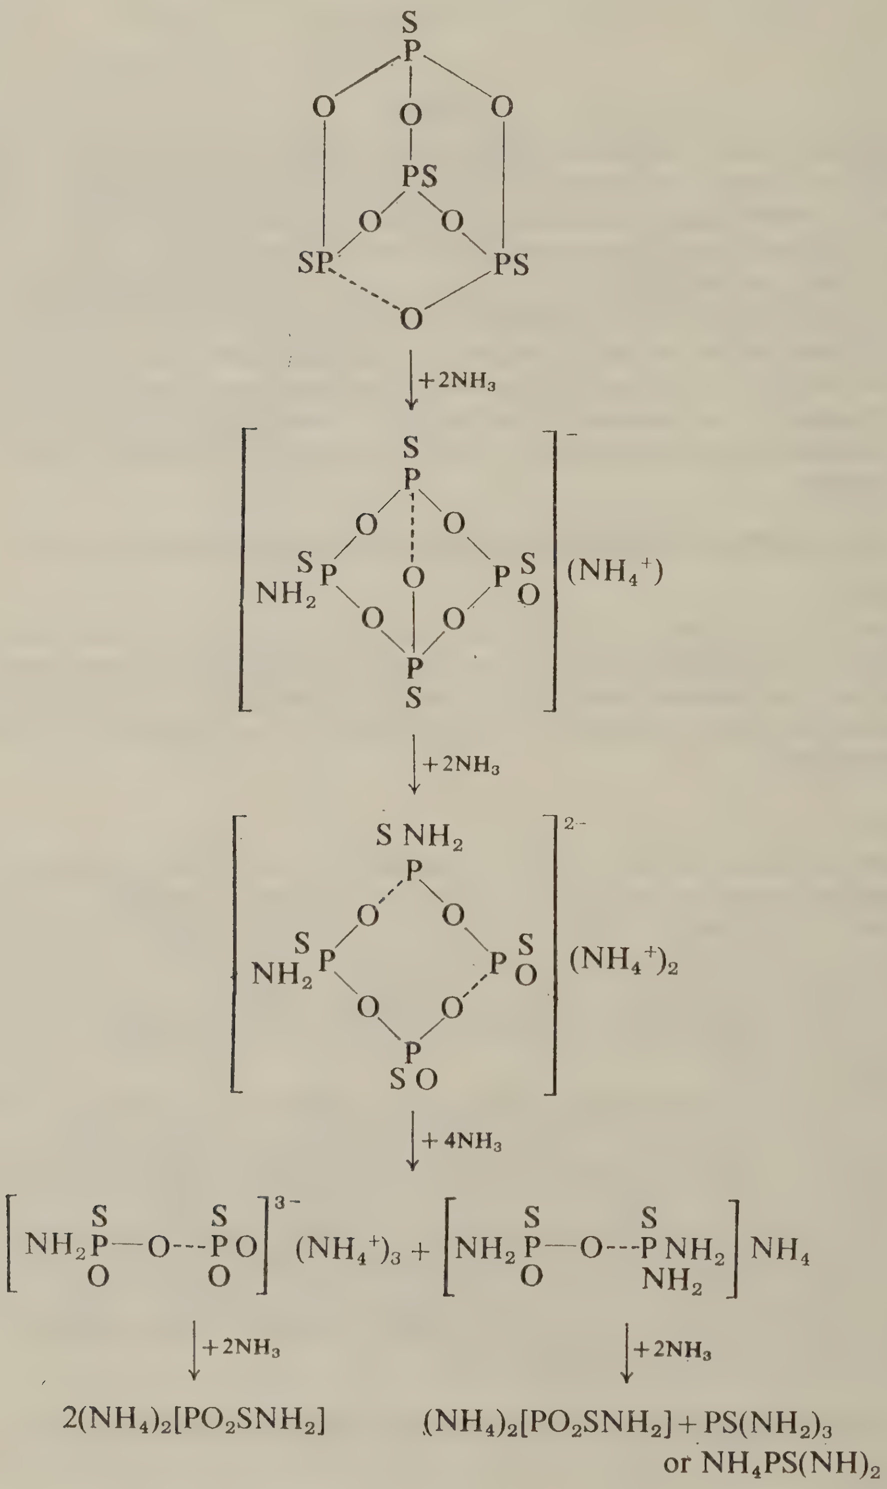

FIG. 1.—The ammonolysis of phosphorus hexaoxytetrasulphide

of sulphur and tetraphosphorus hexaoxide (m.p. 102°C.) is kept at 110°C., the initially yellow liquid becomes colourless, and large crystals of pure $P_4O_6S_4$ appear. On cooling to room temperature part of the substance remains a viscous liquid.[12]

Phosphorus tetraoxytrisulphide is also said to be formed by the action of air on molten phosphorus decasulphide,[5] but this reaction has apparently not been used as a preparative method.

### PHYSICAL PROPERTIES

Tetraphosphorus hexaoxytetrasulphide forms colourless deliquescent tetragonal plates, which decompose rapidly in moist air, and melt somewhat above 110°C.,[12] having b.p. 295°C./atm. pressure, 180–190°C./20 mm. Hg. The structure of the molecule has been determined by electron diffraction[3] and *X*-ray diffraction[12] and shown to be similar to that of phosphoric oxide, $P_4O_{10}$ (see page 389). The four phosphorus atoms are arranged tetrahedrally, oxygen atoms occupying the edges, and sulphur the apices of the tetrahedron. The bond angles are $O\text{–}P\text{–}O = 101{\cdot}5 \pm 1°$, $P\text{–}O\text{–}P = 123{\cdot}5 \pm 1°$, $O\text{–}P\text{–}S = 116{\cdot}5 \pm 1°$. As would be expected, the P–O bond distance of $1{\cdot}61 \pm 0{\cdot}02$ A. corresponds to a normal $\sigma$ bond with little $\pi$ bond character while the P–S bond ($1{\cdot}85 \pm 0{\cdot}02$ A.) exhibits considerable $\pi$ bond character.[6] The bond distances and angles found in the pure solid are closely similar.[12]

The Raman spectrum of phosphorus hexaoxytetrasulphide is broadly that which would be expected from a $P_4O_6S_4$ molecule of symmetry $T_d$, although extra polarized lines are exhibited which have been explained by a polymerization–depolymerization process occurring in the liquid. The appearance of solid particles during the irradiation supports this hypothesis.[7] A calculated value for the P═S bond distance, based on Raman data,[8] agrees exactly with that observed experimentally.[3]

### CHEMICAL PROPERTIES

Besides the reaction with water (Mellor, *loc. cit.*), only that with ammonia has been described.[9] The oxysulphide forms a clear colourless solution in liquid ammonia at −33°C., which slowly (more rapidly at room temperature) gives a sparingly soluble precipitate of diammonium phosphoramidothioate, $(NH_4)_2PO_2SNH_2$, and a solution in which infra-red spectroscopy shows the presence of thiophosphorylamide, $PS(NH_2)_3$, and an ammonium compound, presumably $NH_4PS(NH)_2$, since the white compound $[Ni(NH_3)_4][PS(NH)_2]_2$ can be precipitated. The proportion in which the products are formed is in accordance with the scheme (Fig. 1) based on the established structure of the oxysulphide.

## HEXAPHOSPHORUS DECAOXIDE PENTASULPHIDE, $P_6O_{10}S_5$

An oxysulphide of the above composition is obtained by distillation of tetraphosphorus hexaoxytetrasulphide with excess of phosphorus pentoxide. The hard white crystalline product can be purified by sublimation at 180°C. and 20 mm. Hg, forming white crystals, m.p. 122–125°C., which are hygroscopic and decomposed by water.[10] While nothing is known of its structure, the empirical formula would correspond to a mixed crystal, $P_4O_{10},5P_4O_6S_4$.

## SECTION XIII

# FLUORIDES AND MIXED FLUORIDE HALIDES OF PHOSPHORUS

BY R. H. TOMLINSON

## PHOSPHORUS(III) FLUORIDE, PHOSPHORUS(III) CHLORO-, BROMO- AND IODO-FLUORIDES

### Preparation

Mixtures of phosphorus pentoxide with simple inorganic chlorides or fluorides at 500°C. give phosphoryl halides ($POX_3$) as the major volatile products. With calcium fluoride and sodium chloride together, mixed phosphoryl halides ($POCl_3$, $POCl_2F$, $POClF_2$, $POF_3$) are formed, while in iron reaction vessels or with heated carbon, some further reduction of phosphoryl fluoride to phosphorus(III) fluoride takes place.[1] Halogen exchange occurs when phosphorus(III) chloride or phosphoryl chloride is boiled under reflux with ammonium fluoride, and the main products are the mono- and trifluoro substituents.[2] Potassium fluoride in liquid sulphur dioxide is a convenient fluorinating agent for phosphorus trichloride and oxychlorides,[3] thus:

$$PCl_3 + 3KSO_2F = 3KCl + 3SO_2 + PF_3$$
$$POCl_3 + 3KSO_2F = 3KCl + 3SO_2 + POF_3$$

Addition of powdered antimony(III) fluoride to phosphorus(III) chloride containing antimony(V) chloride catalyst (Swarts' reaction[4]), or to phosphorus(III) bromide containing bromine as catalyst at temperatures above 15°C., gives largely phosphorus(III) fluoride. The threshold temperature of fluorination decreases with each fluorine atom introduced into the $PX_3$ molecule ($X =$ chlorine or bromine), but under precisely controlled conditions of temperature and pressure, such that the unfluorinated liquid halide remains at gentle reflux and the fluorinated product as it is formed distils out of the reaction zone, the reactions are shown to be stepwise, and major yields of the mixed trihalides $PX_2F$ and $PXF_2$ can be obtained.[5–7] Similar observations have been made on the reaction at reduced pressures between phosphorus(III) chloride or bromide vapour and heated calcium fluoride pellets. Mixed fluorochlorides were said to be formed in 50% yield by passing an equimolecular mixture of phosphorus(III) chloride and fluoride vapours through a glass tube packed with broken porcelain at 200°C.[8] Above 400°C. the equilibrium

$$PCl_3 + PF_3 \rightleftharpoons PF_2Cl + PFCl_2$$

shifts appreciably to the right, but side-products (notably $POF_3$ and $SiF_4$ from reactions with the glass) which are difficult to remove from $PF_2Cl$ by distillation, render the method unattractive for preparative purposes.[5] A less equivocal preparation is the action of hydrogen chloride upon dimethylaminophosphorus difluoride.[132] A similar method has been used to obtain phosphorus(III) difluoroiodide[132–3]:

$$Me_2NPF_2 + 2HX \rightarrow XPF_2 + Me_2NH,HX$$

Phosphorus(III) fluoride may be prepared by the dropwise addition, at 15°–40°C., of arsenic(III) fluoride containing antimony(V) chloride catalyst to phosphorus(III)

**Refs. p. 460**

chloride,[9] or of phosphorus(III) chloride to anhydrous zinc fluoride.[10–1] The vapours are led upwards through a column maintained at −80°C. and the product, obtained in approximately 85% yield, is condensed in a receiver cooled in liquid nitrogen. Good yields of phosphorus(III) fluoride have also been obtained by the reaction of phosphorus(III) chloride with disodium hexafluorosilicate,[134] or molten alkali metal fluoride mixtures,[135] and by the interaction of triphenyl phosphite and benzoyl fluoride.[136]

### Physical Properties

Gaseous phosphorus(III) fluoride is colourless when pure, and is only slowly hydrolyzed by moist air. It is odourless in toxic concentrations, producing chest pains, a sharp rise in body temperature and vomiting.[5]

Phosphorus(III) chloro- and bromo-fluorides are colourless in both gaseous and liquid states and form white solids on freezing. The liquid bromofluorides are unstable and decompose slowly at 'dry ice' temperatures to phosphorus(III) fluoride and bromide.[5] Phosphorus(III) difluoroiodide also disproportionates slowly in the vapour state, to phosphorus(III) fluoride and iodide, especially at pressures near atmospheric.[133]

Melting, boiling, vapour pressure and critical data are summarized in Table I.

Electron diffraction measurements[16–7, 164] confirm a pyramidal structure for the $PX_3$ halides in which the P-atom exhibits $p^3$ bonding and a tendency towards $sp^3$ hybridization with the non-bonding pair of $s$ electrons. Measurements on pure rotational transitions in the microwave region[18–21] have permitted precise estimates to be made of intermolecular distances and of dipole moment for phosphorus trifluoride as shown in Table II. Microwave data have also been used to deduce first order centrifugal distortion constants for phosphorus trifluoride and trichloride.[137]

The infra-red spectra for phosphorus(III), phosphorus(V) and phosphoryl fluoride have been obtained.[27] Correlation with the available Raman and structural data permits an assignment of the fundamental frequencies and an evaluation of the force constants for the $PF_3$ and $POF_3$ molecules (Tables III and XI, respectively) using Wilson's method of matrices. A later author[28] has, however, obtained quite different values for $PF_3$. The infra-red and nuclear magnetic resonance spectra of phosphorus(III) chlorodifluoride[138] and difluoroiodide[133] have been recorded.

Values of potential constants based on the Urey and Bradley force field using the earlier frequency assignments[29] have been reported as follows (values in $10^5$ dynes cm.$^{-1}$):

| | $K$ | $H$ | $F$ | $F'$ |
|---|---|---|---|---|
| $PF_3$ | 3·910 | 0·296 | 0·935 | −0·813 |
| $PCl_3$ | 1·680 | −2·212 | 0·743 | −0·420 |
| $PBr_3$ | 1·436 | −0·142 | 0·522 | −0·313 |
| $PI_3$ | 1·031 | −0·080 | 0·338 | −0·214 |

The negative values of $F'$ indicate repulsive forces between the non-bonding atoms.[30]

The heat of formation $\Delta H^\circ_{f_{25}}$ for phosphorus(III) fluoride gas is given as −189 kcal./mole,[31] or as −221·95 kcal./mole with P($\omega$, $\beta$, 0°K.) as standard state.[32] A later value of $\Delta H^\circ_{f_{25}}$ of −226·03 kcal./mole has been derived from the heat of reaction between calcium fluoride and phosphorus trichloride in a fluidized bed,[139] and combined with other values of spectroscopic data to give values of the standard free energy and entropy of formation, $\Delta G^\circ_{25} = -242{\cdot}36$ kcal./mole, $S_0 = 54{\cdot}78$ e.u./mole. The data support a linear relationship of P–X bond energy with P–X bond length for the series of phosphorus(III) halides.[140] Enthalpy, free energy and entropy functions at 100° intervals from 298·1 to 1000°K., have been derived[31, 33–4] from molecular data,[22] and a more recent computation[32] gives free energy, entropy and heat capacity at similar temperature intervals up to 5000°K. A selection of these data is made in Table IV. Similar functions are derived[35] for the mixed trihalide $PFCl_2$ between 100° and 1000°K.

The difference between calculated and experimental molar entropy values for phosphorus(III) fluoride and phosphoryl chloride termed 'entropy of resonance', was 4·5 and 6·7 g.-cal. deg.$^{-1}$ mole$^{-1}$, respectively[36]; the empirical formula used in the calculation involved the Sackur–Lewis and Eastman formulae[37] as special cases.

Three solid forms of phosphorus(III) fluoride (III, II and I) have been reported, with the following thermodynamic properties[141]:

| Transition | $\Delta H$ g.-cal./mole | $S°$ e.u. | $T$°K. |
|---|---|---|---|
| III → II | 59·9 | 0·715 | 83·75 |
| II → I | 552·3 | 4·995 | 110·56 |

Heat capacity values for phosphorus(III) fluoride gas in the temperature range 298·1 to 1000°K. are given[38] by $C_p = 17{\cdot}559 + 0{\cdot}001972T - 456{,}900/T^2$ g.-cal. mole$^{-1}$; heat capacity, viscosity and thermal conductivity data at 100° intervals between 100° and 5000°K. for phosphorus(III) fluoride, phosphorus(III) chloride gases and for the PF radical have been obtained[39]; the specific conductance of liquid form phosphorus(III) fluoride[40] at −113°C. is $0{\cdot}42 \times 10^{-9}$ mho cm.$^{-1}$

## Chemical Properties

Addition of chlorine to phosphorus(III) fluoride gives dichlorofluorophosphorane (see page 451), b.p. 7·1°C.[41] The reaction is catalyzed by glass surfaces,[42] which suffer rapid attack in contact with the liquid product.[5] Phosphorus(III) chlorofluorides take up chlorine in the presence of iodine as catalyst to give unstable liquid products which decompose to phosphorus(V) fluoride and chloride at room temperature. Coloured unstable liquid products thought to be $PBr_4F$ and $PBr_3F_2$ were reported to arise from the interaction of phosphorus(III) bromofluorides and bromine, but were not further characterized.[5]

Reorganization in liquid phosphorus(III) halide mixtures is confirmed both by Raman and by nuclear magnetic resonance studies. Thus, Raman spectra have shown the presence of phosphorus(III) chlorobromides, chloroiodides, bromoiodides and fluorochlorobromide in phosphorus(III) chloride–bromide,[43] chloride–iodide,[44] bromide–iodide[45] and dichlorofluoride–dibromofluoride[46–7] mixtures, respectively. For each of the systems $P(OC_6H_5)_3$–$PCl_3$, $P(OC_6H_5)_3$–$PBr_3$ at 180°C. and $PCl_3$–$PBr_3$ at 25°C., as well as for equimolar mixtures of $P(OC_6H_5)_3$,$PCl_3$ and $PBr_3$ at 180°C., nuclear magnetic resonance measurements at equilibrium showed larger amounts of the possible mixed phosphorus(III) compounds (except for $PClBr_2$) than would correspond to completely random reorganization.[48] For the system $PCl_3$–$PBr_3$ at 25°C., mixed compounds were detected within 15 min. of mixing and equilibrium concentrations were present after 1 week. Attainment of equilibrium in such triply connected systems is considerably faster than in the phosphoryl halide systems containing the same ligands[48]; the presence of fluoride reduces the rate of the reaction.[49]

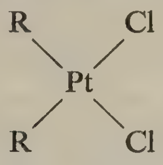
Thermal analysis of the phosphorus trifluoride–boron trifluoride system showed a single eutectic at −163·5°C. (21·5 mole % $BF_3$) and no evidence of compound formation.[50] In contrast, if boron trifluoride is passed through a petroleum ether solution of *n*-propylphosphine, $PPr_3$, the solid complex $PPr_3$,$BF_3$ is immediately precipitated.[51] With diborane under 8 atm. pressure, unstable phosphorus trifluoride–borane is formed as a colourless gas, spontaneously inflammable in air and analogous to carbon monoxide–borane[52]:

| | $PF_3$,$BH_3$ | CO,$BH_3$ |
|---|---|---|
| M.p. °C. | −116·1 | −137·0 |
| B.p. °C. | −61·8 | −64 |
| Latent heat of vaporization (g.-cal.mole$^{-1}$) | 4760 | 4750 |
| Trouton's constant | 22 | 23 |
| Dissociation constant (atm.) at 25°C. | 1·0 ± 0·3 | 2·5 |
| % decomposed in 1 hr. at 25°C. | 14 | 17 |

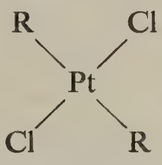
Pentaborane reacts analogously to diborane, giving a mixture of the borane and tetraborane adducts[142]:

$$B_5H_{11} + 2PF_3 \rightarrow BH_3,PF_3 + B_4H_8,PF_3$$

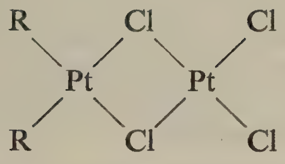
Phosphorus(III) fluoride reacts with platinous chloride at −200°C. to form a mixed sublimate which, when further sublimed in the presence of phosphorus(III) fluoride, gives white crystals of bis(trifluorophosphine)dichloroplatinum, $(PF_3)_2PtCl_2$; this 'dichloride' has m.p. 102°C. Alternatively, if the sublimate is refluxed with platinous chloride in a nitrogen atmosphere at 100 mm. pressure and further resublimed at 15 mm. it gives orange-red crystals of dichlorobis(trifluorophosphine)$\mu\mu'$-dichlorodiplatinum, $(PF_3)_2Pt_2Cl_4$; this 'tetrachloride' has m.p. 155° to 156°C.[10] Boiling points (with rapid decomposition) of the di- and tetrachlorides are 240° and 290°C., respectively, and both chlorides are rapidly hydrolyzed by water. Planar square configuration about the platinum nucleus corresponding to *dsp*$^2$ bonding is established for $PtCl_2R_2$ and $(PtCl_2R)_2$ type compounds,[53–4] the former with two and the latter with three possible *cis-trans* isomerides thus:



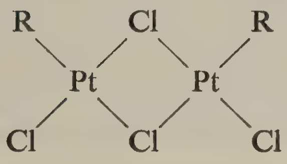
*cis*



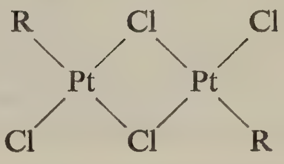
*trans*



*cis*



*trans unsym.*



*trans sym.*

The 'dichlorides' with R = $PF_3$ or CO are considered from their solubilities in inert solvents and from dipole measurements to have a mainly *cis*-configuration in solution. Substitution of X = fluorine atoms for alkyl groups in such complexes where R = $PX_3$, greatly increases the stability of the *cis*-isomer relative to the *trans*.[10] The reaction of platinous chloride with phosphorus(III) fluoride in the presence of copper powder at 100°C. and 100 atm. yields the completely substituted compound $Pt(PF_3)_4$, m.p. −15°C., b.p. 86°/730 mm. $Pd(PF_3)_4$, a white solid m.p. −41°C., decomp. −20°C., can be made in similar fashion[143] or from $Pd(CO)_2Cl_2$ and phosphorus(III) fluoride under pressure.[144] However the copper catalyzed reaction of rhodium trichloride, hydrogen and phosphorus(III) fluoride gives $HRh(PF_3)_4$, a clear mobile liquid with an irritating odour, m.p. −40°C., b.p. 89°/125 mm.[145]

Phosphorus trifluoride forms black, hygroscopic addition compounds with ruthenium or osmium tetroxides:

$$RuO_4 \xrightarrow[-100°C.]{} (RuO_4)_2,PF_3 \xrightarrow[+20°C.]{} RuO_4,PF_3$$
$$OsO_4 \xrightarrow[-100°C.]{} (OsO_4)_2,PF_3 \xrightarrow[+70°C.]{} OsO_4,PF_3$$

Neither product has a stability approaching that of the complexes with platinous chloride and it is reasonable to suppose that similar bonding does not occur.[61] Both phosphorus trichloride and tribromide reduce the tetroxides to give 1:1 addition compounds of the type $RuO_2,PCl_3$.

Phosphorus trifluoride fails to react with finely divided nickel at 150 atm. and 200°C.,[55] but yields $Ni(PF_3)_4$ at 300 atm. and 100°C.[146] It also reacts with nickel tetracarbonyl in the presence of metallic nickel to give a random mixture of compounds of the general formula $Ni(CO)_x(PF_3)_{4-x}$, from which pure compounds may be separated by gas–liquid chromatography.[147] However, substitution of carbonyl in nickel carbonyl with phosphorus trichloride readily goes to completion in the liquid phase, and excess trichloride can be removed by distillation. From the residue pale yellow crystals of tetrakistrichlorophosphine nickel, $Ni(PCl_3)_4$, can be obtained by recrystallization from pentane. Further treatment of the chloro-compound with phosphorus trifluoride at 50 to 100 atm. and 100°C. or with phosphorus tribromide at 70°C. gives 50 to 60% conversion to the fully substituted fluoro- and bromo-compounds respectively. The fluoride reaction has been shown to involve exchange of $PF_3$ for $PCl_3$ and not halogen interchange.[148] The stabilities of the tetrakistrihalogenophosphine nickel compounds decrease in the order fluoride > chloride > bromide. The fluoride is a colourless, odourless, volatile liquid, m.p. $-55°$, b.p. 70·7°C., insoluble in water and volatile in steam with little hydrolysis; the chloride and bromide are thermochromic crystalline solids, decomposing above 80°C.[55] The chloride has been shown to yield phosphorus(III) chloride, nickel(II) chloride, heptanickel triphosphide and dinickel phosphide on decomposition.[148] The chloride is diamagnetic[55] like nickel carbonyl, which was shown by *X*-ray analysis[56] to be tetrahedral. It seems probable that the tetrakistrihalogenophosphine nickel compounds and nickel carbonyl have a similar structure.[55, 57] Interest in these compounds arose from consideration of the nature of the co-ordinate linkage with $C_2H_4$, CO and $PF_3$ type ligands, the boron trifluoride and boron hydride complexes of which are either nonexistent or very unstable, but the platinous chloride complexes are stable to 180°–300°C. Such ligands are *trans*-directing in the latter compounds and contrast with *cis*-directing ligands, such as ammonia and primary amines, which form stable boron complexes containing the classical coordinate link.[51] The failure of phosphorus(III) fluoride to form a boron trifluoride complex implies[58] that the lone pair on the phosphorus atom is withheld from $\sigma$-bond formation; with phosphorus(III) chloride, unstable $PCl_3,BF_3$ was reported to be formed[57] (but see page 475) in agreement with the more electropositive character of the chlorine atom compared with fluorine. Co-ordination with platinum is explained on the assumptions that:

(i) $\pi$ bonding occurs by overlap of a platinum 5*d*-electron pair with a vacant 3*d*-orbital of the P-atom,
(ii) acceptance of electrons by the P-atom makes its 3*s* electrons more readily available for the $\sigma$-bond.

The large inductive effect of the fluorine atoms enhances such $\pi$-bonding, but in the general case of $PX_3$ complexes, decrease in the electronegativity of X (= halogen) decreases electron drift from available *d*-orbitals of the metal to the P-atom.[51, 58] Support for the double bond character of the metal ligand bond in these complexes is suggested by analogy with the *o*-phenylenebisdimethyl arsine and 2:2′-dipyridyl nickel carbonyl disubstituted complexes, where comparison of bond length and stretching force constants for the carbonyl bond indicated considerable double bond character for the Ni–As and Ni–N bonds, respectively.[59] Tetrakistrifluorophosphine nickel and related compounds, viz:

| | | | | |
|---|---|---|---|---|
| $Ni(PF_3)_4$ | m.p. $-55°$C. | b.p.$_{(760\text{ mm.})}$ | 70·5°C. | (20–35% yield) |
| $Ni(PF_2CH_3)_4$ | — | b.p.$_{(3\text{–}4\text{ mm.})}$ | 66–68°C. | (unstable) |
| $Ni(PF_2C_6H_5)_4$ | m.p. 63·5°C. | — | | (stable) |

have been obtained[60] by fluorination of the chloro-analogues with potassium fluorosulphinate in benzene or dichlorobenzene solution. With liquid ammonia, polymeric nickel tetrakis-nitridophosphine is formed:

$$Ni(PF_3)_4 \xrightarrow[NH_3(l)]{} Ni[P(NH_2)_3]_4 \xrightarrow[\text{of } NH_3]{\text{evaporation}} [Ni(PN)_4]_x$$

Iron pentacarbonyl reacts with phosphorus(III) fluoride at high temperatures and pressures yielding the series of compounds of general formula $Fe(CO)_{5-x}(PF_3)_x$ ($x = 1$–5). All are yellow liquids except pentakis-(trifluorophosphine)-iron(0), which is a yellow solid, m.p. 44°C.[149] The same material can also be made by the copper catalyzed reaction of phosphorus(III) fluoride and iron(II) iodide at 140°C. and

500 atm. It is diamagnetic, soluble in the common organic solvents and fairly stable in moist air. Potassium amalgam converts it to potassium trifluorophosphine-ferrate.[150]

Iron nitrosyl bromide, $[Fe(NO)_2Br]_2$, reacts with phosphorus(III) fluoride to give bis-(trifluorophosphine)-dinitrosyl iron(I), $Fe(NO)_2(PF_3)_2$. The analogous tris-(trifluorophosphine)-nitrosyl cobalt, $Co(NO)(PF_3)_3$ is obtained from $[Co(NO)_2Cl]_2$ and $PF_3$. It is a reddish-brown mobile liquid, m.p. −92°C., b.p. 81°/732 mm., decomp. 163°, fairly stable in moist air.[151]

Dicobalt octacarbonyl reacts with phosphorus(III) fluoride under pressure in the presence of hydrogen or hydrogen fluoride forming pale yellow tris-(trifluorophosphine)-carbonyl cobalt hydride, $HCo(PF_3)_3CO$, m.p. −67°, b.p. 80·5°/715 mm. This compound is only slowly decomposed by air, and in aqueous solution behaves as a strong monobasic acid. With potassium amalgam it yields crystalline potassium tris-(trifluorophosphine)-carbonyl cobaltate $K[Co(PF_3)_3CO]$.[152] The analogous tetrakis(trifluorophosphine) cobalt hydride, $HCo(PF_3)_4$, is obtained by the copper catalyzed reaction of cobalt(II) iodide and phosphorus(III) fluoride at 200°C. and 250 atm. It is a greenish mobile liquid, m.p. −51°C., b.p. 80°/730 mm., quite stable in air, but decomposing when heated to 250°C. Again, it is a strong monobasic acid, and with potassium amalgam yields potassium tetrakis(trifluorophosphine)-cobaltate, $K[Co(PF_3)_4]$.[153]

Hexakis (trifluorophosphine)-chromium(0), $M(PF_3)_6$, can be made by treating dibenzene-chromium(0) with phosphorus(III) fluoride. It forms colourless highly refractive prisms, m.p. 193°C., decomp. 300°C., stable in dry air and soluble in polar organic solvents.[154] The analogous molybdenum compound, m.p. 196°C., decomp. 250°C., is made in similar fashion,[155] while hexakis (trifluorophosphine)-tungsten(0), m.p. 214°C., decomp. 320°C., is obtained by treating tungsten(VI) chloride with phosphorus(III) fluoride in the presence of copper at 200°C. and 200 atm.[153] All three compounds are diamagnetic, and their infra-red spectra suggest an octahedral structure.

Mixed carbonyl-trifluorophosphine derivatives of chromium and molybdenum have been made by treating the metal hexacarbonyl, triammine tricarbonyl or mesitylene tricarbonyl with phosphorus(III) fluoride. Tris-(trifluorophosphine)-tricarbonyl molybdenum(0) (m.p. 89°C., decomp. 110°)[155] and the chromium analogue (m.p. 68°C.)[154] have been isolated as colourless highly refractive solids.

A 1:1 mixture of phosphorus trifluoride with oxygen at −75° to −60°C. in the silent electric discharge is partially converted to phosphoryl fluoride, phosphorus pentafluoride, pyrophosphoryl fluoride ($P_2O_3F_4$, m.p. −0·1°C., b.p. 75°C.) and polymeric phosphorus dioxyfluoride $(PO_2F)_n$[62] (see page 459).

Phosphorus trifluoride fails to combine with potassium fluoride on prolonged standing in a sealed tube; above 200°C. some disproportionation of the trifluoride in the mixture to phosphorus and phosphorus pentafluoride occurs.[40] Difluorodiazine, $N_2F_2$, however converts phosphorus trifluoride to phosphorus pentafluoride at room temperature.[156]

## Difluorophosphine, $F_2PH$

Following unsuccessful earlier attempts to make chloro- and bromo-phosphines,[157] difluorophosphine has been prepared in 55% yield by the reduction of phosphorus(III) difluoroiodide by hydrogen iodide in the presence of mercury at room temperature:

$$PF_2I + HI + 2Hg \rightarrow PHF_2 + Hg_2I_2$$

Hydrogen, phosphorus trifluoride and an unstable material, probably $PHF_2,HI$, were observed as by-products.

Difluorophosphine is a colourless gas stable at low pressures, and decomposing less than 5% in 5 hr. even at room temperature and saturation pressure. The formula is supported by hydrogen analysis, molecular weight (vapour density), mass spectrum, and the $^1H$ and $^{19}F$ nuclear magnetic resonance spectra.

Difluorophosphine is associated in the condensed phase but monomeric in the vapour. Its freezing point (−124·2 to −123·6°C.) and boiling point (−64·6°C. (extrap.)) are higher than those of either phosphine or phosphorus(III) fluoride. The vapour pressure is given by the equation:

$$\log p_{(\text{mm.})} = -1126/T + 8{\cdot}280$$

and the Trouton constant is 24·7 g.-cal. deg.$^{-1}$ mole$^{-1}$.

Under alkaline conditions difluorophosphine reduces water:

$$PHF_2 + H_2O \rightarrow PF_2OH + H_2$$

though the more usual reaction:

$$PHF_2 + 2H_2O \rightarrow HP(OH)_2 + 2HF$$

occurs to some extent.[158]

### Diphosphorus Tetrafluoride, $P_2F_4$

Fluorination of diphosphorus tetraiodide by antimony pentafluoride leads mainly to phosphorus trifluoride and pentafluoride, though a small amount of less volatile material of molecular weight approaching $P_2F_4$ is formed.[159] This substance can, however, be made in 85% yield by the reaction of phosphorus(III) difluoroiodide with mercury at room temperature:

$$2PF_2I + 2Hg \rightarrow P_2F_4 + Hg_2I_2$$

After purification by fractional condensation at −135°C., diphosphorus tetrafluoride is obtained as a colourless gas, m.p. −86·5°C., b.p. −6·2°C, Trouton constant 22·11 g.-cal./deg./mole and heat of vaporization 5·90 kcal./mole. The vapour pressure data follow the equation:

$$\log p_{(\text{mm.})} = -1290/T + 7{\cdot}716$$

The analysis, molecular weight (vapour density) and mass spectrum are all in agreement with the formula assigned. The infra-red spectrum of diphosphorus tetrafluoride shows absorptions at 842(s), 830(vs), 820(s), 408(vw) and 356(w) cm.$^{-1}$

A by-product formed in small yield during this preparation has been tentatively identified as diphosphorus oxytetrafluoride, $PF_2OPF_2$, by its molecular weight (vapour density), and infra-red and mass spectra. It may also be prepared directly in 67% yield by reaction between diphosphorus tetrafluoride and oxygen.[160]

## PHOSPHORUS(V) FLUORIDE

### Preparation

Almost theoretical yields of phosphorus(V) fluoride and corresponding metal fluoride are obtained from the thermal decomposition of sodium, calcium or barium hexafluorophosphates between 300° and 1000°C.[63] The action of acidic inorganic chlorides such as hydrogen chloride, phosphorus pentachloride, antimony(V) or ferric chlorides, on sodium hexafluorophosphate at 200–350°C. also yields phosphorus(V) fluoride.[161] Other procedures proposed in the patent literature include the reactions between phosphorus(III) fluoride, chlorine or bromine and calcium fluoride at 325° to 500°C.,[64] and between not less than 5:3 molar mixtures of phosphorus(III) fluoride and chlorine or bromine when passed through a tubular reactor (packed with 'Adsorbite') at 250° to 600°C.[65] Both reactions provide good yields of phosphorus(V) fluoride, but the conditions of the second patent processes afford continuous operation without deposition of solid pentahalides and consequent blocking of cooler parts of the line. Phosphorus(III) chloride and small amounts of mixed trihalide by-products are separated at −80°C. and are later returned to the process after halogen exchange with heated calcium fluoride. The preparation from arsenic trifluoride and phosphorus pentachloride (Thorpe, Mellor, VIII, 996) has been further described[66]; a copper reaction vessel was used. For the reaction between phosphorus(V) chloride vapour, in a nitrogen carrier stream, with calcium fluoride, 80 to 90% conversion to phosphorus pentafluoride is reported.[67] In all these processes strictly anhydrous conditions were found to be essential for efficient recoveries. Phosphorus pentafluoride also results from the fluorination of phosphorus pentachloride by sodium hexafluorosilicate[135] or difluorodiazine.[156]

### Physical Properties

The pure substance boils at −84·5°C., m.p. −93·7°C. Vapour pressures from −125·6° to −84·5°C. are represented by $\log_{10} p_{\mathrm{mm.}} = -A/T + B$ where $A = 1518{\cdot}8$ and $898{\cdot}8$, $B = 11{\cdot}101$ and $7{\cdot}646$ for the sublimation and vaporization curves respectively. The heats of sublimation, fusion and vaporization are 6940, 2830 and 4110 g.-cal. mole$^{-1}$ and Trouton's constant = 21·8. The dielectric constant is 1·002063, independent of temperature,[66] the refractive index (Na$_{\mathrm{D}}$, 760 mm.) is 1·0006416 and the derived electron and atom polarization values are 9·2 and 6·2, respectively.[68] The heat of formation was estimated, by extrapolation from available data for sodium, aluminium, silicon and sulphur fluorides, as −315 kcal./mole.[69] However, two direct determinations by combustion of white phosphorus in fluorine gave higher values, in excellent agreement, of $\Delta H^{\circ}_{f\,\mathrm{PF_5(g)}}$ at 25°C. = $-381{\cdot}4 \pm 0{\cdot}8$[162] and $-380{\cdot}8 \pm 0{\cdot}3$[163] kcal./mole. The latter authors also report values of high temperature thermodynamic functions for gaseous $\mathrm{PF_5}$.

In the vapour state phosphorus(V) halide molecules have trigonal bipyramidal structures approximating to $sp^3d$ hybridization at the P-atom. Early electron diffraction measurements[16, 70] appeared to indicate equal P–F distances of 1·57 ± 0·02 A. in phosphorus pentafluoride. Later determinations,[164–5] while differing from one another, agree in assigning a greater length to the axial than to the equatorial P–F bonds. The chlorine atoms in phosphorus dichlorotrifluoride were first thought to occupy axial positions with fluorine and phosphorus atoms coplanar,[16, 70] but subsequent infra-red and Raman data suggest that the chlorine atoms occupy equatorial positions.[166] Two P–Cl distances are also observed for phosphorus pentachloride in the gaseous state, corresponding to the axial and equatorial chlorine atoms respectively.[71] Raman methods[72–5] show all five P–Cl bonds alike at temperatures above the melting point, but in the solid state the molecule is unsymmetrical and ionic (see page 476). Bond lengths (A.) determined in the above work are:

| | | $\mathrm{PF_5}$ | | $\mathrm{PF_3Cl_2}$ | $\mathrm{PCl_5}$ |
|---|---|---|---|---|---|
| P–F | (axial) | 1·549 ± 0·005,[164] | 1·577[165] | | |
| | (equatorial) | 1·499 ± 0·005 | 1·534 | 1·59(±0·03) | |
| P–Cl | (axial) | | | 2·05(±0·03) | 2·19(±0·06) |
| | (equatorial) | | | | 2·04(±0·06) |

Some controversy on the detailed assignments of the fundamental vibrations in the infra-red spectrum of phosphorus pentafluoride[166] has now been resolved.[167–8] The vapour infra-red spectra and low temperature liquid Raman spectra of phosphorus pentafluoride and the fluorochlorophosphoranes are all consistent with trigonal bipyramidal structures.[27, 166] $\mathrm{PCl_4F}$ has a $C_{3v}$ structure with the fluorine occupying an axial position. In $\mathrm{PCl_3F_2}$ ($D_{3h}$) both fluorine atoms are axial, while in $\mathrm{PCl_2F_3}$($C_{2v}$) the fluorine atoms occupy one equatorial and two axial positions.[166] Nuclear quadruple resonance[180] and dipole moment[181] data are in accordance with these structures.

There is some debate concerning the reason for the conformations adopted by the various chlorofluorides. Some authors claim that the stabilization of a particular isomer of $\mathrm{PCl}_{5-n}\mathrm{F}_n$ is a result of $\sigma$ bonding, and is not due to more favourable $\pi$ bonding or *d* orbital participation, though both are present. They suggest that equatorial orbitals, being more electronegative than axial orbitals, give rise to stronger bonds. Electropositive substituents are then associated with the more electronegative phosphorus orbitals (and vice versa), resulting in the observed isomers.[169] However, it is also claimed[170] that the structure of $PF_5$ itself can be explained on the electron pair repulsion theory, without having to make arbitrary assumptions concerning the types of atomic orbitals which take part in the bonding; and similar arguments could presumably be advanced for the chlorofluorides. The true explanation may contain elements of both theories.

In spite of the infra-red evidence, $^{19}F$ nuclear magnetic resonance studies have shown spectroscopic equivalence for all the fluorine atoms in phosphorus(V) fluoride (both gaseous and liquid states)[76–7] as also in a number of mono-substituted compounds $RPF_4$, where R is an alkyl, aryl or trifluoromethane group.[78–9] Conformity of the spectroscopic equivalence of the P–F bonds in phosphorus(V) fluoride with the electron diffraction evidence of a trigonal bipyramidal structure is proposed on the basis of internal pseudo-rotation,[80] or of rapid interchange between the trigonal bipyramid and related tetragonal pyramid configurations.[78–9] For the compounds $R_2PF_3$ and $R_3PF_2$, nuclear magnetic resonance evidence is consistent with a trigonal bipyramidal structure with the substituent groups located in the planar positions. In cyclic $(CH_2)_4PF_4$, rapid intramolecular exchange between apical and planar F-atoms is thought to occur.[78–9]

## Chemical Properties

Phosphorus(V) fluoride behaves as an acceptor for fluoride ion in hydrofluoric acid solution. Evaporation of such solutions with less than the equivalent amount of silver, sodium, potassium, barium or calcium fluoride results in complete conversion to the respective hexafluorophosphate, and absence of solvolysis indicates that phosphorus pentafluoride in this medium is a reasonably strong acid.[81–2] However, in extraction experiments with *m*- and *p*-xylenes in *n*-heptane solution, phosphorus(V) fluoride in hydrogen fluoride ranks as a weak acid, and tantalum or niobium pentafluoride in hydrogen fluoride as a strong acid. The differences were attributed to the comparative ease of attaining the octahedral anion structure, the former only by expansion of the valence shell, but the last pair presumably by use of an available *d*-orbital.[83]

Hexafluorophosphates are formed with nitryl fluoride[84] and with chloryl fluoride[85]: the product of the first reaction, $NO_2PF_6$, is a white solid, that from the second, $ClO_2PF_6$, boils at −35°C. under high vacuum. Similarly chlorine trifluoride forms $ClF_2PF_6$ which is ionic both in the solid state, and in solvents such as chlorine trifluoride. Its heat of dissociation $\Delta H° = 16{\cdot}4$ kcal./mole.[171] In forming 1:1 adducts with ethers, thioethers, selenoethers, aldehydes, ketones, sulphoxides, esters, nitriles and amines,[172–3] phosphorus pentafluoride behaves as a typical Lewis acid. Such products, however, are readily decomposed by water or alcohols and thus are considerably less stable than the corresponding boron trifluoride compounds. Sulpholane for example, which reacts with $BF_3$, is reported to form no stable solid complex with $PF_5$, although the $^{19}F$ magnetic resonance spectrum shows evidence of interaction.[174] The $^{19}F$ magnetic resonance spectra of solutions in acetonitrile are in agreement with an octahedral structure having four equivalent, coplanar fluorine atoms and one apical fluorine atom.[67] The electrical conductance of such solutions is quite high ($\Lambda_c = 210$ ohm$^{-1}$ cm.$^2$ mol.$^{-1}$, $c = 0{\cdot}01$).[175] Like boron trifluoride and tin tetrafluoride, phosphorus pentafluoride is an effective Friedel–Crafts catalyst for the polymerization of *iso*butene or cyanogen chloride.[86] Catalysts consisting of mixtures of phosphorus pentafluoride with up to 50% of metal oxides[87] or with Lewis bases containing oxygen or sulphur[88] are described in the patent literature, as is the use of the fluoride itself in the polymerization of propylene,[89] trioxane[90] and tetrahydrofuran,[67] and in the formation of poly-ethers.[91–2] By rapid cooling of the products of reaction of phosphorus pentafluoride with carbon, substantial yields of tetrafluoroethylene are obtained.[65, 93]

## PHOSPHORUS(V) CHLORO- AND BROMO-FLUORIDES

Phosphorus(V) chloro- and bromo-fluorides occur as unstable covalent liquids or as relatively stable, isomeric, salt-like solids. The first type is obtained by halogen addition to phosphorus(III) halogenofluorides and the second mainly by fluorination of phosphorus(V) halides in a suitable polar solvent; both types of reaction must be carried out in the absence of moisture. A number of such compounds have been described and are summarized in Table V. The properties of the molecular chlorofluorides are summarized in Table VI.

*Table V.—The Phosphorus(V) Chloro- and Bromo-fluorides*

| Covalent halides | | Salt-like halides | |
|---|---|---|---|
| $PCl_5$ | only as vapour, or as liquid under pressure, or as solute in non-polar solvents[74–5] | $[PCl_4]^+[PCl_6]^-$ | colourless crystals, subl. 160°C., m.p. 167°C. under pressure[74–5, 97–8] |
| | | $[PCl_4]^+[PCl_5F]^-$ | colourless crystals, decomp. 110°C.[96] |
| $PCl_4F$ | mobile liquid, m.p. $-63°$, b.p. 67°C.,[94] m.p. $-59$°C.[95] | $[PCl_4]^+F^-$ (or $[PCl_4]^+[PCl_4F_2]^-$ [176]) | colourless crystals, subl. 175°C.[94, 96] |
| $PCl_3F_2$ | m.p. $-63$°C.[95] | — | |
| $PCl_2F_3$ | stable gas, m.p. $-125$°C., b.p. 7·1°C.[7, 41–2, 95–6] | $[PCl_4]^+[PF_6]^-$ | white crystalline powder, subl. 135°C. with decomposition[41, 99] |
| $PClF_4$ | gas, m.p. $-132$°C., b.p. $-43·4$°C., decomp. at room temp.[177] | — | |
| $PBr_5$ | only as solute in non-polar solvents[74–5] | $[PBr_4]^+[Br]^-$ | red-brown crystals, melting with decomposition above 83·8°C.[100–2] |
| $PBr_4F$* | clear liquid, decomp. at room temperature[5, 7] | $[PBr_4]^+[F]^-$ | yellow cryst. powder, m.p. 87°C. with decomposition[7] |
| $PBr_3F_2$* | [5] | — | |
| $PBr_2F_3$ | unstable liquid, decomp. 15°C. (Mellor, VIII, 1042) | $[PBr_4]^+[PF_6]^-$ | white cryst. powder, subl. 135°C. with decomposition[103] |

* Formation indicated, but not further characterized.

Ionic lattice structures are established for crystalline phosphorus pentachloride[97–8] and phosphorus pentabromide,[100–2] each having a tetrahedral cation (approximating $sp^3$ hybridization at the P-atom, with bond lengths P–Cl = 1·98 A., P–Br = 2·2 A.) the former with an octahedral anion ($sp^3d^2$ hybridization, P–Cl = 2·06 A.) and the latter a bromide anion. Typical of the salt-like pentahalides, both compounds behave as electrolytes in polar solvents, and transport experiments in acetonitrile solution have confirmed the presence of $[PCl_4]^+$ and $[PCl_6]^-$ [104] and of $[PBr_4]^+$ and $[PBr_6]^-$ [105] ions respectively.

The covalent chlorofluorophosphoranes are conveniently synthesized in an all-glass apparatus[95] by condensing excess chlorine on the appropriate phosphorus(III) chlorofluoride cooled in liquid nitrogen, and subsequently fractionating *in vacuo* after holding 30 min. at somewhat higher temperatures, $-78°$ for $PCl_4F$ and $PCl_3F_2$, $-127$°C. for $PCl_2F_3$, in order to complete the reaction. Chlorotetrafluorophosphorane, $PClF_4$, cannot be isolated from this reaction, but has been obtained by the controlled fluorination of the molecular form of $PCl_2F_3$, using antimony trifluoride.[177] Fluorotetrachlorophosphorane, $PCl_4F$, can also be conveniently prepared by the action of silver fluoride on phosphorus pentafluoride.[176] The compounds react with excess of pyridine in the liquid phase to form white, thermally unstable, solid complexes; *viz.*, $C_5H_5N,PCl_4F$, $C_5H_5N,PCl_3F_2$ and $3C_5H_5N,PCl_2F_3$, all soluble

*Table VI.—Physical Properties of the Chloro- and Fluoro-phosphoranes*

in nitrobenzene.[95] The heats of reaction of phosphorus(V) chloride and chlorofluorides with pyridine to form 1:1 complexes in nitrobenzene solution at 30°C. were: $PCl_3F_2$ 35·3 ± 0·3, $PCl_4F$ 27·0 ± 0·2 and $PCl_5$ 22·0 ± 0·2 kcal. mole$^{-1}$.[106] It was concluded[106–7] that the order of Lewis acid strength towards pyridine was therefore the same as that expected from electronegativity or steric effect considerations, and in fact the reverse of that found earlier[108] (viz. $BBr_3 > BCl_3 > BF_3$) for the boron trihalides. Nuclear magnetic resonance spectra (resolution = 2 c.p.s.) for liquid forms of $PCl_2F$, $PClF_2$, $PCl_4F$, $PCl_3F_2$ and $PCl_2F_3$ at −15°C. and for the 1:1 pyridine adducts of $PCl_4F$ and $PCl_3F_2$ in nitrobenzene solution, consisted of one doublet without any secondary splitting. This evidence supports a common structural model for the phosphorus(V) chlorofluorides, with equivalent fluorine atoms in each compound, and absence of any ionization process involving fluorine for the 1:1 adducts in nitrobenzene.[95] The derived data in Table VII exhibit opposing trends in $^{19}F$ shift with increasing fluorine content in the phosphorus(III) and phosphorus(V) chlorofluorides. Although a trigonal bipyramidal structure has been established[166] for dichlorotrifluorophosphorane in which the 2 chlorine atoms occupy equatorial positions, complete assignment for the tetrachloro- and trichlorofluorophosphoranes is made more difficult by the apparent spectroscopic equivalence of all the fluorine atoms in phosphorus(V) fluoride,[76–9] and by the very small chemical shift (0·07 p.p.m.) for the difference between apical and equatorial fluorine atoms in trifluoromethyltetrafluorophosphorane.[78–9] A similar study of dichloro- and dibromo-trifluorophosphorane, $PCl_2F_3$ and $PBr_2F_3$, shows that there are two fluorine environments at very low temperatures, which become equivalent at ambient temperatures. The intramolecular exchange activation energy of both compounds is about 7·2 kcal./mole.

*Table VII.—$^{19}$F Nuclear Magnetic Resonance Data for the Phosphorus(III), (V) and Phosphoryl Chlorofluorides*

| Compound | Chemical shift from $CF_3COOH$ p.p.m. | P–F coupling constant c.p.s. |
|---|---|---|
| $PF_5$ | −5·0 | 930 |
| $PCl_2F_3$ | −108·0 | 1048 |
| $PCl_3F_2$ | −191·8 | 1045 |
| $PCl_4F$ | −220·0 | 996 |
| $PBr_2F_3$ | −135·0 | 1124 |
| $PF_3$ | −43·4 | 1400 |
| $PClF_2$ | −39·9 | 1390 |
| $PCl_2F$ | −20·7 | 1320 |
| $C_5H_5N,PCl_3F_2$ | −101·8 | 983 |
| $C_5H_5N,PCl_4F$ | −140·0 | 1049 |
| $POF_3$ | 15·8 | 1055 |
| $POClF_2$ | −30·4 | 1120 |
| $POCl_2F$ | −69·0 | 1175 |

Data for $PF_5$, $PF_3$ and $POCl_xF_{3-x}$ are taken from references 78–9.
Data for the two resonances shown by the apical and equatorial fluorine atoms in $PCl_2F_3$ and $PBr_2F_3$ are given in reference 179.
The $^{31}P$ spectrum of $PCl_4F$ consists of a sharp doublet with chemical shift −56 ± 2 p.p.m. relative to 85% $H_3PO_4$ and a coupling constant of 1010 ± 25 c.p.s.

Beginning with the 'covalent' and then passing to the 'salt-like' group, the more important members of the phosphorus(V) halogenofluorides (cf. Table V) will be discussed individually.

### *Dichlorotrifluorophosphorane, $PCl_2F_3$*

The formation reaction from gaseous phosphorus trifluoride and chlorine is photosensitive and catalyzed by glass surfaces. Raising the temperature from 0 to

25°C. reduces the reaction rate by about half, while at low temperatures in the liquid state the reaction is many times more rapid.[42] Preparation is carried out with slight excess of phosphorus trifluoride, and pure dichlorotrifluorophosphorane is obtained on repeated fractionation *in vacuo*. Varying small amounts of mixed white solid tetrachlorophosphonium hexafluorophosphate, $[PCl_4]^+[PF_6]^-$, and tetrachlorophosphonium fluoride, $[PCl_4]^+[F]^-$, in the molar ratio of approximately 9:1 are also formed.[41] When equilibrium proportions of the liquid reagents contained in a pressure vessel lined with Hastelloy C are allowed to equilibrate at room temperature, pressure versus time measurements are in accord with a fast reaction: $PF_3+Cl_2=PCl_2F_3$, followed by two slow reactions:

$$\begin{array}{lcll} 2PCl_2F_3 & = & [PCl_4]^+[PF_6]^- & \\ 5PCl_2F_3 & = & [PCl_4]^+[PCl_6]^- & +3PF_5 \\ \text{(liquid)} & & \text{(solid)} & \text{(gas)} \end{array}$$

After 140 hr. the bulk of the product is solid, while the volatile fraction is essentially phosphorus pentafluoride.[67]

Vapour pressures from 213 to 263°K. are represented by $\log_{10} p_{\text{mm.}} = 7{\cdot}264 - 1288/T$, from which b.p. (extrapolation to 760 mm.) = 7·1°C., latent heat of vaporization = 5·66 kcal. mole$^{-1}$ and Trouton's constant = 20·2. The m.p. lies between −130° and −125°C. and the vapour density at 20°C. is in accord with that expected from $PCl_2F_3$ molecules.[41] More recent data[183] are given in Table VI. Peaks in the infra-red spectra at 40 and 80 mm. pressure are observed at:

$$\left.\begin{array}{llllllll} 932 & \text{s.} & 675 & \text{s.} & 564 & \text{m.} & 492 & \text{m.} \\ 899 & \text{s.} & 668 & \text{s.} & 530 & \text{s.} & 432 & \text{w.} \\ 870 & \text{s.} & 635 & \text{s.} & 500 & \text{m.} & 415 & \text{m.} \end{array}\right\} \text{cm.}^{-1}$$

Mass spectroscopy gives $PF_3Cl_2^+$, $PF_3Cl^+$, $PF_2Cl^+$, $PF_3^+$, $PClF^+$, $PF_2^+$ and $Cl^+$ ion species at an ionization energy of 15 e.v. From these results it appears that loss of fluorine occurs only from monochloro fragments.[41] Nuclear quadrupole resonance[180, 178] and spectroscopic[166] data are in accordance with a structure in which the chlorine atoms lie in the equatorial plane, and not axially as suggested by previous workers.[16] The asymmetric structure is supported by the high value of the gas-phase dipole moment of $PCl_2F_3$ (0·68 D) compared with that of $PCl_4F$ (0·21 D),[182] and the zero value shown by $PCl_3F_2$.[181]

The specific conductance of liquid dichlorotrifluorophosphorane is $<10^{-7}$ mho cm.$^{-1}$ For 0·0452 and 0·09053 M. solutions in acetonitrile at 20°C., molar conductances are 9·63 and 9·31 mho cm.$^2$ mole$^{-1}$, respectively[41] (cf. 90·9 mho cm.$^2$ mole$^{-1}$ for a 0·042 M. solution of the salt-form analogue $[PCl_4]^+[PF_6]^-$ at 30°C.[99]), i.e. of the order for limited ion formation.

Above 150°C. disproportionation of dichlorotrifluorophosphorane occurs, giving tetrachlorofluorophosphorane and phosphorus pentafluoride: $2PCl_2F_3 = PCl_4F + PF_5$ (cf. Mellor, VIII, 1042), but this is complicated by the reactions:

$$\begin{array}{rcl} PCl_4F+PF_5 & = & [PCl_4]^+[PF_6]^- \\ \text{and } PCl_4F & = & [PCl_4]^+[F]^- \end{array}$$

and also by the formation of phosphoryl fluoride and silicon tetrafluoride resulting from attack on the glass apparatus.[96]

*Dibromotrifluorophosphorane*, $PBr_2F_3$. The stability of the halogenofluorophosphoranes is decreased by substitution of bromine for chlorine. Thus dibromotrifluorophosphorane decomposes at 15°C. while the corresponding dichloro-compound is stable up to 200°C.[7]

*Tetrachlorofluorophosphorane*, $PCl_4F$, f.p. −63°, b.p. +67°C. may be obtained by distillation of tetrachlorophosphonium fluoride, $[PCl_4]^+[F]^-$,[109] or of the pyrolysate of tetrachlorophosphonium hexafluorophosphate, $[PCl_4]^+[PF_6]^-$,[94] both in arsenic(III) chloride suspension at 70° to 90°C.

The isomerization $PCl_4F \rightarrow [PCl_4]^+[F]^-$ is a first-order reaction with rate constants 5·62, 3·02, 1·58 and $0{\cdot}843\times10^{-4}$ min.$^{-1}$ at 30, 20, 10 and 0°C., respectively.

The activation energy, attributed to exchange of chlorine between apical and equatorial positions, is 10·6 kcal. mole$^{-1}$ and the frequency factor is 4·37 min.$^{-1}$ [109] A more recent study by infra-red, cryoscopic and conductivity methods suggests that the ionic form of $PCl_4F$ is in fact tetrachlorophosphonium difluorotetrachlorophosphate, $[PCl_4^+][PCl_4F_2^-]$, contaminated by traces of $[PCl_4^+][PF_6^-]$ and $[PCl_4^+][PCl_6^-]$.[176] Values of the equilibrium constant for the dissociation:

$$PCl_4F(g) \rightleftharpoons PCl_2F(g) + Cl_2(g)$$

are:

| °C. | 133·8 | 148·0 | 163·5 | 182·3 | 193·5 | 212·5 |
|---|---|---|---|---|---|---|
| $\log_{10} K_{p(\text{min.})}$ | −0·6120 | −0·6630 | +0·1701 | 0·4060 | 0·7593 | 0·9393 |

from which $\Delta H = 11$ kcal. mole$^{-1}$,[96] cf. 22 kcal. mole$^{-1}$ for:

$$PCl_5(g) = PCl_3(g) + Cl_2(g)^{31}$$

*Tetrabromofluorophosphorane*, $PBr_4F$, is formed as a clear liquid by passing bromine vapour in a nitrogen gas stream through liquid phosphorus(III) dibromofluoride at −75°C. It decomposes at room temperature into phosphorus(V) bromide and fluoride.[7]

*Tetrachlorophosphonium hexafluorophosphate*, $[PCl_4^+][PF_6^-]$, is a white hygroscopic salt subliming at 135°C. with partial decomposition. It is obtained in quantitative yield by the dropwise addition of arsenic(III) fluoride to a stirred solution of phosphorus(V) chloride in arsenic(III) chloride at room temperature:

$$[PCl_4^+][PCl_6^-] + 2AsF_3 = [PCl_4^+][PF_6^-] + 2AsCl_3$$

Its formation is proposed[99] as confirmatory evidence of the nature of the ionization of phosphorus(V) chloride in polar solvents. The specific conductance of acetonitrile solutions at 30°C. increases linearly with concentration over the range 0·02 to 0·05 M. giving molar conductance values of 40·9 and 94·8 mho cm.$^2$ mole$^{-1}$ at 0·0208 and 0·0485 molality, respectively.[99]

Hydrolysis in aqueous alkali leads to hexafluorophosphates:

$$3[PCl_4^+][PF_6^-] + 7KOH = K_2HPO_4 + 4KCl + KPF_6 + 3H_2O$$

Reaction with arsenic(III) fluoride at room temperature is a convenient source of phosphorus pentafluoride:

$$3[PCl_4^+][PF_6^-] + 4AsF_3 = 6PF_5 + 4AsCl_3{}^{99}$$

Similarly a suspension of tetrachlorophosphonium hexafluorophosphate in either arsenic(III) chloride or carbon tetrachloride under reflux evolves phosphorus pentafluoride and dichlorotrifluorophosphorane, while tetrachlorofluorophosphorane, b.p. 67°C., is retained by the reflux condenser. If the residue from the arsenic chloride reaction is filtered while hot, and then allowed to stand overnight at 0°C. it deposits crystals of tetrachlorophosphonium fluoride containing some hexafluorophosphate. The residue from the reaction in carbon tetrachloride, however, comprises a mixture of tetrachlorophosphonium fluoride and tetrachlorophosphonium pentachlorofluorophosphate.[94, 96] Heating tetrachlorophosphonium hexafluorophosphate *in vacuo* at 100° to 150°C. gives dichlorotrifluorophosphorane; at higher temperatures the products are those arising from disproportionation of this compound and side reactions with the glass apparatus.[96]

*Tetrachlorophosphonium fluoride*, $[PCl_4^+][F^-]$ (or $[PCl_4^+][PCl_4F_2^-]$[176]), is a white hygroscopic solid, subl. 175°C., m.p. 177°C. under pressure. It may be obtained from tetrachlorophosphonium hexafluorophosphate by decomposition in arsenic(III) chloride suspension at 70° to 85°C. under reflux as outlined above. The solid separating from the liquid phase at 0°C. is freed from arsenic(III) chloride and tetrachlorophosphonium hexafluorophosphate impurities by heating up to 80°C. under 1 mm. pressure.[94]

Reaction with phosphorus pentafluoride is rapid at 50°C. according to the equation $[PCl_4^+][F^-]+PF_5=[PCl_4^+][PF_6^-]$. Cryoscopy in acetic acid gives mol. wt. = 80 (*cf.* half formula weight = 96). Hydrolysis in aqueous alkali gives one third of the fluorine as monofluorophosphate, i.e. it requires 6·7 equivalents of caustic soda per mole instead of 7 according to the equation:

$$[PCl_4^+][F^-]+7NaOH = Na_2HPO_4+4NaCl+NaF+3H_2O$$

The specific conductance of tetrachlorophosphonium fluoride solutions in acetonitrile at 21°C. increases linearly with concentration over the range 0·05 to 0·1 M. giving molar conductance values of 15·8 and 25·5 mho cm.$^2$ mole$^{-1}$ at 0·0501 and 0·1031 M., respectively. The specific conductances for the melt at 190°C. under pressure and for liquid tetrachlorofluorophosphorane are 0·16 and $2{\cdot}0\times10^{-6}$ mho cm.$^{-1}$, respectively.[94]

Reversion of molten tetrachlorophosphonium fluoride to the crystalline form occurs only slowly at 20°C. under sealed tube conditions and subsequent remelting takes place at an appreciably lower temperature, viz. 161° against the original 177°C. Some tetrachlorophosphonium hexafluorophosphate crystallizes from the melt. The equilibria are expressed[94] by:

$$\text{(i)}\qquad \underset{\text{(solid)}}{[PCl_4]^+[F]^-} \underset{\text{slowly at 0° to 30°C.}}{\overset{\text{at 177°C. (closed tube)}}{\rightleftharpoons}} \underset{\text{(liquid)}}{PCl_4F}$$

$$\text{(ii)}\qquad \begin{cases} 5PCl_4F \rightleftharpoons 4PCl_5+PF_5 \\ PCl_4F+PF_5 \rightleftharpoons [PCl_4]^+[PF_6]^- \end{cases}$$

*Tetrachlorophosphonium pentachlorofluorophosphate*, $[PCl_4]^+[PCl_5F]^-$. The solid product from the decomposition of tetrachlorophosphonium hexafluorophosphate in boiling carbon tetrachloride loses tetrachlorophosphonium fluoride when heated at 85°C. in dry air. The residue had an analysis corresponding to $PCl_{4\cdot5}F_{0\cdot5}$ and a unique *X*-ray powder pattern.[96] Molar conductance values in acetonitrile at 20°C. were 72·2, 68·5 and 66·1 mho cm.$^2$ mole$^{-1}$ for 0·0227, 0·0433 and 0·0685 molar solutions, respectively, and transport experiments confirmed the presence of both phosphorus and fluorine in the anion which had a transport number close to 0·5. Above 110°C. disproportionation to phosphorus pentachloride and tetrachlorofluorophosphorane occurred.[96]

Mass spectroscopy at an ionization energy of 50 e.v. gave ion species derived from a $P_2X_{10}$ parent thus:

| | | | | |
|---|---|---|---|---|
| $P_2Cl_8F^+$ | $P_2Cl_7F^+$ | $P_2Cl_6F^+$ | $P_2Cl_5F^+$ | $P_2Cl_3F^+$ |
| $P_2Cl_2F^+$ | $P_2ClF^+$ | $P_2Cl_2^+$ | $PCl_4^+$ | $PCl_3^+$ |
| $PCl_2^+$ | $PClF^+$ | $PCl^+$ | $Cl^+$ | $P^+$ |

The equilibrium

$$\underset{\text{(solid)}}{[PX_4]^+[PX_6]^-} \rightleftharpoons \underset{\text{(vapour)}}{P_2X_{10}}$$

is suggested to account for this cracking pattern.[110] The $P_2X_{10}$ and derived $P_2$ ion species contain Cl-bridges in a 4-membered ring with octahedrally connected phosphorus atoms (*cf.* phosphorus pentachloride, page 478).

*Tetrabromohexafluorophosphonate*, $[PBr_4]^+[PF_6]^-$, is formed as a white hygroscopic crystalline solid (subl. 135°C. with decomposition) by the dropwise addition of arsenic(III) fluoride to a stirred suspension of phosphorus(V) bromide in carbon tetrachloride or carbon disulphide at 30° to 50°C. In contact with arsenic(III) fluoride the formation of $[PBr_4]^+$ and $[PBr_6]^-$ ions is postulated[103] and fluorination of the cation follows. With phosphorus(V) bromide in arsenic(III) chloride solution, halogen exchange occurs and white tetrachlorophosphonium hexafluorophosphate is the main product of subsequent fluorination with arsenic(III) fluoride.[103]

Tetrabromophosphonium hexafluorophosphate is readily soluble in both phosphorus and arsenic(III) chlorides or bromides. The chloride solutions slowly deposit tetrachlorophosphonium hexafluorophosphate on standing, while the bromide solutions decompose on warming to give phosphorus(V) fluoride thus:

$$[PBr_4][PF_6] \xrightarrow[\text{in AsCl}_3\text{ at 20°C.}]{} [PCl_4][PF_6]$$

$$[PBr_4][PF_6] \xrightarrow[\text{in AsBr}_3\text{ at > 30·8°C.}]{} [PBr_4][F] + PF_5$$

$$\hookrightarrow \tfrac{4}{5}PBr_5 + \tfrac{1}{5}PF_5$$

$$cf.\quad [PCl_4][PF_6] \xrightarrow[\text{in AsCl}_3\text{ at > 70°C.}]{} PCl_4F + PF_5$$

The specific conductance of tetrabromophosphonium hexafluorophosphate solutions in arsenic(III) fluoride at 0°C. increases linearly with concentration over the range 0·0186 to 0·0832 M; molar conductances at these concentrations are 46·2 and 42·4 mho cm.$^2$ mole$^{-1}$ respectively. In water alone, hydrolysis is vigorous and leads to free bromine and reduced acids. With sodium acetate buffer or with excess of alkali, no bromine is liberated and $PF_6^-$, $PO_2F_2^-$, $PO_3F^{2-}$ and $PO_4^{3-}$ anions are formed.[103]

*Tetrabromophosphonium fluoride*, $[PBr_4]^+[F]^-$, m.p. 87°C. (decomp.), separates as a yellow powder from tetrabromofluorophosphorane after about 16 hr. at $-75°$ to $-30°$C. By conducting the process in carbon tetrachloride solution, bright yellow crystals of composition $[PBr_4][F],2CCl_4$ are obtained, which lose two carbon tetrachloride molecules when under vacuum at room temperature. Both compounds give conducting solutions in acetonitrile and cryoscopic measurements correspond to half and quarter formula weights, respectively. Hydrolysis is vigorous and free bromine forms in acid solution. With excess of alkali no bromine is formed and the hydrolysate contains $PO_4^{3-}$, $PO_3F^{2-}$, $F^-$ and $Br^-$ anions.[7]

## PHOSPHORYL FLUORIDE, PHOSPHORYL CHLORO- AND BROMO-FLUORIDES

### Preparation

Phosphoryl halogenofluorides are obtained from phosphoryl chloride or bromide ($POX_3$) by methods analogous to those for obtaining phosphorus(III) halogenofluorides from phosphorus(III) chloride or bromide ($PX_3$). Thus fluorination of $POX_3$ can be effected, (*a*) at reduced pressure in the vapour state, with heated calcium fluoride pellets; or (*b*) at temperatures between 75°C. and the boiling point by controlled addition of powdered antimony(III) fluoride in the presence of antimony(V) fluoride catalyst[111]; or (*c*) by refluxing with ammonium fluoride;[2] or (*d*) by passing through mixed alkali metal fluoride melts.[135] Relative yields where X = chlorine are indicated by the methods (*a*), (*b*) and (*c*), respectively, in Table VIII.

*Table VIII.—Fluorination of Phosphoryl Chloride or Bromide* ($POX_3$)

| X | Method (see text) | Atom ratio P:F:X in original mixture | Temp. °C. | Yield, wt. % of volatile product | | | | | Ref. |

| Br | e | — | 60–100 | — | 60 | 10 | 30 | — | 112 |

Phosphorus pentoxide–calcium fluoride mixtures at 500° to 600°C. give phosphoryl fluoride, but in the presence of sodium chloride, and in iron reaction vessels, phosphoryl fluorochlorides and phosphorus(III) fluoride are also formed ('d' Table VIII). Trace amounts of water give rise to hydrogen fluoride or chloride among the volatile products; with calcium fluoride alone, the amount of phosphoryl fluoride formed closely corresponds to the equation $3CaF_2+4P_2O_5=2POF_3+3Ca(PO_3)_2$.[1, 113] Other effective fluorinating agents for phosphoryl chloride are potassium fluoride in liquid sulphur dioxide[3] and anhydrous hydrofluoric acid.[114] Phosphorus pentoxide dissolves in a large excess of hot iodine pentafluoride[115] or reacts on dropwise addition of fluorosulphonic acid,[116] both with formation of phosphoryl fluoride. The reactions are thought to be:

$$P_2O_5+3IF_5 = 2POF_3+3IOF_3$$

and

$$P_2O_5+3HSO_3F = POF_3+HPO_3+2SO_3+H_2SO_4$$

The latter proceeds to 80% in the presence of excess of phosphorus pentoxide. Phosphoryl fluoride and phosphoryl fluorobromides are obtained[112] from the usual fractionation methods following slow addition of powdered antimonous fluoride to phosphoryl bromide at 25 to 50 mm. pressure. The initial reaction is vigorous at 60°C., proceeding without added catalyst on gradually raising the temperature to 100°C. Relative yields are indicated at 'e' Table VIII.

### Physical Properties

Physical data for the phosphoryl fluorides are summarized in Table IX.

Electron diffraction measurements[16, 117–8] point to tetrahedral structures for the phosphoryl halides, approximating $sp^3$ hybridization at the P-atom. The molecular data are summarized in Table X together with those derived from measurements of pure rotational transitions in the microwave region.[119–21] Observed P–F, P–Br and P–O distances are appreciably shorter than the calculated values for the respective single and double bonds, and hypothetical resonance structures for $POF_3$ have been suggested. Multiple bonding amounting to 0·8 to 2 $\pi$ bonds per P-atom is calculated for the phosphoryl halides from bond length, and from thermochemical data.[122–3] The observed P–Cl distances, however, allow for little or no $\pi$ bond shortening, and in the case of phosphoryl chloride all the multiple bonding character of the P-atom would appear to be contained in the P–O bond. For P–F and P–Br bonds, such shortening corresponds to approximately $\frac{1}{3}\pi$ bond per $\sigma$-bond.[122–3] Bond order calculations[124] based on force constants derived from their vibration spectra, gave values of 2·34, 2·09 and 2·02 for phosphoryl fluoride, chloride and bromide respectively; these are taken to imply a tendency to achieve a closed shell structure of 12 rather than 8 electrons in these compounds. Fundamental frequency assignments for a number of the phosphoryl and thiophosphoryl halides were made[27–8, 125, 184, 186] on the basis of their infra-red and Raman spectra. Force constant data evaluated by Wilson's method of matrices are summarized in Table XI and some authors[125–6] have attempted more complete solutions by using available data for the corresponding $PX_3$ halide.

The same authors give heat content, free energy, entropy and heat capacity values for both $POX_3$ and $PSX_3$ molecules (ideal gas state, 1 atm. pressure) at temperatures between 50° and 1000°K., calculated by a rigid rotator, harmonic oscillator approximation from their probable absorption frequencies. For the reaction:

$$PX_3(g)+\tfrac{1}{2}O_2(g) = POX_3(g)$$

comparison of the derived $\Delta H$, viz. $-63{\cdot}3$ kcal. mole$^{-1}$ for X=Cl (*cf.* $-68{\cdot}3$ kcal. using the more recent data[31]) with the experimentally determined value $-70{\cdot}6$ kcal. mole$^{-1}$ for X=F was taken[129] as indicating a strengthening of the P–O bond by substitution of fluorine for chlorine. A nuclear magnetic resonance study of the series $POF_3$, $POF_2Cl$, $POFCl_2$, $POCl_3$, showed that with increasing substitution of the more electronegative atom (fluorine) by the less electronegative, the $^{31}P$ resonance

signal is shifted to a lower field, while in the series $POCl_3 \rightarrow POBr_3$ the reverse is true. This was explained by the decreasing effect of the more electronegative ligands in screening the phosphorus nucleus, and also by a double bonding character of the P–F bond.[185]

## Chemical Properties

The phosphoryl halogenofluorides are colourless in all states when pure; they are hydrolyzed by moist air and react vigorously with water. Dry phosphoryl fluoride gas undergoes only slight decomposition in contact with glass, copper or carbon at 600°C. or silicates at 900°C. With iron at 600°C., slow reduction to phosphorus(III) fluoride occurs; with steel wool at 950°C. absorption is complete, solid products being formed.[1] With carbon at 950°C., decomposition occurs to phosphorus(III) fluoride, carbon monoxide, small amounts of phosphorus and an unidentified gas thought to be carbon tetrafluoride.[1] Difluorodiazine converts phosphoryl fluoride to phosphorus(V) fluoride[156]

$$POF_3 + N_2F_2 \rightarrow PF_5 + N_2 + O_2$$

whilst $\cdot NF_2$ radicals from the photolytic decomposition of $N_2F_4$ yield nitrosonium hexafluorophosphate, $[NO^+][PF_6^-]$.[187]

Phosphoryl fluoride hydrolyzes in a stepwise manner according to the scheme:

$$POF_3 \xrightarrow[+H_2O]{} HOPOF_2 \xrightarrow[+H_2O]{} (HO)_2POF \xrightarrow[+H_2O]{} (HO)_3PO + 3HF$$

It is possible, after conducting the reaction in weakly basic solution, to isolate the intermediate acids as their nitron salts.[130]

Evidence of the probable formation of a 1:1 addition compound $F_3PO,BF_3$, f.p. about −20°C., comes from thermal analysis of the phosphoryl fluoride–boron trifluoride system.[50] Phosphoryl chloride and phosphoryl dichlorofluoride form 2:1 addition compounds with zirconium and hafnium tetrachlorides which decompose at

50° to 60°C. *in vacuo* to the 1:1 compound and phosphoryl halide. Phosphoryl monochlorofluoride and phosphoryl fluoride, however, form 1:1 compounds only. The respective m.p., etc. in °C. are:

|  | $2POX_3,MCl_4$ |  | $POX_3,MCl_4$ |  |
|---|---|---|---|---|
| M= | Zr | Hf | Zr | Hf |
| $POCl_3$ | decomp. 50–60° | decomp. 50–60° | sublimes 130° | decomp. 145° |
| $POFCl_2$ | 74–78° | 80–83° | 161–163° | 165–167° |
| $POF_2Cl$ | — | — | 116–119° | 110–113° |
| $POF_3$ | — | — | 85° | 85° |

With a more prolonged contact time and in the presence of excess of phosphoryl mono- or dichlorofluorides, halogen exchange occurs and compounds of the type $2POCl_3,MCl_4$ finally separate out.[131]

## HYDROGEN FLUOROPHOSPHORANES

The reaction of anhydrous hydrogen fluoride and hypophosphorous acid at $-22$°C. yields dihydrogentrifluorophosphorane, $PH_2F_3$.[188–90] $PH_2F_3$ is a colourless gas, m.p. $-51$°C.,[188] b.p. (extrap.) $+2$°C.,[188] 3·8°C.[190] The vapour pressure from $-52$ to 0°C. obeys the relation $\log p_{(\text{mm.})} = (-1473{\cdot}0/T) + 8{\cdot}1991$, the heat of vaporization is 6·7 kcal./mole and the Trouton constant 24 e.u.[190] The infra-red spectrum shows absorptions at 328, 389, 471, 655, 765, 820, 867, 995, 1026, 1292, 2465 and 2538 cm.$^{-1}$ In the gaseous state the molecule appears to be a trigonal bipyramid of $C_{2v}$ symmetry with two of the fluorine atoms axial. In the solid and liquid states association through fluorine bridges occurs.[189]

Hydrogen tetrafluorophosphorane, $PHF_4$, is formed analogously from phosphorous acid and anhydrous hydrogen fluoride at $-50$°C., as a colourless gas, m.p. $-89$°C.,[188] b.p. (extrap.) $-37$°C.,[188] $-39{\cdot}0$°C.[190] The vapour pressure is given by $\log p_{(\text{mm.})} = (-1158{\cdot}9/T) + 7{\cdot}8290$, from $-80$° to $-45$°C. the heat of vaporization is 5·30 kcal./mole and the Trouton constant 22·6 e.u.

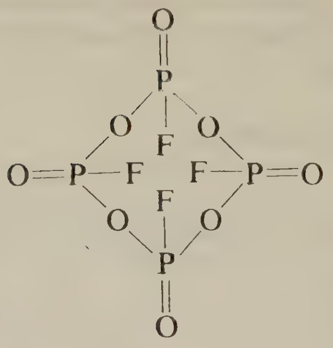
The $^1H$, $^{19}F$ and $^{31}P$ nuclear magnetic resonance spectra suggest that both molecules are undergoing ligand exchange, with retention of P–H and P–F bonding only at the lowest temperatures studied. Both substances react rapidly with quartz or borosilicate glass, and must be studied in metal vacuum systems.[190]

## CONDENSED PHOSPHORYL FLUORIDES

Pyrophosphoryl fluoride, $P_2O_3F_4$, a colourless mobile liquid, m.p. $-0{\cdot}1$°, b.p. 72°C. (extrap.) and phosphorus dioxyfluoride, $(PO_2F)_n$, a white hygroscopic solid, were separated[62] by vacuum fractionation up to 20°C. from the white solid obtained (in as much as 30% yield) by subjecting equimolar mixtures of phosphorus(III) fluoride and oxygen at $-75$° to $-60$°C. to a silent electric discharge. Pyrophosphoryl fluoride boils with decomposition at atmospheric pressure; its vapour pressure between 273° and 318°K. is expressed by $\log_{10} p_{\text{mm.}} = 8{\cdot}957 - 2096{\cdot}7/T$; its molar heat of vaporization is 9581 g.-cal.; Trouton's constant = 27·8 and $d_{20} = 1{\cdot}65$. It undergoes vigorous hydrolysis with water giving difluorophosphoric acid according to the equation $P_2O_3F_4 + H_2O \rightarrow 2F_2PO(OH)$. On heating to 500°C., phosphorus dioxyfluoride decomposes without melting:

$$4(PO_2F) = P_2O_5 + P_2O_3F_4$$

Hydrolysis with water leads to monofluorophosphoric acid $FPO(OH)_2$. It has a crystalline type of *X*-ray powder diagram and is thought[62] to be the cyclic tetramer:



The reaction of phosphoryl dichloride fluoride with phosphorus pentoxide yields small quantities of pyrophosphoryl dichloride difluoride, a colourless liquid, b.p. 36°C./12 mm., $n_D^{20}$ 1·3860, $d_{20}^{20}$ 1·7918.[191] It rearranges if heated at 50°C. for several days, giving phosphoryl dichloride fluoride and a higher polymeric chlorofluoride containing F(Cl)PO–O end groups and $\text{–O–}\underset{\underset{\displaystyle \text{F}}{|}}{\text{P}}\text{(O)–O}$ middle groups.[192] Diethylamine replaces the chlorine atoms only, giving a diethylamide of the formula $O(PO(NEt_2)F)_2$, but ethanol breaks the pyrophosphoryl linkage, giving EtOP(O)ClF.[191]

## SECTION XIV

# CHLORIDES AND MIXED CHLORIDE HALIDES OF PHOSPHORUS

BY R. H. TOMLINSON

## PHOSPHORUS DICHLORIDE (DIPHOSPHORUS TETRACHLORIDE), $P_2Cl_4$

This substance had been previously described as a colourless, oily, strongly fuming liquid, f.p. $-28$°C. but (in contrast to Mellor, VIII, 998) was not identified[1–2] as a product of subjecting phosphorus(III) chloride–hydrogen mixtures to an electric discharge. Similarly, although metastable species of long life are formed by a micro-wave discharge in phosphorus(III) chloride vapour, they finally react or disproportionate yielding $PCl_5$, $PCl_3$ and subchlorides such as '$P_5Cl$' rather than $P_2Cl_4$.[492] However, when $PCl_3$ was irradiated in a reactor the percentage of $^{32}P$ present as $^{32}PCl_3$ increased with irradiation time, and this effect has been attributed[2] to radiation-induced oxidation of $^{32}P_2Cl_4$ to $^{32}PCl_3$. When phosphorus(III) chloride at $-63$°C. was vaporized through a mercury discharge, red and yellow solids were deposited and small quantities of a volatile liquid product, f.p. $-34$° to $-35$°C., were obtained.[3] The liquid, which decomposed to phosphorus(III) chloride and a yellow non-volatile solid at room temperature, had a composition and molecular weight in agreement with $P_2Cl_4$. Fluorination to give phosphorus difluoride was unsuccessful,[3] as also were similar attempts with phosphorus di-iodide, $P_2I_4$, and various fluorinating agents.[4] In a micro-wave discharge, phosphorus(III) chloride vapour at flow rates of 0·08 g. $PCl_3$/min. at 1 mm. pressure and 1·00 g. $PCl_3$/min. at 5 mm. pressure, was decomposed to extents of 71·5 and 3·5%, respectively.[5] Fractional condensation showed the presence of phosphorus(V) chloride and of red and yellow-tan products with P:Cl atom ratios of 5·5–50:1 and 2·5–5:1, respectively, while retention for 15 hr. at room temperature of all the decomposition products in an evacuated receiver resulted in their complete reversion to phosphorus(III) chloride. Streams of phosphorus(III) chloride vapour mixed with hydrogen in volume ratios $<1:1$ deposited red phosphorus beyond the discharge. A plug of bronze wool placed just beyond the discharge reacted to form cuprous chloride; no phosphorus(V) chloride or red or yellow solids were then deposited in the subsequent cold traps, but phosphorus dichloride was formed in 0·5% yield.[5] In a static system where a 60-cycle discharge was established between bronze wool plugs situated above a pool of phosphorus(III) chloride at 0°C., 75 mg. of phosphorus dichloride were obtained in 15 min., but further conversion was said to be inhibited by poisoning of the bronze.[5] The highest yields of phosphorus dichloride so far reported (viz., 3·5 g./hr) were obtained[6] by subjecting a phosphorus(III) chloride–hydrogen gas stream (optimum mole ratio$=2:1$) at $-78$°C. to a continuous electric discharge between molybdenum electrodes at 7500 v. and pumping out the unreacted hydrogen together with product hydrogen chloride at 19 mm. pressure. Phosphorus dichloride was then separated from the unreacted trichloride by fractional distillation. The authors observed a freezing point closer to $-28$°C. than to $-34$°C.; the density was 1·701 at 0° and the vapour pressure $\sim 1$ mm. at 25°C. The nuclear magnetic resonance spectrum showed a single peak with chemical shift $-155$ p.p.m. relative to 85%

orthophosphoric acid. Mass spectrometry at an ionization potential of 70 e.v. gave[7] the principal ion species as $P_2Cl_4^+$, $P_2Cl_3^+$, $P_2Cl_2^+$, $PCl_2^+$, $P_2Cl^+$, $PCl^+$ and $P_2^+$ with relative abundances of 4·6, 5·3, 1·5, 100·0, 5·8, 36·5 and 9·9, respectively. Probable mechanisms with values of heat of formation for the various ions were deduced; the P–P sigma bond energy was 58 kcal. $mole^{-1}$ which, by comparison with the published value for P–P in $P_4$, was taken[7] as indicative of $\pi$ bonding of the order 1·1 to 1·2$\pi$ bonds/sigma bond.

The infra-red spectrum from 33–1000 $cm.^{-1}$, and the Raman spectrum of phosphorus dichloride have been reported. They are consistent with a *trans*-$Cl_2P$–$PCl_2$ structure, with $C_{2h}$ symmetry, in the solid, liquid and gaseous states.[493]

The hydrolysis of phosphorus dichloride (and di-iodide) has been studied in acid and basic solution under anaerobic conditions. Ionic products were determined by ion exchange chromatography and the results are summarized below.

*Percentage of phosphorus species arising during hydrolysis of dihalides*

| Dihalide | $P_2Cl_4$ | $P_2I_4$ | $P_2Cl_4$ | $P_2I_4$ |
|---|---|---|---|---|
| Conditions | basic | basic | acidic | acidic |
| P Species | | | | |
| $P^1$ anions | 23·7 | 17·2 | 19·5 | 7·5 |
| $P^3$ anions | 14·3 | 14·8 | 52·1 | 73·7 |
| $P^5$ anions | 6·5 | 7·7 | 13·2 | 14·9 |
| Anions containing > 1 P atom | 1·4 | 2·2 | — | — |
| $P_2H_4$ | 50·4 | 53·2 | — | — |
| $PH_3$ | 3·7 | 4·9 | 10·3 | 3·1 |
| P Subhydride | — | — | 4·9 | 0·8 |

These results are compatible with a primary hydrolysis:

$$2P_2X_4 + 2H_2O \rightarrow P_2H_4 + [P_2(OH)_4]$$

followed by further hydrolysis of the unstable hypodiphosphorous acid:

$$[P_2(OH)_4] + H_2O \rightarrow H_3PO_2 + H_3PO_3$$

and dismutation of some of the phosphorous acid:

$$4H_3PO_3 \rightarrow 3H_3PO_4 + PH_3$$

The different results observed in acid solution may be due to oxidation of $P_2H_4$ by hypohalous acid.[494]

Phosphorus dichloride reacts readily with nickel tetracarbonyl.[492, 495] If an excess of the dichloride is used, it behaves as a monofunctional base:

$$Ni(CO)_4 + P_2Cl_4 \rightarrow Ni(CO)_2(P_2Cl_4)_2 \ (+ Ni(CO)(P_2Cl_4)_3\,?)$$

while with excess carbonyl it behaves as a difunctional base:

$$Ni(CO)_4 + P_2Cl_4 \rightarrow (CO)_3Ni - P_2Cl_4 - Ni(CO)_3$$

Equivalent amounts of the two reagents yield polymers containing mono- and difunctional $P_2Cl_4$. $P_2Cl_4$ is more strongly basic towards nickel carbonyl than is $PCl_3$. Iron pentacarbonyl, or chromium or molybdenum hexacarbonyl does not react with phosphorus dichloride.[492]

Phosphorus dichloride undergoes dismutation in the presence of boron tribromide, giving a mixture of phosphorus trihalides and subhalides. Halogen exchange also occurs as far as possible, so that the final product with excess boron tribromide is the complex $PBr_3,BBr_3$.[495] Diborane reacts with phosphorus dichloride yielding hydrogen, boron trichloride, dichloroborane, and subhydrides or subhalides of phosphorus. It may be noted that all the reactions of phosphorus dichloride noted above, with the exception of that with nickel carbonyl, lead to P–P bond fission.[492]

## PHOSPHORUS(III) CHLORIDE

### Preparation

Phosphorus trichloride has been variously obtained by the reduction of phosphoryl chloride vapour with carbon monoxide and active carbon above 400°C.,[8] by the action of chlorine upon calcined phosphate rock, calcium phosphate or phosphoric acid mixtures with carbon and silica[9–18] or of chlorine upon heated ferrophosphorus.[19–23] In the last reaction the volatile complex $FeCl_2,PCl_3$ first formed is decomposed by addition of further ferrophosphorus below red heat. The phosphorus trichloride of commerce is obtained by continuous chlorination of yellow phosphorus in a phosphorus trichloride medium.[24–9] The heat of reaction is dissipated by the reflux rate, and the distillate, which may contain up to 1% of yellow phosphorus, is finally treated in a stirred vessel with just sufficient chlorine to complete the reaction. An apparatus for the laboratory preparation of the pure compound has been described.[30] Phosphorus purified by nitric acid treatment and vacuum distillation has been used as a starting material for this preparation.[496]

### Physical Properties

Molar volumes at 0°K. extrapolated from density measurements at −79°C. for various phosphorus halides and oxyhalides are given[31] as:

| | | |
|---|---|---|
| $PCl_3$ = 67 ml. | $PCl_5$ = 91·5 ml. | $POCl_3$ = 72·1 ml. |
| $PBr_3$ = 76·1 ml. | — | $POBr_3$ = 82·8 ml. |
| $PI_3$ = 93·2 ml. | $PI_5$ = 115 ml. | — |

Vapour pressure and related data for phosphorus trichloride include:

| Range, °C. | $\log_{10} p_{mm.}$ | Latent heat of vaporization kcal. mole$^{-1}$ | b.p. °C. | f.p. °C. | Trouton constant | Ref. |
|---|---|---|---|---|---|---|
| −20 to +70 | $7{\cdot}6455–1657{\cdot}3/T$ | 7·585 (7·415 at 74·7°C.) | 74·7 | −93·6 | 21·3 | 32 |
| 15 to 75 | $7{\cdot}6285–1653{\cdot}6/T$ | 7·57 | 75·2 | | | 33 |
| 19 to 85 | $7{\cdot}472–1600/T$ | 7·32 | 75·3 | | | 34 |

Vapour/liquid equilibrium measurements for the binary system $PCl_3–POCl_3$[35] approximate to ideality; those for the system $PCl_3–SiCl_4$[34] show large deviations from the ideal. The heat capacity of phosphorus trichloride vapour between 298·1 and 1000°K. is given[36] by $C_p^\circ = 20{\cdot}068–0{\cdot}000289T–270600T^2$; the specific heat of the liquid is 28·9 g.-cal. mole$^{-1}$ at 25°C.[33]

Remeasurement of the heat of hydrolysis for the reaction:

$$PCl_3(l) \rightarrow H_3PO_3(aq.) + 3HCl(aq.)$$

together with available thermal data, gave values of $\Delta H$ and $\Delta H^\circ_{f25}$ in kcal. mole$^{-1}$ as −67·5 ± 0·03 and −79·6[37] and as −67·7 and −79·4,[38] respectively. The preferred value for the heat of formation of phosphorus trichloride liquid, viz.: $\Delta H^\circ_{f25} = -74{\cdot}4$ kcal. mole$^{-1}$,[39] has been derived from the hydrolysis–oxidation reaction:

$$PCl_3(l) + Br_2(aq.) \rightarrow H_3PO_4(aq.) + 3HCl(aq.) + 2HBr(aq.)$$

so avoiding the use of uncertain data for $H_3PO_3$(aq). (The value of −81 kcal. mole$^{-1}$ listed[40–2] is based on the original heat of hydrolysis measurements (Mellor, VIII, 1001).) The standard heat ($\Delta H^\circ_f$), free energy ($\Delta G^\circ_f$) and equilibrium constant of formation (log $K_f$) for phosphorus trichloride vapour at 25°C. are given[40–2] as −73·22, −68·42 (both in kcal. mole$^{-1}$) and 50·151, respectively. Enthalpy and free energy functions at 100° intervals from 298·1–1000°K. derived[43–4] from equilibrium and spectroscopic data are reproduced in Table I.

*Table I.—Thermodynamic Functions of* $PCl_{3(g)}$ *in Ideal Gas State*[41]

| $T$°K. | $-\frac{G^\circ - H^\circ_0}{T}$ g.-cal. mole$^{-1}$ deg.$^{-1}$ | $H^\circ - H^\circ_0$ g.-cal. mole$^{-1}$ | $S^\circ$ g.-cal. mole$^{-1}$ deg.$^{-1}$ |
|---|---|---|---|
| 298·1 | 61·66 | 3·840 | 74·54 |
| 350 | 63·75 | 4·740 | 77·29 |
| 400 | 65·61 | 5·650 | 79·74 |
| 500 | 68·87 | 7·500 | 83·87 |
| 600 | 71·68 | 9·400 | 87·35 |
| 700 | 74·09 | 11·320 | 90·26 |
| 800 | 76·30 | 13·260 | 92·88 |
| 900 | 78·31 | 15·210 | 95·21 |
| 1000 | 80·67 | 17·160 | 97·23 |

Equations for the calculation of standard free energies of formation at temperatures up to 1800°C. have been proposed.[45]

Ebullioscopy indicates compound formation with dissolved tin(IV), arsenic(III) and titanium(IV) chlorides; with anthracene as solute the ebullioscopic constant $K = 50$.[46]

The dielectric constant of phosphorus(III) chloride decreases from 3·498 at 17°C. to 3·139 at 59·8°C.[47] Dielectric constant measurements for dilute solutions in carbon tetrachloride, benzene and dioxan have led to dipole moment values (Debye units) for phosphorus(III) chloride and bromide as follows:

| | $PCl_3$ | $PBr_3$ | Ref. |
|---|---|---|---|
| carbon tetrachloride | 0·80, 1·00 | 0·61, 0·52 | 48, 49 |
| benzene | 0·90, 1·16* | — | 50 |
| dioxan | 1·89 (0·01014 M) | 1·65 (0·01142 M) | 51 |
| | 1·49 (0·03819 M) | 1·33 (0·03572 M) | |

* From polarization at 25°C. and refractivity.

The high values in dioxan solution are thought to arise from co-ordination with the solvent.[51] Calculations based on the molecular orbital theory and observed values of dipole moment[52] have given the percentage hybridization of the *p*-orbitals of the phosphorus atom in $PCl_3$ and $PF_3$ as 8 and 5·6, respectively, and percentage ionic character in $PF_3$ as 65. Molar polarization ($P_M$ c.c.) in carbon tetrachloride and benzene between −25° and 40°C. is given as:

| | Carbon tetrachloride | | | Benzene | | | Ref. |
|---|---|---|---|---|---|---|---|
| | −25° | 0° | +25° | 10° | 25° | 40° | |
| $PCl_3$ | — | — | — | — | 54 | 53·2 | 50 |
| $PCl_3$ | 43·8 | 42·2 | 42·2 | 48·2 | 46·8 | 45·6 | 49 |
| $PBr_3$ | 47·4 | 46·5 | 45·8 | 43·0 | 41·5 | 40·5 | |

Measurements in the vapour state (up to 463°K.) show deviations from linearity in the plot of $P_M$ against $1/T$; the explanation offered[53] is of two separate moments corresponding to different internal energy levels. Values of electron polarization ($P_E$) in carbon tetrachloride solution are $PCl_3$ 28·64, $PBr_3$ 39·02, giving interatomic distances, calculated from $(P_E/4\pi N)^{1/3}$, in general agreement with those derived from other sources.[54] The infra-red and Raman spectra of phosphorus(III) chloride have been described.[493, 497] Molecular data for phosphorus(III) chloride are listed in Table II, page 441; other useful references[55–8] include information on bond angles and lengths, and stereochemistry. A recent electron diffraction study in the vapour state at 300° and 500°K.[59–61] has shown a significant increase in P–Cl and Cl–Cl distances (0·3 and 0·4% respectively) and of associated mean amplitudes (19 and 31%, respectively) at the higher temperature. By using the mean square amplitudes of vibration in conjunction with the accepted vibration frequencies, force constants for the $PCl_3$ molecule (cf. Table III, page 441) have been evaluated as follows: $f_d$ 2·82 ± 0·37, $f_{dd}$ 0·58 ± 0·29, $f_\alpha$ 0·27 ± 0·03, $f_{\alpha\alpha}$ 0·045 ± 0·03, $f_{d\alpha}$ 0·27 ± 0·21, $f_{d\alpha'}$ 0·07 ± 0·28. Summation of the characteristic volumes for bound atoms (derived from $v_{\text{minimum}}$, $v_{\text{covalent}}$ and the number of bonds of a given type) gives[62] values of 82·70, 96·05 and $120{\cdot}86 \times 10^{-24}$ c.c. for the $PCl_3$, $PBr_3$ and $P(C_2H_5)_3$ molecules, respectively. The first-order centrifugal distortion constants of phosphorus(III) chloride have been calculated from the microwave rotational spectra. They are $D_J = 1{\cdot}7$, $D_{JK} = -1{\cdot}879$ kMc.[498] The measured molar diamagnetic susceptibility $-\chi_m \times 10^6$ for phosphorus trichloride was 66·0[63] or 63·4[64] c.g.s. units; the diamagnetic anomaly (6·3 c.g.s. units), i.e. the difference between calculated and observed values, was related[64] to structural constraint.

The mass spectrum at 120 e.v. showed the presence of $PCl_3^+$, $PCl_2^+$, $PCl^+$, $P^+$, $PCl_2^{++}$, $PCl^{++}$, $P^{++}$ and $Cl^+$ ions.[65] At 70 e.v. the relative abundances, appearance potentials, probable processes and heats of formation for the principal positive ions are given[7] as:

| Ion | $m/e$ | Relative abundance | Appearance potential (e.v.) | Process | $\Delta H_f^+$ kcal. mole$^{-1}$ |
|---|---|---|---|---|---|
| $PCl_3^+$ | 138 | 31·5 | 10·7 | $PCl_3 \rightarrow PCl_3^+$ | 175 |
| | 136 | 30·8 | | | |
| $PCl_2^+$ | 101 | 100·0 | 12·3 | $\rightarrow PCl_2^+ + Cl$ | 182 |
| $PCl^+$ | 66 | 29·2 | 16·8 | $\rightarrow PCl^+ + 2Cl$ | 257 |
| $Cl^+$ | 35 | 48·3 | 20·2 | $\rightarrow Cl^+ + P + Cl_2$ | 317 |
| $P^+$ | 31 | 20·9 | 21·2 | $\rightarrow P^+ + 3Cl$ | 329 |

$^{31}P$ nuclear magnetic resonance shifts (p.p.m.) for the phosphorus trihalides referred to 85% phosphoric acid are given[66] as:

| | | | |
|---|---|---|---|
| $PF_3$ | −97 | $POClF_2$ | −14·8 |
| $PI_3$ | −178 ($P_2I_4$ in $CS_2$ −170) | $POCl_2F$ | 0·0 |
| $PCl_3$ | −215 | $POCl_3$ | −5·4 |
| $PBr_3$ | −222 | $PSCl_3$ | −30·8 |

The chemical shifts of the following mixed halide-pseudohalides have been measured: $PX_{3-n}(NCO)_n$, X = F, Cl, Br; $PX_{3-n}(NCS)_n$, X = Cl, Br; $OPCl_{3-n}(NCS)_n$, and $SPCl_{3-n}(NCS)_n$ ($n = 0$–3). The increments in the $^{31}P$ chemical shift for 3-coordinate phosphorus compounds are −32 p.p.m. for NCO and −29 p.p.m. for NCS. Except in the PF compounds in which strong P–F ($\pi$) bonding occurs, the chemical shifts can be accurately predicted from these increments. For the 4-coordinate compounds, where only electronegativity differences are responsible for the alteration of the chemical shift, the corresponding increments are +13 and +21 p.p.m. Hence the electronegativity of the ligands decreases in the series Cl > NCO > NCS > Br.[501]

Viscosity/temperature data[67–9] for phosphorus(III) chloride, bromide and phosphoryl chloride conform to the Bachinskii[70] formula $\eta_{(\text{poise})} = C/(v - \omega)$, where $v$ is the specific volume, and $C$ and $\omega$ are characteristic constants with the values:

| | Temperature | $C$ | $\omega$ |
|---|---|---|---|
| $PCl_3$ | −15 to +70°C. | 0·000852 | 0·5029 |
| $PBr_3$ | −15 to +60°C. | 0·000521 | 0·3205 |
| $POCl_3$ | 2 to 80°C. | 0·000712 | 0·5352 |

Other data for phosphorus(III) chloride[72] were found to conform less closely to the Andrade[71] formula, $\eta_{(\text{poise})} = Av^{-1/3} \exp\{c/vT\}$ where $A$ and $c$ are arbitrary constants, than did those for phosphoryl chloride and for normal liquids.

| | Temperature | *A* | *c* |
|---|---|---|---|
| $PCl_3$ | 0 to 50°C. | 0·001830 | 163 |
| $POCl_3$ | 0 to 80°C. | 0·0005014 | 506 |

The deviation is indicative of change in associative tendency with temperature.[72] Later values for the viscosity of phosphorus(III) chloride between −65·1 and +60·1°C. were in reasonable agreement with the data of Bowden and Morgan,[72] the logarithm of the viscosity being inversely proportional to temperature over the whole range.[323] Density, $d_4^t$ from 0° to 76°C., is given by: $1{\cdot}6128-1{\cdot}869\times10^{-3}t+1{\cdot}84\times10^{-7}t^2-7{\cdot}92{\cdot}10^{-9}t^3$ [73–4] and derived values together with viscosity–temperature data are summarized in Table II. Later authors give the equation:

$$p_{PCl_3} = 1{\cdot}6095-1{\cdot}762\times10^{-3}t-1{\cdot}51\times10^{-6}t^2$$

for the density of phosphorus(III) chloride over the temperature range 0–115°C. They found a critical temperature of 290·0°C. and a critical density 0·520 g./c.c.,[500] in good agreement with earlier values.

*Table II.—Density (g./c.c.) and Viscosity (poise) Data for Phosphorus(III) Chloride*

| Ref. | 73, 74 | 67–69 | 72 | |
|---|---|---|---|---|
| °C. | $d_4^t$ | $\eta$ | $\eta_{\text{observed}}$ | % deviation (obs.–calc.) |
| 0 | 1·6128 | 0·00755 | 0·00656 | +14·3 |
| 15 | 1·5848 | 0·00661 | 0·00560 | +6·6 |
| 25 | 1·5661 | 0·00616 | 0·00501 | +0·2 |
| 35 | 1·5473 | 0·00584 | 0·00479 | −0·2 |
| 50 | 1·5188 | 0·00548 | 0·00453 | Nil |
| 70 | 1·4802 | 0·00508 | — | — |
| b.p. °C. | 75·95 | — | 75·7 (758 mm.) | |

Cryoscopy in nitrobenzene[75] gave association factors for phosphorus(III) chloride and phosphoryl chloride of 1·09 and 1·08, respectively (cf.[76] where normal freezing point lowering was observed for phosphorus(III) chloride in benzene). Viscosity isotherms between 0° and 30°C. indicate ideality for each of the phosphorus(III) chloride–diethyl ether,[77] –benzene and –nitrobenzene[78] systems; parachors for the phosphorus trichloride–benzene system agree with values calculated from $[P]=(1-x)[P]_1+x[P]_2$, where $x$ is the mole fraction of solute with parachor value $[P]_2$.[79] Linear relationships have been demonstrated between the surface tension of the $PX_3$ halides at 75°C., the covalent radius of the halogen atom[80–2] and the energy of the P–X bond,[83] where X is chlorine, bromine or iodine.

*Table III.—Molecular Properties Derived[84] from Ultrasonic Measurements*

| Halide | Molar sound velocity | $K_{\text{ad.}}$ | $K_{\text{is.}}$ | $C_p/C_v$ | Thermal pressure coefficient dyne cm.$^{-2}$ deg.$^{-1}$ | Energy volume coefficient dyne cm.$^{-2}$ |
|---|---|---|---|---|---|---|
| | | ($10^{-12}$ cm.$^2$ dyne$^{-1}$) | | | | |
| $PCl_3$ | 831·3 | 72·07 | 104·4 | 1·45 | $11{\cdot}56\times10^6$ | $3504\times10^6$ |
| $PBr_3$ | 922·4 | 41·74 | — | — | — | — |
| $POCl_3$ | 916·5 | 64·26 | — | — | — | — |

Ultrasonic measurements[84] gave the sound velocity ($v$) in phosphorus(III) chloride, bromide and phosphoryl chloride at 30°C. as 944·1, 916·7 and 969·3 m. sec.$^{-1}$, respectively. Derived values for molar sound velocity $[(M/d)\times v^{1/3}]$ and adiabatic compressibility ($K_{ad.} = 1/v^2d$) are listed in Table III, as are values for isothermal compressibility ($K_{is.} = K_{ad.} + T\alpha^2/C_p.d$), specific heat ratio ($C_p/C_v$), thermal pressure coefficient $(\delta P/\delta T)_v$ and energy–volume coefficient $(\delta E/\delta V)_T$ for phosphorus trichloride, calculated[84] from $v$, and available data for coefficient of thermal expansion ($\alpha$) and heat capacity ($C_p$).

### ISOTOPE EXCHANGE

Halogen exchange between radiochlorine and phosphorus(III) or (V) chlorides, and between radiobromine and phosphorus(III) bromide, each in carbon tetrachloride solution at 23°C., was complete in less than 3 min.[85] In contrast, exchange of phosphorus with phosphorus(III) chloride in carbon disulphide solution was approximately 4% in a few minutes and 30% in a few days.[86] In chloroform solution at 20°C. under strictly anhydrous conditions, halogen exchange between $^{36}$Cl-pyridinium chloride and phosphorus(III) chloride at 20°C. was again complete in less than 3 min.[87] Halogen exchange between $^{35}$Cl-labelled hydrogen chloride and phosphorus(III) chloride in the vapour phase at 20°C. was complete in 45 min. but with phosphoryl chloride it appeared to take much longer.[88] Exchange between $^{32}$P- or $^{36}$Cl-labelled phosphorus trichloride and phosphorus pentachloride in carbon tetrachloride solution indicates[89] equal reaction rates for both phosphorus and chlorine. The reaction is of first order in $PCl_5$ ($k \times 10^3$ hr.$^{-1} = 0{\cdot}90 \pm 0{\cdot}08$ at 0·1°, $10{\cdot}6 \pm 1{\cdot}4$ at 25°, $82 \pm 6$ at 50°C., activation energy $15{\cdot}9 \pm 0{\cdot}1$ kcal. mole$^{-1}$) and of zero order in $PCl_3$.

### REORGANIZATION IN THE PHOSPHORUS TRIHALIDES

Nuclear magnetic resonance methods following complete equilibration of $P(OPh)_3$–$PCl_3$, $P(OPh)_3$–$PBr_3$ and $P(OPh)_3$–$PCl_3$–$PBr_3$ mixtures in sealed tubes at 180°C. have indicated[90] higher concentrations of phosphorus(III) mixed compounds (type $PCl(OPh)_2$,$PCl_2.OPh$, etc.) than would be predicted on a statistical basis for truly random processes (Ph = phenyl). Except for the relatively unstable $PClBr_2$, equilibrium constants of formation and free energy values calculated from the experimental data demonstrated the higher stability of the mixed compounds. It was concluded that ligand exchange was considerably faster and deviations from the theoretical random distribution more pronounced than those which occur with the same ligands in the phosphoryl or thiophosphoryl systems, i.e. systems based on the quadruply connected P-atom.[90–2] Enthalpy, free energy and entropy functions have been calculated for $PCl_2Br$ and $PClBr_2$ over the temperature range 298·2–1000°K.[516]

Phosphorus trichloride vapour sorption on activated sugar charcoal was represented[93] by: $a_{(\text{mg. }PCl_3/\text{g. charcoal})} = xp^n$, where $p$ = equilibrium pressure in cm. and $x$ and $n$ = 22·945 and 0·2255 at 20°, 16·260 and 0·2540 at 30° and 6·427 and 0·3300 at 50°C. respectively.

## Chemical Properties

### REDUCTION AND OXIDATION

Phosphorus trichloride, tribromide and phosphoryl chloride undergo gas-phase reduction with hydrogen under electrodeless electric discharge giving small yields of red and yellow phosphorus and of incompletely identified liquid products.[1, 5] By subjecting a phosphorus trichloride–hydrogen gas stream (mole ratio = 2:1) at −78°C. and 19 mm. pressure to continuous electric discharge at 7500 v. between molybdenum electrodes, maximum yields of phosphorus dichloride (= 3·5 g./hr.) were obtained.[6] Organic phosphoryl chlorides, $RPOCl_2$, are formed when a slow stream of a paraffin hydrocarbon and oxygen is passed through phosphorus trichloride at 60°C.[94]; sulphuric acid and iodine behave as inhibitors. The analogous reaction fails to occur with phosphorus tribromide. On passing dry oxygen into rapidly stirred phosphorus(III) chloride–*cyclo*hexane mixtures at 20°C. or below, up to 30% conversion to *cyclo*hexyl phosphoryl chloride was obtained under optimum conditions.[95–6] There was no change in yield over the temperature range −40° to +70°C. and the speed of the reaction appeared to be governed only by the rate of dissolution of oxygen in the mixture. From a recent study[97] it is deduced that the reaction proceeds by a free radical chain mechanism in which Cl atoms participate as one chain carrier. When hydrogen plus oxygen was passed through phosphorus(III) chloride the only certain products of the resulting exothermic reaction were phosphoryl chloride and 'phosphorus suboxide' $P_4O$.[98] The reaction between gaseous oxygen and liquid phosphorus(III) chloride to give phosphoryl chloride is of commercial importance (page 487) and a kinetic study[99] has shown it to be initially heterogeneous, with dissolution of oxygen the rate-determining step. The energy of activation is small and a free radical mechanism involving the $Cl_3\overset{+}{P}O\overset{-}{O}$ biradical was proposed. Phosphorus(III) chloride was found to be the most readily oxidized by dimethyl sulphoxide of a series of P(III) compounds. This is presumably because the chlorine atoms confer strong acceptor properties on the phosphorus atom, favouring electrophilic attack on the oxygen atom of the sulphoxide.[502]

HYDROLYSIS

Aqueous hydrolysis of phosphorus trichloride gave solutions for which surface tension and pH measurements at 20°C. changed with concentration and time and tended towards limiting values.[100] The facts were said to be in agreement with the presence of two forms of phosphorous acid in equilibrium. Mild oxidants were said[101] to convert α- and β-phosphorous acids to hypophosphoric and phosphoric acids, respectively:

$$2P(OH)_3 \xrightarrow[+O]{} (HO)_2PO.PO(OH)_2 + H_2O;\ HPO(OH)_2 \xrightarrow[+O]{} H_3PO_4$$

(but see Section XXI). The existence of hydrolysis products stable in neutral solution and resistant to iodine was reported.[102] Chromatographic and iodimetric analyses following hydrolysis of phosphorus(III) chloride, bromide or iodide in buffered or alkaline solution at 0°C. led[103] to the identification of a number of phosphorus oxyacids in the form of their sodium salts, including:

| | | |
|---|---|---|
| (i) | pyrophosphite | $(NaO)HPO.OPO.H(ONa)$ |
| (ii) | phosphite | $HPO(ONa)_2$ |
| (iii) | diphosphite | $(NaO)HPO.PO(ONa)_2$ |
| (iv) | hypophosphate | $(NaO)HOPO.PO(ONa)_2$ |
| (v) | phosphate | $HOPO(ONa)_2$ |
| (vi) | pyrophosphate | $(NaO)HOPO.OPO.OH(ONa)$ |
| (vii) | *iso*hypophosphate | $(NaO)HPO.OPO(ONa)_2$ |
| (viii) | unidentified salt, believed to contain 3 or 4 P atoms and both P–O–P and P–P linkages. Gives (iv) and (vii) by acid hydrolysis | |

Under mild conditions phosphorus trichloride gives (i) and (ii) together with small amounts of (iii) to (vii); at increased alkalinity the products were (ii) with much less (i) and increased amounts of (iii) to (vii). Phosphorus tribromide gave some phosphine and approximately equal amounts of (ii) to (v), (vii) and (viii); phosphorus tri-iodide gave mainly phosphine, (iv) and (viii), some (iii), (v) and (vii) and a little (ii) and (vi). Thus the tendency to form P–P bonded compounds increases on passing from phosphorus(III) chloride to the less polar iodide. Similar results were obtained from the hydrolysis of a series of P(III) halides and pseudohalides. The hydrolysis was carried out by 5N NaOH at 0°C. under nitrogen, with a molar ratio $PX_3 : NaOH = 1:7$. The relative molar percentages of various phosphorus oxyanions formed were as follows[503]:

| Species | $PCl_3$ | $PBr_3$ | $PI_3$ | $P(NCO)_3$ | $P(NCS)_3$ | $P(CN)_3$ |
|---|---|---|---|---|---|---|
| $P^1$ | — | 1·3 | 0·9 | 10·6 | — | 3·7 |
| $P^3$ | 84·3 | 41·9 | 42·3 | 84·7 | 92·5 | 79·0 |
| $P^5$ | 6·1 | 8·9 | 18·6 | — | — | — |
| $P^2$–$P^4$ | 4·9 | 17·1 | 3·6 | 3·8 | 3·3 | 3·8 |
| $P^4$–$P^4$ | 2·4 | 5·9 | 4·6 | — | 0·1 | — |
| $P^3$–O–$P^5$ | — | — | 3·6 | — | — | † |
| $P^5$–O–$P^5$ | — | — | 1·6 | — | — | — |
| Anions cont. >2P atoms* | 2·9 | 23·8 | 24·7 | 1·0 | 3·2 | 4·2 |

* Some isohypophosphate detected, but contaminated with an unidentified species.
† $P^4$–$P^3$–$P^4$ was identified in every case. No detectable amount of phosphine was formed.

The preparation and properties of reduced phosphorus acids and their salts are discussed in Sections XX to XXII, but those reactions which involve controlled hydrolysis of phosphorus(III) halides are summarized in Table IV. In this Table use is made of a systematic skeletal nomenclature[104] based on the assignment of an oxidation number to each phosphorus atom.

*Table IV.—Preparation of Reduced P-acids by the Controlled Hydrolysis of Phosphorus(III) Halides*

| Preparation recipe | Product | | Ref. |
|---|---|---|---|
| | Systematic designation of the acid | Common name, empirical formula, yield | |
| Stir 1 mole $PCl_3$ with 5 moles crystalline $H_3PO_3$ at 35°C. for 5 hr. Then keep under vacuum over KOH and $P_2O_5$. | $P^3$–O–$P^3$ | pyrophosphorous acid $H_4P_2O_5$ (i) | 105<br>106 |
| Add $PCl_3$ to 80 to 98% $H_3PO_3$ at 85° to 90°C. in a counter-current process. | $P^3$ | phosphorous acid $H_3PO_3$ (ii) (100% conversion) | 107 |
| Add 1 mole $PBr_3$ to 4 moles $NaHCO_3$ in 200 ml. water with stirring at 0° to 5°C.* | $P^2$–$P^4$ | trisodium diphosphite $Na_3HP_2O_5,12H_2O$ (iii) (45 g.) | 108 |
| Add 1 mole $PCl_3$ to 1/3 mole $NaH_2PO_4$+2/3 mole $Na_2HPO_4$ in 600 ml. water with stirring at 0°C.* | $P^3$–O–$P^5$ | trisodium isohypophosphate $Na_3HP_2O_6,8H_2O$ (vii) (50 g.) | 109<br>110 |
| Add $PCl_3$ to bromine water at 0°C.* | $P^4$–$P^3$–$P^4$ | $Na_5P_3O_8,14H_2O$ | 111 |

* For subsequent separative procedures, see reference.

When progressive increments of water were added to ethereal solutions of phosphorus trichloride, the plot of temperature rise against water added showed breaks at 1, 2 and 3 moles $H_2O$/mole $PCl_3$ in accord with the probable formation of intermediate mono- and dichlorophosphorous acids[112] (see Section XXXI). Other workers[98] found no evidence for the formation of chlorophosphorous acids, either in reactions with free or salt-hydrate water carried out in various solvents between −70° and −20°C. The only identifiable products were phosphorous and hypophosphorous acids, phosphoryl chloride and a phosphorus suboxide, $P_4O$. However, a detailed study[504] of the reaction between phosphorus(III) chloride and phosphorous acid showed that, although reversible, it could be made to give very high yields of pyrophosphorous acid, $H_4P_2O_5$, because of the sparing solubility of hydrogen chloride in the reactants. No vapour phase reaction between phosphorus trichloride and water was observed at 25° to 200°C.[113] But for phosphoryl chloride, hydrolysis was found to proceed at a rate proportional to the absorption of water vapour by the phosphoric acid deposited on the walls of the containing vessel. At higher temperatures no reaction occurred.

### REACTIONS WITH SULPHUR AND SULPHUR COMPOUNDS

The addition reaction of sulphur with phosphorus (III) chloride to give thiophosphoryl chloride goes to completion in 2 to 5 hr. at 150° to 160°C. in the presence of 1% of alkali or alkaline earth sulphide catalyst.[114] Commencing with a mixture of sulphur (14), phosphorus trichloride (40), thiophosphoryl chloride (44 wt. %) containing 2 wt. % of carbon activated with potassium sulphide, the reaction is said to be complete (accompanied by a temperature rise to 125°C.) after approximately 3 hr. boiling under reflux.[115] Sulphur monochloride can also be used as a catalyst.[116] With sulphur trioxide[117] and hydrogen disulphide[118] the respective reactions are given as:

$$PCl_3 + SO_3 \rightarrow POCl_3 + SO_2$$
$$3PCl_3 + 3H_2S_2 \rightarrow PSCl_3 + P_2S_5 + 6HCl$$

Phosphorus(III) chloride is miscible in all proportions with liquid sulphur dioxide[119] and liquid carbon dioxide.[120] The former solutions show amphoteric property, and with the $SO_2$-base tetraethylammonium sulphite deposit phosphorus trioxide, soluble in excess of the reagent.[121] With potassium fluoride in liquid sulphur dioxide, phosphorus trifluoride is formed.[122] Sulphur nitride in benzene solution reacts with thionyl chloride in phosphorus(III) chloride on vigorous agitation to give phosphonitrilic chloride, $(PNCl_2)_3$. The latter crystallizes on the walls of the vessel after standing and may be separated by sublimation *in vacuo*.[123] Sulphur nitride dissolves in excess of phosphorus trichloride with formation of a white precipitate having the composition $P_2NCl_7$. This compound was also obtained by heating phosphonitrilic chloride trimer with phosphorus pentachloride (mole ratio 1:3) in phosphoryl chloride as solvent in a sealed tube at 250°C.[124] Infra-red analysis after recrystallization from chloroform at −55°C. indicated a $NPCl_2,PCl_5$ structure. Cryoscopy and $^{31}P$ nuclear magnetic resonance spectroscopy on 0·02 M. solutions in nitrobenzene showed 95% dissociation to $PCl_4^+$ and $NPCl_3^-$ ions.[125]

### REACTIONS WITH HALOGENS AND HALOGEN COMPOUNDS

Phosphorus trichloride reacts with fluorine in the vapour phase to give appreciable yields of 'salt-form' tetrachlorophosphonium hexafluorophosphate $[PCl_4^+][PF_6^-]$ together with molecular tetrachlorofluorophosphorane $PCl_4F$.[126] The reactions with chlorine to give phosphorus pentachloride and with bromine to give a complicated series of phosphorus bromochlorides are discussed on pages 476 and 486–7. Phosphorus trichloride is slightly soluble in molten iodine, but no compounds are formed.[127–8] However, the transient formation of $PCl_3I_2$ may be responsible for the acetyl iodide and hydrogen iodide formed when acetic acid is treated with a mixture of phosphorus(III) chloride and iodine.[505] Fluorination giving phosphorus(III) fluoride and mixed chlorofluorides occurs with antimony, calcium[129] and ammonium[130] fluorides, while mixtures of phosphorus(III) halides in the liquid phase undergo reorganization to mixed halides at room temperature.[131–5] With tetrachloroantimony(V) fluoride vigorous fluorination occurs; phosphorus(III) fluoride is formed and white tetrachlorophosphonium hexachloroantimonate $[PCl_4^+][SbCl_6^-]$ is precipitated,[136] the latter giving conducting solutions in acetonitrile. The reaction: $PCl_3 + 3ICl = [PCl_4^+][ICl_2^-] + I_2$ occurs on addition of phosphorus trichloride to iodine chloride and is strongly exothermic. The resulting solutions have high electrical conductivities (max. = 0·037 mho cm.$^{-1}$ at 6·8 mole % $PCl_3$ and 45°C.) and the product (identical with that from $PCl_5 + ICl$) can be isolated following repeated extraction with carbon tetrachloride.[137]

REACTIONS WITH NITROGEN-CONTAINING COMPOUNDS

The principal products of reaction with nitrogen tetroxide at $-10°C.$ are phosphoryl, pyro- and tetraphosphoryl chlorides, a crystalline compound of composition $P_2O_6NCl_2$, nitric oxide, nitrogen trioxide and nitrosyl chloride[138] (but see pages 506–7). With liquid ammonia, the phosphorus triamide first formed undergoes thermal decomposition with loss of ammonia and hydrogen to give phosphorus pernitride[139]:

$$\begin{array}{ccccc} P(NH_2)_3 & \xrightarrow[0°C.]{} & P_2(NH)_3 & \longrightarrow & P_4N_6 \\ \text{amide} & & \text{imide} & & \text{pernitride} \end{array}$$

With nitryl chloride an exothermic oxidation reaction occurs, the products being phosphorus pentachloride, phosphoryl chloride, nitrosyl chloride and nitrogen tetroxide.[140] Heating phosphorus(III) chloride with silver cyanide at 100°C. for 24 hr. and then at 130° to 150° *in vacuo* for 2 days, gave[141] a white needle sublimate of phosphorus tricyanide, readily hydrolyzed by water and reacting with dicyanogen under pressure to form the pentacyanide. Reaction with mercurous thiocyanate, silver *iso*cyanate or silver thiocyanate in benzene or carbon disulphide solution followed by careful fractionation at reduced pressures has led[141–4] to the isolation of a number of phosphorus(III) compounds containing pseudo-halogen. Phosphorus trithiocyanate ($\text{b.p.}_{(16\ \text{mm.})} = 164°C.$) and the black solid polymer formed at 170°C were described by earlier workers.[145–6] The chief physical properties of the newer compounds are:

| | m.p. °C. | b.p. °C. | $d_4^{20}$ g. c.c.$^{-1}$ | Refractive index | $\log_{10} p_{\text{mm.}}$ | Ref. |
|---|---|---|---|---|---|---|
| $P(NCO)_3$ | $-2\pm0{\cdot}5$ | $169{\cdot}3\pm0{\cdot}3$ | 1·439 | 1·5352 | $8{\cdot}7455–2595/T$ | 142 |
| $PCl(NCO)_2$ | $-50\pm2$ | $134{\cdot}6\pm1$ | 1·505 | — | $8{\cdot}880–2445/T$ | 144 |
| $PCl_2(NCO)$ | $-99\pm2$ | $104{\cdot}4\pm0{\cdot}5$ | 1·513 (31°C.) | — | — | 143 |
| $PCl_2(SCN)$ | $-76$ | 148 | 1·546 | — | $9{\cdot}427–2757/T$<br>(30–54 mm.) | 144 |

The mixed compounds undergo appreciable rearrangement at elevated temperatures, e.g., the reaction $3PCl_2(SCN) \rightarrow 2PCl_3 + P(SCN)_3$ proceeds at approximately 1% per hr. at 80°C. or 1% per min. at 148°C. while analogous rearrangement of the monochloro-compound, $PCl(SCN)_2$, appeared[143] to be sufficiently rapid to prevent its isolation. Exchange of pseudo-halogen for halogen readily occurs where conditions permit elimination of a more volatile compound,[147–8], e.g. by heating:

$$\begin{array}{r} P(NCO)_3 + 3PhCOCl \rightarrow PCl_2NCO \\ P(NCO)_3 + 2HgCl_2 \rightarrow PCl_2NCO \\ P(NCO)_3 + 2AlCl_3 \rightarrow PCl_3 \\ PO(NCS)_3 + 3HgCl_2 \rightarrow POCl_3 \end{array}$$

Sulphonation to the corresponding thiophosphoryl compound,[149] or fluorination to mixed phosphorus(III) fluoro compounds[150] also occurs:

$$\left.\begin{array}{c} P(NCO)_3 + S \text{ in sealed tube at} \\ 140°C. \end{array}\right\} \rightarrow PS(NCO)_3 \qquad \text{b.p., } 215°C.$$

$$P(NCO)_3 + SbF_3 \xrightarrow[\text{at } 36°–90°C.]{} \left\{\begin{array}{l} PF(NCO)_2 \\ PF_2NCO \end{array}\right. \qquad \begin{array}{l} \text{b.p., } 98{\cdot}7\pm0{\cdot}3°C. \\ \text{b.p., } 12{\cdot}3\pm1°C. \end{array}$$

$$P(NCS)_3 + SbF_3 \xrightarrow[\text{at } 150°–200°C.]{} PF_2NCS \qquad \text{b.p., } 90{\cdot}3\pm0{\cdot}3°C.$$

COMPLEX FORMATION

The phosphorus(III) halides may be expected (see under phosphorus trifluoride, page 444) to show an increasing electron donor activity towards acceptor molecules, and a decreasing electron acceptor behaviour in $\pi$ bond formation by *d*-orbitals, proportional to the reduction in halogen electronegativity which occurs on passing from fluoride to chloride, bromide and iodide. For the typically electron acceptor boron halides, complex compounds with phosphorus(III) chloride have been reported as follows:

$PCl_3,BF_3$ formed as white crystals below $-12$°C., decomposes at $-6$°C.[151]
$PCl_3,BCl_3$ formed as white crystals below $-10$°C., sublimes *in vacuo*, and is vigorously hydrolyzed.[152]
$PCl_3,BBr_3$, m.p. 42°C., dissociates to liquid $PCl_3$ + gaseous $BBr_3$ after 3 days *in vacuo*, and is vigorously hydrolyzed[153–4, 506] (cf. $PBr_3,BBr_3$, m.p. 61°C. stable *in vacuo* at room temperature).
$PCl_3,BI_3$, yellowish white crystals, formed in $CS_2$ at $-40$°C., decomposes at 35°C.[506]

In the case of $PCl_3,BI_3$ and $PCl_3,BBr_3$ ligand interchange is said to occur, with evolution of $BCl_3$, at 0° and 35°C., respectively.[506] Other addition complexes described in the literature include:

$(CuCl)_2,PCl_3$, dissociation pressure = 16, 47 and 170 mm. at 0, 20 and 50°C., respectively. With methanol, MeOH, gives $CuCl.P(OMe)_3$, m.p. 216° to 217°C.[155]
$GaCl_3,PCl_3$, m.p. 28°C. with decomposition. Heat of formation from its components at 25°C. = 3·4 kcal. $mole^{-1}$.[156]
$[RPCl_3]^+[AlCl_4]^-$ liquid or solid at ordinary temperatures depending on the nature of the alkyl group R. Formed by direct addition from equimolar alkyl, phosphorus(III) and aluminium chloride mixtures. Controlled hydrolysis gives alkyl phosphoryl dichlorides $RPOCl_2$; $H_2S$ gives alkylthiophosphoryl chlorides, $RPSCl_2$, then dithiophospho-alkanes, $RPS_2$. Reduction with powdered antimony gives alkylphosphonous-dichlorides, $R_2P_2Cl_2$.[157–9]
$CCl_4,PCl_3,AlCl_3$ from $CCl_4$–$PCl_3$–$AlCl_3$ mixtures after 4 hr. at 45° to 55°C. Forms $CCl_3POCl_2$ on hydrolysis.[160]

However, a recent vapour pressure/composition study,[154] using purified reagents in an all-glass high vacuum apparatus, failed to show any evidence of stable complex formation between phosphorus trichloride and either aluminium or gallium trichlorides, or boron trifluoride at $-78$°C., or boron trichloride at $-45$° and $+25$°C. A comparison of their boron trichloride adducts[154] shows phosphorus(III) chloride to be a much weaker Lewis base than either phosphine or trimethylphosphine thus:

$Me_3N,BCl_3$ undergoes negligible dissociation in the gas phase at 100°C.
$H_3P,BCl_3$ dissociates above 20°C.
$Cl_3P,BCl_3$ fails to associate down to $-78$°C.

With liquid diboron tetrachloride at low temperatures, the 1:2 complex $B_2Cl_4,2PCl_3$ is precipitated, m.p. $-16·3$° to $-15·8$°C., completely dissociated in the vapour phase but unchanged after 8 weeks in the dark at room temperature.[161] Phosphorus(III) chloride reacts with trimethylarsine at $-29·5$°C. giving white solid $Me_3As,PCl_3$, decomp. 0°C.; with trimethylstibine reduction to $Me_3SbCl_2$ and elemental phosphorus occurs.[162] Trimethylphosphine at 0°C. gives the 2:1 complex $(Me_3P)_2,PCl_3$[163] while with trimethylamine at $-78$° to 0°C. white solid $Me_3N,PCl_3$ is formed, m.p. 0°C., heat of dissociation $Me_3N,PCl_3(s) \rightarrow Me_3N(g) + PCl_3(g) = 22·4$ kcal. $mole^{-1}$.[164] In these compounds phosphorus(III) chloride appears to behave as an electron acceptor and thus in the Lewis sense is amphoteric.[154] The P–N bond energies for $Me_3N,PCl_3$ and $Me_3N,PBr_3$ are estimated at 6·4 and 3·1 kcal. $mole^{-1}$, respectively, indicating that either the greater electronegativity of chlorine increases the bonding or the greater steric effect of the bromine atom reduces it.[165] For $Me_3N,PMeCl_2$ the energy of complexing is estimated[166] as 2·9 kcal. $mole^{-1}$. The existence of white solid $F_3P,NMe_3$ at temperatures below its melting point is also confirmed, but to date there is insufficient evidence to decide whether the $PF_3$ molecule is a stronger acceptor than $PCl_3$ in these compounds. Phosphorus(III) chloride behaves as a typically $\pi$-bonding ligand in replacing the carbon monoxide from dimeric platinum carbonyl chloride, $[PtCl_2CO]_2$, even at low temperatures.[167] Direct action with nickel carbonyl in the liquid phase gives tetrakistrichlorophosphine nickel, $Ni(PCl_3)_4$, which separates as thermochromic crystals (pale yellow up to 120°C., white on cooling to $-30$°C.), following distillation of excess phosphorus(III) chloride and recrystallization from *n*-pentane.[168] Cryoscopy in benzene confirms the monomeric formula while magnetic susceptibility indicates the absence of unpaired electrons. When heated with phosphorus(III) fluoride $Ni(PCl_3)_4$ undergoes ligand exchange with formation of $Ni(PF_3)_4$. Thermal decomposition of $Ni(PCl_3)_4$ occurs with evolution of phosphorus(III) chloride and nickel(II) chloride, and formation of a mixture of heptanickel triphosphide and dinickel phosphide.[507] The products of reaction between phosphorus trichloride and cobalt carbonyl in benzene could not be characterized.[169]

## PHOSPHORUS(V) CHLORIDE

### Preparation

Phosphorus pentachloride is obtained commercially as a fine crystalline powder by addition of dry chlorine to approximately equal volumes of phosphorus trichloride and carbon tetrachloride contained in a stirred, lead-lined reaction vessel fitted with cooling water jacket and reflux condenser.[27, 29] Chlorination in phosphoryl chloride medium has also been described.[170] In either case the product is separated by filtration and the filtrate recycled. The direct reaction between phosphorus trichloride and chlorine gas has been used commercially[28, 171–2] and is also prescribed for laboratory synthesis of the pure material.[173–4] Other methods include passing chlorine gas into a suspension of red phosphorus in carbon tetrachloride[175] (a laboratory process), chlorine on aluminium phosphate,[176] the action of liquid chlorine upon phosphorus trichloride[177] and the reaction between phosphoryl chloride, carbonyl chloride and carbon at 400°C.[8]

### Physical Properties

In the liquid state or in solution in non-polar solvents, Raman spectrographic methods have shown all the P–Cl bonds in phosphorus(V) chloride to be alike; in the solid state however, the molecule is unsymmetrical and ionic.[178–82] Electron diffraction measurements for the vapour at 100°C.[183–4] indicated a trigonal bipyramidal structure with two P–Cl distances, viz.: 2·19 and 2·04 A., corresponding to apical and planar chlorine atoms, respectively. A complete vibrational assignment was made[185] based on $D_{3h}$ symmetry, the infra-red spectra for the vapour and solution in carbon-disulphide, and on the Raman spectrum for the solution in benzene. Conversely, normal co-ordinate analysis by the Urey–Bradley field, with introduction of an angle–angle interaction force, gave good agreement between calculated and observed infra-red and Raman frequencies.[508] Force constant data, in $10^5$ dynes cm.$^{-1}$, viz.: $k_r$ 2·892, $k_{r'}$ 1·805, $k_\alpha$ 0·111, $k_\beta$ 0·449, $g_r$ 0·236 and $g_{r'}$ 1·440 were evaluated such that P–Cl bond lengths by Badger's rule[186] were in close agreement with those derived from the electron diffraction measurements.[183–4] Earlier data[187–8] for both the molecular and ionic forms had been based on Raman evidence alone; recent infra-red and Raman studies[189–91] have led to further modification of the vibrational assignments for molecular $PCl_5$ and for the $PCl_4^+$ ion. In this work, phosphorus(V) chloride was shown to be fully dissociated to unsolvated $PCl_4^+$ and $PCl_6^-$ ions at 1 w/v. % dilution in methyl cyanide.[189] The solid formed by vapour deposition at 90°K. had an infra-red spectrum identical with those for the vapour or solution in carbon disulphide, and changing in an irreversible manner to that of the ionic form on allowing the sample to warm up.[190] Later cryoscopic, spectroscopic and conductimetric studies of phosphorus(V) chloride in various solvents have shown that it is predominantly present as molecular $PCl_5$ in phosphoryl chloride, benzene, 1,2-dichloroethane and *cyclo*hexane. In acetonitrile it is partly dissociated to $PCl_4^+$ and

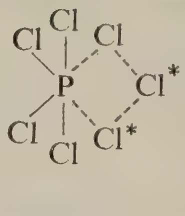
$PCl_6^-$ ions, while in carbon tetrachloride it appears to exist as a dimer, $P_2Cl_{10}$, of covalent structure.[509] *X*-Ray studies[192–3] showed crystalline phosphorus pentachloride to be tetragonal with $a = 9{\cdot}22$, $c = 7{\cdot}44$ A., 4 molecules per unit cell (density was 2·12 g./c.c.) and the space group *P*4/*n*. The arrangement of $PCl_4$ tetrahedra and $PCl_6$ octahedra was essentially of the cæsium chloride type, with P–Cl distance 1·97 A. in $[PCl_4]^+$ and 2·08 A. in $[PCl_6]^-$; the Cl–Cl distances ranged from 3·43 to 3·9, average 3·6 A. The constitutional change on melting is accompanied by an alteration in electrical properties,[194] viz.:

| | Specific conductance (mho cm.$^{-1}$) | Dielectric constant |
|---|---|---|
| $PCl_5$ crystals | $3{\cdot}3 \times 10^{-7}$ at 20°C. | — |
| | $3 \times 10^{-8}$ at 100°C. | 4·2 at 135°C. |
| $PCl_5$ liquid | $6 \times 10^{-9}$ at m.p. | 2·7 at 165°C.<br>(under pressure) |

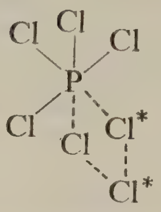
and is reflected in the non-coincidence of the melting range (159° to 160·5°) crystallization point (157°) and halt in the temperature/time cooling curve (154° to 148°C. dependent on the cooling rate) observed[195] under sealed tube conditions. Dielectric constant measurements in carbon disulphide or carbon tetrachloride solution at 25°C. gave[196] molar polarization and molar refraction values (infinite dilution) of 51 and 35·5 c.c., respectively, and a dipole moment of 0·8 D. Phosphorus pentachloride behaves as an electrolyte in polar solvents and transport experiments[197] have supported the presence of $[PCl_4]^+$ and $[PCl_6]^-$ ions in solution. Equivalent conductance values in various solvents were:

| Solvent | Concentration moles $PCl_5$/litre | Equivalent conductance mho cm.$^2$ moles$^{-1}$ |
|---|---|---|
| Dioxan | 0·0825 | 0 |
| Diethyl ether | 0·05 | 0 |
| Phosphoryl chloride | 0·409 | 0·49 |
| Benzonitrile | 0·0301 | 1·03 |
| Benzoyl chloride | 0·0325 | 1·57 |
| Nitrobenzene | 0·0517 | 3·43 |
| Nitrobenzene | 0·0137 | 3·30 |
| Nitrobenzene | 0·00137 | 3·64 |
| Acetonitrile | 0·1870 | 26·3 |
| Acetonitrile | 0·0495 | 30·0 |
| Acetonitrile | 0·00554 | 34·5 |

Differences are attributed to the stabilization of the ionization by complex formation rather than to differences in dielectric constant of the medium. Cryoscopy in nitrobenzene showed negligible association to double molecules[197]; in carbon tetrachloride solution however, apparent molecular weight values of 259 and 473 at 0·0241 and 0·0959 M. concentrations, respectively, were obtained.[198] Chloride ion exchange in acetonitrile solution at 25°C. between $^{36}Cl$ labelled tetraethylammonium chloride and the tetrachlorophosphonium cation $[PCl_4]^+$ followed second-order kinetics with $k = 2{\cdot}00 \times 10^{-2}$ l. mole$^{-1}$ sec.$^{-1}$ and $t_{1/2}$ for 0·3 to 0·01 M. concentrations ranging from 1 to 19 min.; by contrast, $t_{1/2}$ for the exchange reaction with the hexachlorophosphonate anion $[PCl_6]^-$ was 0·6 sec. Conductimetry in acetonitrile solution confirmed that no such reaction as $[PCl_4]^+ + 2Cl^- = [PCl_6]^-$ occurs.[198] In carbon tetrachloride solution, three of the chlorine atoms in phosphorus pentachloride are much more rapidly exchanged for labelled molecular chlorine than the other two. Further, the formation reaction from phosphorus trichloride and chlorine, and the decomposition reaction with mercury, both in carbon tetrachloride media, were shown[199, 200] to proceed mainly through the equatorial positions. Differences in the two apical and three equatorial positions for trigonal bipyramidal molecules have been explained in terms of repulsion on the bonding pair,[126] of the maximum overlap principle,[510] or of differences in hybridization.[201–3] It is suggested[203] that hybridized *dp* bonds extend in the apical direction and $sp^2$ bonds extend in the equatorial direction. Possible intermediate states in the rapid exchange with chlorine ($Cl_2^*$) written:



(i)



(ii)

must lead[199, 200] either to no exchange, or (i) to exchange in the equatorial positions, (ii) to simultaneous exchange in both apical and equatorial positions. Steric hindrance should be no less at (ii) than at (i) and the experimental results therefore, were considered[199–200] to confirm a difference in bonding at the apical and equatorial positions. A study of overlap integrals for the *d*-orbitals in free atoms of P and S showed them too diffuse for useful contribution to bonding. For such molecules as $PCl_5$ and $SF_6$ a type of polarization was proposed[204–5] by which diffuse *d*-orbitals of the parent atom are sufficiently contracted to participate in $sp^3d$ and $sp^3d^2$ covalent bonding, respectively. On the basis of the cryoscopic evidence in carbon tetrachloride solution, it was suggested[198] that the observed[199–200] non-linear exchange rate with molecular chlorine may be due to simultaneous exchange reactions involving both simple and associated species. Mass spectroscopy at 50 e.v. gives peaks corresponding to: $P_2Cl_9^+$, $P_2Cl_7^+$, $P_2Cl_5^+$, $P_2Cl_3^+$, $P_2Cl_2^+$, $P_2Cl^+$ ion species as well as to a number of others containing one phosphorus atom. A solid–vapour equilibrium at the crystal surface, viz.: $[PCl_4]^+[PCl_6]^- \rightleftharpoons P_2Cl_{10}$, is proposed, wherein $P_2Cl_{10}$ molecules contain a 4-membered ring with two Cl-bridges involving $d_\pi$–$p_\pi$ bonding to two octahedrally connected phosphorus atoms. However, molecular weight determinations at relatively low temperatures provided no evidence of association in the vapour phase.[206–7]

Phosphorus(V) chloride sublimes at 159°C., 760 mm. pressure, and melts at 160°C. at slightly higher pressure or at 167°C. at 919 mm.[208] The vapour pressure of the solid from 100° to 159°C. is given by $\log_{10} p_{\text{mm.}} = 11{\cdot}034 – 3523/T$, where $T$ is in °K., and the density of the liquid from 162° to 190°C. is given by $d_4^t = 1{\cdot}599 - 0{\cdot}0019 (t - 160°\text{C.})$ with $t$ in °C. The heat of sublimation to equilibrium vapour composition is 16·1 kcal. mole$^{-1}$, and to undissociated $PCl_5$ molecules 15·5 kcal. mole$^{-1}$. Equilibrium constant values for the dissociation $PCl_5(g) \rightarrow PCl_3(g) + Cl_2(g)$ between 422° and 502°K. are given by $\log_{10} K_{p(\text{mm.})} = 6{\cdot}66 + 1{\cdot}75 \log T – 4376/T$; the heat of dissociation at 200°C. is 22 kcal. mole$^{-1}$, and at 160°C., 760 mm., the vapour is 13% dissociated.[208] Experimentally determined thermal conductivities ($K$) for the dissociating vapour system at 145° to 175°C. at pressures below 1 atm. agreed well with the calculated values[209] thus:

| °C. | $P_{\text{total}}$ (mm. Hg) | $K_{\text{experimental}}$ (g.-cal. cm.$^{-1}$ | $K_{\text{calculated}}$ sec.$^{-1}$deg.$^{-1}$ × $10^5$) |
|---|---|---|---|
| 145 | 151·0 | 11·28 | 11·42 |
| | 248·0 | 9·64 | 9·75 |
| | 309·0 | 8·85 | 8·88 |
| | 315·0 | 8·86 | 8·83 |

| | | | |
|---|---|---|---|
| 160 | 164·5 | 14·04 | 14·31 |
| | 289·4 | 12·20 | 12·27 |
| | 350·3 | 11·60 | 11·53 |
| | 363·9 | 11·53 | 11·40 |
| 175 | 188·0 | 15·95 | 16·51 |
| | 333·0 | 14·75 | 14·67 |
| | 386·3 | 14·42 | 14·13 |
| | 422·5 | 13·92 | 13·79 |

Values of standard heat, free energy and equilibrium constant of formation at 298·15°K. are given[40–2] as:

| | crystals | vapour |
|---|---|---|
| $\Delta H_f^\circ$ | $-110{\cdot}7$ | $-95{\cdot}35$ kcal. mole$^{-1}$ |
| $\Delta G_f^\circ$ | — | $-77{\cdot}59$ kcal. mole$^{-1}$ |
| $\log K_f$ | — | $56{\cdot}872$ kcal. mole$^{-1}$ |

and equations giving free energy of formation from 432° to 1500°K. have been derived as follows[45, 210]:

$$P_4(l)+10Cl_2(g) \rightleftharpoons 4PCl_5(g); \quad \Delta G = -35{,}340+3{\cdot}44\,T\log T+12{\cdot}47T \text{ g.-cal. mole}^{-1}$$
$$P_4(g)+10Cl_2(g) \rightleftharpoons 4PCl_5(g); \quad \Delta G = -36{,}900+2{\cdot}01T\log T+19{\cdot}17T \text{ g.-cal. mole}^{-1}$$
$$P_2(g)+5Cl_2(g) \rightleftharpoons 2PCl_5(g); \quad \Delta G = -40{,}150+2{\cdot}01T\log T+21{\cdot}21T \text{ g.-cal. mole}^{-1}$$

The estimated error is ±3–5 kcal. mole$^{-1}$.

For the dissociation to phosphorus trichloride and chlorine in the gas phase, values of $\Delta H_0^\circ = -21{\cdot}32 \pm 0{\cdot}03$[43] and $20{\cdot}52 \pm 0{\cdot}16$ kcal. mole$^{-1}$ [185] were obtained using the available spectrographic data for $PCl_5$, $PCl_3$ and $Cl_2$. Free energy, heat content, and entropy changes, and equilibrium constant values for the dissociation reaction between 298° and 600°C. are summarized in Table V.[41]

*Table V.—$\Delta G^\circ$, $\Delta H^\circ$, $\Delta S^\circ$ and $K_{\text{atm.}}$ for the Reaction*
$PCl_5(g) = PCl_3(g)+Cl_2(g)$

| Temperature °K. | $\Delta G^\circ$ g.-cal. mole$^{-1}$ | $\Delta H^\circ$ g.-cal. mole$^{-1}$ | $\Delta S^\circ$ e.u. | $K_p$ atm. |
|---|---|---|---|---|
| 298·1 | 9140 | 22,130 | 43·6 | $2{\cdot}0 \times 10^{-7}$ |
| 400 | 4600 | 21,980 | 43·4 | $3{\cdot}1 \times 10^{-3}$ |
| 450 | 2350 | 21,890 | 43·4 | $7{\cdot}22 \times 10^{-2}$ |
| 500 | 100 | 21,800 | 43·4 | 0·904 |
| 550 | −2190 | 21,720 | 43·5 | 7·42 |
| 600 | −4420 | 21,640 | 43·4 | 40·8 |

A correlation of selected dissociation data based on a $\log_{10} K_p$ against $1/T$ relationship has provided a reasonable estimate of the percentage dissociation at elevated temperatures and pressures, thus:

| ref. | range °K. | $\log_{10} K_p$(atm.) | mean $\Delta H$ kcal. mole$^{-1}$ |
|---|---|---|---|
| 45, 210 | 462–623 | $9{\cdot}36-4810/T$ | 22·01 |
| 208 | 420–500 | $6{\cdot}66+1{\cdot}75\log T-4376/T$ | 22·00 |
| 41 | 298–600 | $9{\cdot}70-4860/T$ | 22·23 |
| calc.* | 400–800 | $9{\cdot}48-4840/T$ | 22·14 |
| mean | 300–800 | $9{\cdot}50-4830/T$ | 22·10 |

* From available thermodynamic data.[40, 42, 212–3]

Where $\alpha$ is the fraction of the pentachloride dissociated, and $P$ is the total pressure in atmospheres

$$K_p = \frac{\alpha^2 P}{1-\alpha^2} \quad \text{and} \quad \alpha = \sqrt{\frac{K_p}{K_p+P}}$$

Using these relationships values of $\alpha$ expressed as a percentage given in Table VI were calculated.[211]

*Table VI.—Dissociation at Elevated Temperatures and Pressures for the Reaction* $PCl_5(g) \rightleftharpoons PCl_3(g)+Cl_2(g)$

| Temperature °K. | $K_p$ atm. | % dissociation at total pressure in atm. | | | | |
|---|---|---|---|---|---|---|

## Chemical Properties

Reduction of phosphorus(V) chloride in ether solution with excess of lithium, lithium boron or lithium aluminium hydrides leads only to phosphine, hydrogen and a solid hydride $PH_x$. It was concluded therefore[214] that phosphorus pentahydride does not exist.

In liquid ammonia solution, the phosphorus pentamide $P(NH_2)_5$ first formed dissociates irreversibly at 0°C. to give a mixture of tri- and tetrameric phosphonitrilic diamides $[PN(NH_2)_2]_n$. These, on further heating, lose ammonia according to the scheme:

$$[PN(NH_2)_2]_n \xrightarrow[\text{50–400°C.}]{} (PN.NH)_3 \xrightarrow[\text{480°C.}]{} P_3N_5 \xrightarrow[\text{700°C.}]{} P+N$$

i.e., with stepwise decomposition to phospham, phosphoric nitride and finally to elemental phosphorus and nitrogen.[215–8] Phosphorus(V) chloride in chloroform solution reacts vigorously with liquid ammonia at $-50$°C. to give a 36% yield of the solid trimer, $[PN(NH_2)_2]_3$.[219] With ammonium chloride in refluxing tetrachloroethane, phosphonitrilic chlorides, mainly the cyclic trimer and tetramer, are formed.[220–3] A similar reaction with ammonium bromide leads to the formation of some of the monobromo compound $P_3N_3Cl_5Br$,[224] but with ammonium or potassium fluoride the product is hexafluorophosphate according to the reaction,

$$PCl_5 + 6MF = MPF_6 + 5MCl^{225}$$

For a fuller account of these and related reactions, see Section XVIII.

Phosphorus pentachloride reacts with a midosulphonic acid in carbon tetrachloride solution to give trichlorophosphazosulphuryl chloride, m.p. 35° to 36°C.[226] (cf. Mellor, VIII, 1014) according to the equation:

$$2PCl_5 + H_2NSO_2H = POCl_3 + 3HCl + Cl_3P{=}NSO_2Cl$$

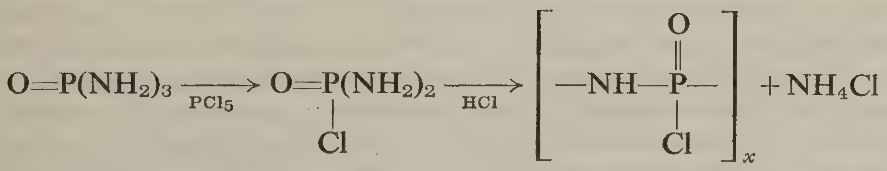
With sulphuryl diamide in a slow stream of dry air, the reaction

$$2PCl_5 + (H_2N)_2SO_2 = 4HCl + (Cl_3P{=}N)_2SO_2$$

occurring spontaneously at room temperature, is virtually complete in the presence of a slight excess of phosphorus(V) chloride (removable *in vacuo*) after keeping at 60° to 90°C. for 1 hr.[227] The product, m.p. 39·7° to 41°C., decomposes on distillation at 0·5 mm., is hygroscopic and reacts vigorously with water, ammonia, amines, alcohols and phenols. Recently,[228] reactions of similar type have been reported for the amidophosphoric acids and for triamidomonothiophosphate. Thus, with monoamidophosphoric acid in tetrachloroethylene solution (subject to removal of hydrogen chloride as it is formed) the reaction:

$$3PCl_5 + H_2N\text{–}PO(OH)_2 = 2POCl_3 + 4HCl + Cl_3P{=}NPOCl_2$$

proceeds vigorously and quantitatively at ordinary temperatures. The product, trichlorophosphazophosphoryl chloride, forms as colourless crystals, m.p. 35°C., which hydrolyze in water giving monoamidophosphoric, orthophosphoric and hydrochloric acids in dilute solution, ammonium phosphate in concentrated solution, or tetrasodium imidodiphosphate, $(NaO)_2PO\text{–}NH\text{–}PO(ONa)_2$, in excess of dilute caustic soda. With phosphorus(V) chloride and triamidophosphoric acid several reactions are possible. Thus, in the presence of hydrogen chloride, substitution of chlorine for an amino group occurs, and subsequent condensation leads to up to 80% yields of solid polymer according to:



$$O{=}P(NH_2)_3 \xrightarrow[PCl_5]{} O{=}\underset{\displaystyle Cl}{\underset{|}{P}}(NH_2)_2 \xrightarrow[HCl]{} \left[\text{—}NH\text{—}\overset{\displaystyle O}{\overset{\|}{\underset{\displaystyle Cl}{\underset{|}{P}}}}\text{—}\right]_x + NH_4Cl$$

Removal of the hydrogen chloride as soon as it is liberated ensures formation of trichlorophosphazophosphoryl chloride in up to 50% yield as follows:

$$O{=}P(NH_2)_3 \xrightarrow[+2PCl_5]{} Cl_3P{=}NPOCl_2 + NH_4Cl + 2HCl + (NPCl_2)_x$$

Some phosphoryl chloride from the reaction

$$O{=}P(NH_2)_3 \xrightarrow[+PCl_5]{} POCl_3 + (NPCl_2)_2 + 2NH_3$$

as well as products from the reaction between phosphonitrilic chloride and phosphorus(V) chloride, of the type $(NPCl_2)_x,PCl_5$,[229] are also formed. With diamidophosphoric acid *ca.* 50% conversion to the trichlorophosphazophosphoryl chloride can be achieved, while with triamidothiophosphate, $SP(NH_2)_3$, in tetrachloromethane, the sulphur is readily replaced by 2 chlorine atoms and colourless crystals of tris-(trichlorophosphazo)-phosphorus dichloride separate. The low solubility of the latter compound in benzene, carbon tetrachloride, etc., and its high decomposition temperature, 170°C., and m.p., 200° to 202°C. (rapid measurement), point to an ionic formulation: $[Cl{-}P(N{=}PCl_3)_3]^+Cl^-$ rather than the covalent $Cl_2P(N{=}PCl_3)_3$. Cryoscopy in nitrobenzene, however, indicated[228] a molecular weight of 547; theory, 556.

The course of the reaction of phosphorus(V) chloride with amides of the general structure $RSO_2NHPOCl_2$ depends upon the nature of the group R.[512] The normal reaction is that given by the equation (1):

$$(1) \qquad RSO_2NHPOCl_2 + PCl_5 \rightarrow HCl + POCl_3 + RSO({=}NPOCl_2)Cl$$

while if R is very electronegative, trichlorophosphazosulphonyl derivatives are formed:

$$(2) \qquad RSO_2NHPOCl_2 + PCl_5 \rightarrow RSO_2N{=}PCl_3 + HCl + POCl_3$$

However, where R = $PhCH_2$ the reaction takes yet a third course:

$$\begin{aligned}(3) \quad & PhCH_2SO_2NHPOCl_2 + 2PCl_5 \\ & \qquad \rightarrow PhCH_2Cl + Cl_2S{=}NPOCl_2 + 2POCl_2 + HCl\end{aligned}$$

The products of reactions (1) and (3) can react further with more $PCl_5$, e.g.:

$$\begin{aligned}& CH_3SO({=}NPOCl_2)Cl + PCl_5 \rightarrow CH_3Cl + POCl_3 + Cl_2S{=}NPOCl_2 \\ & Cl_2S{=}NPOCl_2 + 3PCl_5 \rightarrow Cl_2 + SCl_2 + Cl_3P{=}NPOCl_2 \\ & Cl_3P{=}NPOCl_2 + 2PCl_5 \rightarrow POCl_3 + Cl_3P{=}NPCl_4{,}PCl_5\end{aligned}$$

By causing phosphorus(V) chloride to react with hydroxylamine hydrochloride in tetrachloroethane as solvent at 100°C. (hydrogen chloride and chlorine evolved) and subsequently removing the solvent and the concomitant product, phosphoryl chloride, at 45° to 60°C. *in vacuo*, a compound of composition $PCl_5NO$ was obtained,[230] b.p. 270° to 280°C. (decomp.), f.p. 34·1°C., $d_4^{38}$ 1·796 and $n_D^{38}$ 1·5260.

The graph of molar conductivity plotted against concentration for solutions of phosphorus(V) chloride in bromine passes first through a minimum and then through a maximum[231]; some initial ionization of the pentachloride and then of a chloride–bromide complex was suggested. Red-brown crystals of composition $PCl_5{,}5Br_2$, m.p. 25°C. (decomp.) were obtained[232] from carbon disulphide solutions of phosphorus(V) chloride–bromine mixtures on cooling. With iodine bromide–phosphorus(V) chloride mixtures in carbon tetrachloride solution, yellow crystals of composition $[PCl_4][ClIBr]$ were obtained.[233] The fusion diagram for the phosphorus(V) chloride–iodine chloride system shows a eutectic at 9·2 mole % $PCl_5$ (9·6°C.) and evidence of a maximum at 50 mole % $PCl_5$ (> 180°C., not realized due to excessive sublimation of the compound $PCl_6I$) analogous to that at 50 mole % $PBr_5$ (114·6°C.) in the phosphorus(V) bromide–iodine bromide system. Both equimolar complexes give electrically good conducting solutions in bromine, iodine chloride, methyl cyanide and nitrobenzene; their apparent molecular weights in the last solvent are approximately half of the expected values. The experimental results[234] may be summarized thus:

| Specific conductance (mho cm.$^{-1}$) of 5–15% solutions in: | $PCl_6I$ | $PBr_6I$ |
|---|---|---|
| Br at 25°C. | $2{\cdot}0 \times 10^{-2}$ | $2{\cdot}4 \times 10^{-2}$ |
| ICl at 45°C. | $2{\cdot}5 \times 10^{-2}$ | (in IBr) $3{\cdot}4 \times 10^{-2}$ |
| ICl at 55°C. | $3{\cdot}3 \times 10^{-2}$ | ( ,, ) $3{\cdot}8 \times 10^{-2}$ |
| $CH_3CN$ at 25°C. | $7{\cdot}7 \times 10^{-3}$ | $3{\cdot}4 \times 10^{-3}$ |
| $C_6H_5NO_2$ at 25°C. | $1{\cdot}3 \times 10^{-3}$ | $1{\cdot}1 \times 10^{-3}$ |
| Apparent mol. wt. in $C_6H_5NO_2$ solution | 185 | 355 |
| formula wt. | 370·7 | 637·5 |

The values indicate extensive dissociation according to the general equation: $PX_6I = [PX_4]^+ + [IX_2]^-$. An *X*-ray study of the $PCl_6I$ complex confirms[235–6] an ionic structure with tetrahedral $[PCl_4]^+$ and linear $[ClICl]^-$ ions.

The products of reaction between phosphorus(V) chloride and phosphorus(III) or (V) bromides with or without additional bromine have been studied by a number of investigators (see phosphorus chlorobromides pages 486–7); the system, however, is complex and remains incompletely clarified.

Phosphorus(V) chloride reacts with fluorosulphonic acid at −16°C. to give phosphoryl fluoride, hydrogen chloride, pyrosulphuryl chloride and chlorosulphonic acid,[237] cf.:

$$2SO_2(OH)Cl + PCl_5 \rightarrow S_2O_5Cl_2 + 2HCl + POCl_3 \quad \text{(Mellor, VIII, 1013)}$$

With dihydroxydifluoroboric acid, reactions are reported[238] as follows:

$$3H_3BO_2F_2 + 3PCl_5 \xrightarrow[\text{temperature}]{\text{at room}} BPO_4 + 2POCl_3 + 2BF_3 + 9HCl$$

$$3H_3BO_2F_2 + 3PBr_5 \xrightarrow[\text{on heating}]{} BPO_4 + 2POBr_3 + 2BF_3 + 9HBr$$

The chlorination rates for tantalum, niobium, titanium and zirconium oxides with liquid phosphorus(V) chloride, at 225°C. in sealed tubes, were found[239] to be dependent upon the method of preparation, the structural form and the specific surface area of the oxides.

COMPLEX FORMATION

Phosphorus(V) chloride gives rise to a large number of ionic complexes, evidence for which comes mainly from conductimetry in anhydrous solvent systems. Thus, in sulphuryl chloride solution it behaves as a chloride ion donor or 'solvo-base', and breaks in the conductimetric titration curves with solvo-acids coincide with[240] complex formation as follows:

| | | |
|---|---|---|
| — | $[PCl_4]_2.SbCl_7$ | $[PCl_4].SbCl_6$ |
| — | $[PCl_4]_2.TiCl_6$ | $[PCl_4].TiCl_5$ |
| $[PCl_4]_3.AsCl_6$ | $[PCl_4]_2.AsCl_5$ | $[PCl_4].AsCl_4$ |
| $[PCl_4]_4.SnCl_8$ | $[PCl_4]_2.SnCl_6$ | — |
| $[PCl_4]_3.SbCl_6$ | $[PCl_4]_2.SbCl_5$ | $[PCl_4].SbCl_4$ |

The existence of the compounds $[PCl_4]^+[AlCl_4]^-$ and $[PCl_4]^+[FeCl_4]^-$ was established by thermal analysis of the respective binary systems, as well as by cryoscopic, conductimetric and ionic transference methods in nitrobenzene[208, 241–2]; specific conductances at 25°C. for 0·13 to 0·77 M. solutions are of the order $10^{-2}$ mho cm.$^{-1}$ [241] The compounds (m.p. 343° and 332°C., respectively) are conveniently prepared from their components in chloroform or carbon tetrachloride solution. The former is insoluble in benzene, while the latter gives non-conducting solutions for which the freezing point depression corresponds to a molecular weight close to $FePCl_8$. Mixtures of phosphorus(V) chloride and stannic chloride in nitrobenzene show maximum conductivity ($4 \times 10^{-4}$ mho cm.$^{-1}$) at mole ratio 2:1; while for such solutions, cryoscopy indicates appreciable dissociation of the 2:1 complex according to: $[PCl_4]_2.SnCl_6 \rightleftharpoons 2[PCl_4]^+ + [SnCl_6]^{2-}$.[243] In phosphoryl chloride solutions of tin, titanium or zirconium tetrachlorides, antimony pentachloride, etc., addition of phosphorus(V) chloride causes a rapid increase in conductivity due to breakdown of the solvent complex (probably oxygen co-ordinated, see pages 497–502) and release of the complex-forming chloride.[244] With stannic chloride a subsequent drop in conductivity is accompanied by precipitation of the 2:1 complex, $[PCl_4]_2SnCl_6$; with zirconium chloride the conductivity titration curve shows breaks at the mole ratios $PCl_5:ZrCl_4 = 2:1$, 1:1 and 1:2.[245] The 1:2 complexes with zirconium or hafnium tetrachlorides are formed from stoicheiometric mixtures at 300°C., and repeated fractionation affords a separation of the zirconium (b.p. = 416°C.) from the hafnium compound, the latter concentrating in the tail fractions.[246-7] Similarly the complex $[PCl_4]_2TiCl_6$ can be prepared by boiling solid phosphorus(V) chloride with excess of titanium(IV) chloride for 1 hour. It is a yellow solid, slightly soluble in methylene chloride, and very soluble in nitromethane.[513] Titration of vanadium(IV) chloride with phosphorus(V) chloride in phosphoryl, arsenic(III) or thionyl chloride solution indicates formation of 2:1 and 3:1 complexes believed to contain $VCl_6^{--}$ and $VCl_7^{---}$ ions.[248] Two general preparative methods, viz., causing the metallic chloride to react either in hot phosphoryl chloride solution with phosphorus(V) chloride, or in thionyl chloride solution with phosphorus(III) chloride ($PCl_5$ is first formed) gave phosphorus(V) complexes[249] with each of the following:

Zn and Hg dichlorides
Al, Bi, Cr, Fe, Tl, B, Au trichlorides
Sn, Ti, Zr, Se, Te, Pt, V tetrachlorides
Sb, Mo, W pentachlorides

Reaction of phosphorus(V) chloride with metallic oxides generally leads to the formation of phosphoryl chloride. However, with chromium trioxide in phosphoryl, acetyl, or benzoyl chloride solutions, an orange-red precipitate of composition $CrPCl_7O_2$ is obtained. The same precipitate is formed by addition of phosphorus(V) chloride to chromyl chloride, both in solution in phosphoryl chloride; the formula $PCl_4^+.CrO_2Cl_2^-$ was proposed for the product,[250] wherein the negative part may be polymeric. The uranium complex $UCl_5,PCl_5$ forms as orange-red crystals on mixing anhydrous uranium trioxide (orange, reactive form) with phosphorus(V) chloride and recrystallizing from phosphoryl chloride. In this solvent it behaves as $PCl_4^+.UCl_6^-$.[251] With nitrosyl perchlorate in phosphoryl or arsenic(III) chloride solution, phosphorus(V) chloride decomposes to phosphorus pentoxide and phosphoryl chloride; nitrosyl chloride, chlorine dioxide and chlorine are also formed.[250]

Conductimetric titration of tellurium(IV) chloride in arsenic(III) chloride solution with phosphorus pentachloride showed breaks at mole ratios $PCl_5:TeCl_4 = 2$, 1 and 0·5[252]; the respective compounds can be isolated by evaporation of the solvent. Cryoscopic and conductimetric data for 0·1 M. solutions of phosphorus(V) chloride in arsenic(III) chloride indicate that the equilibrium:

$$2AsCl_3 + PCl_4^+ + PCl_6^- \rightleftharpoons 2PCl_4^+ + 2AsCl_4^-$$

lies 70% to the left. Evaporation of more concentrated solutions gave hygroscopic prismatic crystals of composition $2PCl_5,5AsCl_3$, m.p. 40°C. Addition of phosphorus(V) chloride to antimony(III) chloride in chloroform solution precipitates white hygroscopic crystals of composition $2PCl_5,4SbCl_3$, m.p. 106°C. (decomp.). Cryoscopic and conductimetric evidence for the latter compound in antimony(III) chloride solution favours its formulation as the solvate $[PCl_4]^+[PCl_6]^-,4SbCl_3$ rather than as the ion donor compound $[PCl_4]^+[SbCl_4]^-,SbCl_3$. Specific conductances for 0·05 M. solutions of $P_2Cl_{10}$, $P_2Cl_{10},5AsCl_3$ and $P_2Cl_{10},4SbCl_3$ in acetonitrile at 20°C. were 1·4, 2·1 and $3{\cdot}0 \times 10^{-3}$ mho cm.$^{-1}$, respectively.[253]

Titration of phosphorus(V) chloride or of tetrachlorophosphonium fluoride with tetraethylammonium chloride in the same solvent[198] provided no evidence of any reaction such as: $PCl_4^+ + 2Cl^- \rightarrow PCl_6^-$. The formation of $PCl_6^-$ ions in the acetonitrile–hydrogen chloride–phosphorus(V) chloride system, however, was confirmed from conductivity and ion transfer evidence[254]; the formula $[(MeCN)_xH]^+[PCl_6]^-$ was proposed for the complex. Conductimetric titrations, in iodine chloride solution, with antimony(V) chloride[255] show phosphorus(V) chloride to be typically solvobasic, but against potassium, cæsium or tetramethylammonium chlorides it is solvo-acidic.[256-7] From the latter group of titration solutions in iodine chloride, or from those from precisely similar titrations in arsenic(III) chloride or phosphoryl chloride solution, no compounds of type $MPCl_6$ could be isolated. However, from phosphorus(V) chloride in arsenic(III) chloride solution saturated with chlorine, the compound $AsPCl_{10}$ was obtained[258]; it is unstable, insoluble in carbon tetrachloride and thought to contain $AsCl_4^+$. The amphoteric property of phosphorus(V) chloride in both thionyl and phosphoryl chloride solutions has also been demonstrated.[259] In thionyl chloride, titrations with tetramethylammonium chloride (solvo-basic) and with antimony(V) chloride (solvo-acidic) were followed conductimetrically, potentiometrically and by the use of acid–base indicators.[260–1] In phosphoryl chloride solution against tetraethylammonium chloride, white finely crystalline tetraethylammonium hexachlorophosphonate, $Et_4NPCl_6$, was precipitated.[262] Phosphorus(V) chloride is readily soluble in liquid hydrogen chloride and behaves in such solutions as a strong solvo-base thus:

$$PCl_4.PCl_6 + 2HCl \rightarrow 2PCl_4^+ + 2HCl_2^-$$

The molar conductance at 0·2 M. concentration is 25 mho cm.$^2$ mole$^{-1}$. Conductimetric titration with boron trifluoride shows a break at mole ratio 1:1; the solid complex corresponding to this break, and for which infra-red spectroscopy confirmed the ionic formula $[PCl_4]^+[BF_3Cl]^-$, was separated on evaporation of the solvent.[263–5] Titration in the same medium with boron trichloride gave a white precipitate of composition $PCl_5,2BCl_3$, which decomposed to the 1:1 complex and boron trichloride at room temperature.[263–5] A white 1:1 $BCl_3,PCl_5$ complex is precipitated by passing boron trichloride into refluxing phosphorus(V) chloride in triethylamine solution. This compound melts with decomposition; at 300°C. in a sealed tube the products are chlorine and a boron phosphide of composition varying between BP and $B_5P_3$.[266–7, 514] A general review of the addition compounds of the Group V pentahalides has appeared.[515]

1:1 Adducts were reported[268] between phosphorus(III) or (V) chlorides and triethylamine; the results, however, were not confirmed in a later study using purified reagents in an all-glass high vacuum apparatus. Under such conditions[162–3] with trimethylamine, triethylamine or trimethylarsine, reduction of phosphorus(V) to phosphorus(III) chloride occurs:

$$\left.\begin{array}{l} Me_3N \xrightarrow[+PCl_5 \text{ at } 100°C.]{} \underset{\text{white}}{(Me_3N)_2Cl_2} + PCl_3 \\ Et_3N \xrightarrow[+PCl_5 \text{ at } 20°C.]{} \underset{\text{orange}}{Et_3NCl_2} + PCl_3 \end{array}\right\} \text{cf. } Me_3N \xrightarrow[+SbCl_5]{} 1:1 \text{ complex}$$

$$Me_3As \xrightarrow[+PCl_5 \text{ at } 20°C.]{} Me_3AsCl_2 + PCl_3$$

$$\text{cf.} \left\{\begin{array}{l} Et_3N + PCl_3 \xrightarrow[-78° \text{ to } 0°C.]{} \text{no reaction} \\ Me_3N + PCl_3 \xrightarrow[-78° \text{ to } 0°C.]{} 1:1 \text{ complex*} \\ Me_3As + PCl_3 \xrightarrow[-29.5°C.]{} 1:1 \text{ complex*} \end{array}\right.$$

* see page 475.

With trimethylstibine some elemental phosphorus is formed:

$$Me_3Sb \xrightarrow[+PCl_5 \text{ (or } PCl_3\text{) at } 0°C.]{} Me_3SbCl_2 + P$$

Trimethylphosphine forms a 2:1 complex with both phosphorus(V) and (III) chlorides; (cf. it forms both a 2:1 and a 1:1 complex with antimony(V) chloride)

$$Me_3P \xrightarrow[+PCl_5 \text{ in bromobenzene at } 0°C.]{} (Me_3P)_2,PCl_5$$

$$Me_3P \xrightarrow[+PCl_3 \text{ at } 0°C.]{} (Me_3P)_2,PCl_3$$

Phosphorus(V) chloride is insoluble in boron trichloride at 0°C. but reacts in the vapour state or in carbon tetrachloride solution to give a 1:1 complex, $PCl_5,BCl_3$.

The complex is also formed by chlorination of phosphorus(III) chloride–boron trichloride mixtures at −78°C. (see page 475). It sublimes with reversible dissociation at 340°C. in a sealed tube[269]:

$$PCl_5,BCl_3 \rightleftharpoons PCl_3 + Cl_2 + BCl_3$$

Phosphorus(V) chloride with gallium chloride in carbon tetrachloride gives a 1:1 complex, and the respective high melting points, viz.:

| | | |
|---|---|---|
| | $PCl_5,GaCl_3$ | m.p. 368° to 371°C.[269] |
| | $PCl_5,BCl_3$ | sublimes at 340°C.[269] |
| cf. | $PCl_5,AlCl_3$ | m.p. 375° to 379°C.[208] |

compared with those of their components, indicate probable salt-like structures for each of these compounds.

## PHOSPHORUS CHLOROBROMIDES

Interaction between phosphorus(III) and (V) chlorides and bromides, bromine and chlorine leads to various crystalline and liquid phases of mixed composition, the nature of the compounds formed having received much attention in the past thirty years but without, as yet, it being completely clarified.

Early workers[270–2] obtained liquid phosphorus(III) and crystalline phosphorus(V) chlorobromides either by substitution of elemental bromine into phosphorus(III) or (V) chlorides, or by reaction between the respective phosphorus(III) and (V) halides. No compound of composition $PCl_3Br_2$ was so isolated,[270–1] but two series of unstable polybromides, viz: $PCl_2Br_n$ (with $n > 3$) and $PCl_3Br_n$ (with $n = 4$ to 18) thought to be derived from $PCl_2Br$ + bromine and from $PCl_4Br + PCl_2Br$ + bromine, respectively, were postulated.[272] Equilibration of phosphorus(V) chloride/bromide mixtures at 135°C. in sealed tubes gave coloured crystalline and liquid phases of varied composition.[273–4] The same reaction mixtures in carbon disulphide solution gave similar products.[275] With chlorine and phosphorus(III) bromide or with bromine and phosphorus(III) chloride, yellow crystals of limiting compositions $PClBr_4$ or $PCl_4Br$ were obtained. Crystalline $PCl_4Br$ loses chlorine at 135°C. to give crystalline $PCl_{4\cdot5}Br_{0\cdot5}$ and mixed liquid phases.[276] Recrystallization of $PCl_4Br$ from carbon disulphide produced only crystals of higher chlorine content, while from products of composition close to $PClBr_4$ and $PCl_{0\cdot5}Br_{4\cdot5}$ crystals of lower chlorine content than the original were always obtained.[275] Evidence that three of the chlorine atoms in $PCl_4Br$ are attached to the phosphorus in a manner different from the fourth and from the bromine atom was claimed[277] from the manner of the reaction with phenol, PhOH; in this reaction the hydrogen bromide is released only after a subsequent hydrolysis step:

$$PCl_4Br + 3PhOH \rightarrow (PhO)_3PClBr + 3HCl$$
$$(PhO)_3PClBr + H_2O \rightarrow (PhO)_3PO + HBr + HCl$$

Maxima in the fusion diagram for the phosphorus(III) chloride–bromine system occur at 24·5° and 37°C. corresponding to the compositions $PCl_3Br_{18}$ and $PCl_3Br_4$, respectively. A maximum in the viscosity curve occurs at $PCl_3Br_8$ and in both the density and the electrical conductance curves at $PCl_3Br_{18}$. The conductances of the various complexes in nitrobenzene solution increase in the order $PCl_3Br_4 < PCl_3Br_8 < PCl_3Br_{18}$ and results from ionic migration experiments have suggested the general structure $[PCl_3Br]^+[Br(Br_2)_n]^-$. Orange red crystals of composition $PCl_3Br_4$, m.p. 36·7°C., separated on cooling from heated phosphorus(V) chloride/bromide or from phosphorus(III) bromide/phosphorus(V) chloride mixtures of mole ratio 3:2. With excess of phosphorus(III) bromide the second mixture gives yellow crystals of composition $PClBr_4$.[278–80]

A spectrophotometric study provided no evidence of compound formation between phosphorus(III) chloride and bromine in carbon tetrachloride or nitrobenzene solution,[281] but a cryoscopic study in the latter solvent[282] has shown the existence of equilibria involving both $PX_5$ and $PX_7$ species. From such solutions in carbon tetrachloride, substances approximating to $PCl_3Br_7,CCl_4$ and $PCl_3Br_7,2CCl_4$ were crystallized; these, however, decomposed with loss of bromine on attempting to remove the carbon tetrachloride.[282] Direct reaction between phosphorus(III) chloride and bromine led[281] to the formation of an unstable crystalline aggregate (composition $PCl_3Br_{5\cdot7}$, m.p. 36·8° to 38°C.) which, after keeping under vacuum at 30°C. and further heating at 50°C., yielded a stable yellow sublimate ofcomposition $PCl_{4\cdot67}Br_{0\cdot33}$, m.p. 145° to 148°C., refractive index 1·64, and shown by *X*-ray diffractometry to be a single compound with unit cell equal to $P_{12}Cl_{56}Br_4$.[281]

Dropwise addition of bromine to phosphorus(III) chloride in arsenic(III) chloride solution, and subsequent cooling to 0°C., gave[283] crystals of tetrachlorophosphonium pentachlorobromophosphate, $[PCl_4]^+[PCl_5Br]^-$, separable by filtration and evacuation at 0°C. The crystals were strongly hygroscopic, reacted vigorously with water liberating bromine, had a typically crystalline *X*-ray powder diagram, and decomposed at 142°C. (sealed tube) or on dissolution in non-polar solvents to phosphorus(V) chloride and phosphorus(V) bromide. Fluorination takes place in arsenic(III) chloride solution according to:

$$3[PCl_4][PCl_5Br] + 6AsF_3 \rightarrow 3[PCl_4][PF_6] + 5AsCl_3 + AsBr_3$$

The molar conductance for 0·048 and 0·2 M. solutions of the product in acetonitrile at 17°C. was 8·16 and 11·0 mho cm.$^2$ mole$^{-1}$ respectively. The compound is thought[283] to be the limiting case for the series of others with variable compositions described by earlier authors.

## PHOSPHORYL CHLORIDE, $POCl_3$

### Preparation

Phosphoryl chloride can be obtained by the action of phosgene upon molten ferric phosphate, metaphosphoric acid or heated calcium phosphate,[284–8] of chlorine upon heated mixtures of carbon with either phosphate rock,[14–5, 17, 289–97] alkaline earth metaphosphate,[298–9] aluminium phosphate[176, 300] or phosphoric acid,[18, 301–3] or alternatively upon phosphoric acid–water–phosphorus trichloride,[304] phosphorous acid–phosphorus in phosphoryl chloride[305] or phosphorus pentoxide–phosphorus trichloride[306–8] mixtures at reflux temperatures. The last process, formulated

$$P_2O_5 + 3PCl_3 + 3Cl_2 = 5POCl_3$$

is commonly used on the commercial scale and gives a 95 to 98% yield based on phosphorus pentoxide. Phosphoryl chloride is also manufactured by direct oxidation of phosphorus(III) chloride with gaseous oxygen.[27–9, 309–12] By admitting the oxygen as fine gas bubbles at 3 ft. depth, complete absorption occurs with up to 95 to 98% conversion at reflux temperatures. Traces of iron, copper and vulcanized rubber act as inhibitors while manganese oxides, phosphorus acids, etc., have been suggested as catalysts. Numerous other variations of the process occur in the patent literature.[313–6] The simultaneous reaction of chlorine and oxygen with yellow phosphorus gives good yields of phosphoryl chloride if the O:Cl ratio is 30% in excess of that required by the equation:

$$P + \tfrac{1}{2}O_2 + 1\tfrac{1}{2}Cl_2 \rightarrow POCl_3$$

Below this ratio phosphorus(V) chloride is formed, and above it, pyrophosphoryl chloride. The primary step in the reaction appears to be attack on the phosphorus by oxygen, since the reaction rates observed are much higher than would be expected if oxidation of phosphorus(III) chloride were a rate-determining step.[517] Liquid or gaseous sulphur dioxide–chlorine mixtures react with phosphorus in phosphorus oxychloride or with phosphorus(III) chloride[317–8] according to:

$$P + SO_2 + \tfrac{5}{2}Cl_2 = POCl_3 + SOCl_2$$
$$PCl_3 + SO_2 + Cl_2 = POCl_3 + SOCl_2$$

Sulphur trioxide with phosphorus(III) chloride gives phosphoryl chloride and sulphur dioxide.[117] Phosphoryl chloride is also formed by the interaction of phosphorus pentoxide and aluminium(III) chloride in an alkali halide melt.[518] Labelled phosphoryl chloride is conveniently obtained from phosphorus(V) chloride and $^{32}$P phosphoric acid,[319] or (for small amounts) by exchange with aqueous $^{32}$P phosphoric acid at 150°C.[320]

### Physical Properties

The boiling point of phosphoryl chloride is variously reported between 105·1° and 107·4°C.[27, 34, 41, 321–2] The value 107·4°C. is regarded[33] as the more reliable, and much of the variability in the literature is probably due to the presence of hydrochloric acid, phosphoric acid or phosphorus(III) chloride impurities which are difficult to eliminate. An apparatus for the preparation of pure phosphoryl chloride, permitting fractionation in an entirely inert atmosphere, was recently described.[324] The determined boiling point was 107·7 ± 0·1°C., and the specific conductance $2 \times 10^{-8}$ mho cm.$^{-1}$ The available vapour pressure data may be summarized:

| Range °C. | $\log_{10} p$(mm.) | Latent heat of vaporization (kcal. mole$^{-1}$) | B.p. °C. | Ref. |
|---|---|---|---|---|
| 75–107·4 | $7{\cdot}9816 - 1940{\cdot}7/T^{(a)}$ | 8·90 | 107·37 | 33 |
| 50–107·4 | $7{\cdot}734 - 1846/T^{(b)}$ | 8·41 | 107·4 | 33 |
| 41–113 | $7{\cdot}782 - 1864/T^{(c)}$ | 8·54 | 107·2 | 34 |
| 20–105 | $7{\cdot}7386 - 1836{\cdot}4/T$ | 8·39 | 105·3 | 325, 326 |
| 0–60 | $7{\cdot}7886 - 1850{\cdot}2/T$ | 8·45 | 104·0 | 35 |
| 7–25 | $8{\cdot}1395 - 1982{\cdot}9/T$ | 9·06 | — | 327 |
| | | 9·22$^{(d)}$ | — | 327 |

(a) From vapour pressure and boiling point measurements
(b) From vapour pressure data[325–6] plus boiling point measurements.
(c) From boiling point measurements.
(d) From calorimetric measurement at 25°C., $p = 30{\cdot}9$ mm.

Vapour–liquid equilibrium data[34] confirm that the $POCl_3$–$PCl_3$ system is reasonably ideal. The melting point of phosphoryl chloride is given as 1·18 ± 0·05°,[327] 1·20°[328] and 1·15 ± 0·05°C.[329] The latent heat of fusion is 3132 ± 3 g.-cal. mole$^{-1}$ [327] and the cryoscopic $K$ is given as 1°C. depression per 2·2 mole % impurity.[328] The heat capacity for the solid and liquid states between 13° and 304°K. has been measured[327] (data included in Table VIII) and for the vapour state between 298·1° and 1000°K. was expressed[36] by

$$C_p^\circ = 23{\cdot}294 + 0{\cdot}002185T - 353400/T^2 \text{ g.-cal. deg.}^{-1} \text{ mole}^{-1}$$

Remeasurement of the heat of hydrolysis for the reaction:

$$POCl_3(l) \rightarrow H_3PO_3(aq) + 3HCl(aq)$$

together with the available thermal data gave values of $\Delta H$ and $\Delta H^\circ_{f25}$ in kcal. mole$^{-1}$ as:

| Ref. | 37 | 38 | 330 | 519 |
|---|---|---|---|---|
| $\Delta H$ | −79·9 ± 3 | −80·4 | −79·6 ± 0·5 | −80·2 |
| $\Delta H^\circ_{f25}(l)$ | −144·4 | −143·8 | — | −143·4 |
| $\Delta H^\circ_{f25}(g)$ | — | −134·3 | — | — |

The O═PCl$_3$ bond dissociation energy calculated therefrom is 121·8 kcal. mole$^{-1}$,[38] cf. 119·3 (from hydrolysis data[38]) and 129·8 kcal. mole$^{-1}$ (from a direct measurement of the heat of oxidation of $PF_3$ gas[331]) for the dissociation energies of the P═O bonds in $POBr_3$ and $POF_3$, respectively. These values were taken[38] as indicating a considerable degree of double bond character in the O–PX$_3$ linkage. The above values for standard heat of formation supersede those given elsewhere.[40–2] The free energy ($\Delta G_f^\circ$) and equilibrium constant of formation (log $K_f$) for phosphoryl chloride vapour at 25°C. are given[40–2] as $-130·3$ kcal. mole$^{-1}$ and 95·508, respectively; enthalpy and free energy functions for the vapour in the temperature range 298·1° to 1000°K. have been evaluated[43] and are further tabulated[41] together with the corresponding entropy values. The entropy of the ideal gas at 1 atm. and 298·15°K. derived from calorimetric data is 77·75 g.-cal. mole$^{-1}$ deg.$^{-1}$ [327]; the calculated value from a selected assignment of the fundamental frequencies being 77·77 g.-cal. mole$^{-1}$ deg.$^{-1}$ The same authors[327] have calculated the thermodynamic properties for solid or liquid phosphoryl chloride in the temperature range 15° to 300°, and for the vapour state in the range 15° to 500°K.; a selection of these more recent values is made in Table VIII.

Fundamental frequency assignments were made[332–5] from the available infra-red and Raman data, and force constant values derived[334, 336–7] by E. B. Wilson's method are given in Table X, page 491. Other authors[332–3, 335] have attempted a more complete solution using the available data for $PX_3$. The same authors have re-calculated the thermodynamic properties for gaseous phosphoryl chloride between 50° and 1600°K. The calculated values[332–3, 335] are reasonably close to those given in Table VIII.

Ebullioscopy with 4 chloro-1:3-dinitrobenzene as solute gave $K$ (unit molal elevation) = 5·58°C.[338] (cf. 5·02 calculated from the latent heat of vaporization which is 8·39 kcal. mole$^{-1}$,[325–6] and 5·47[339] from the specific cohesion and b.p. 107·3°C.). The density, $d_4^t$, from 0° to 105°C. is given by:

$$d_4^t = 1{\cdot}7116 - 1{\cdot}839 . 10^{-3}t + 1{\cdot}66 . 10^{-7}t^2 - 5{\cdot}5 . 10^{-9}t^3$$ [340–1]

and subsequent density determinations noted in the literature serve only to confirm these early measurements. Density and viscosity data are briefly summarized in Table IX.

*Table IX.—Density and Viscosity Data for Phosphoryl Chloride*

(a) Conform to the Bachinskii[70] formula with $C = 0{\cdot}00712$, $\omega = 0{\cdot}5352$.
(b) Calculated values from the Andrade[71] formula with $A = 0{\cdot}0005014$, $C = 506$.
(c) Interpolated from a log $\eta$ versus $1/T$ plot (range 4·5° to 105°C.).

Cryoscopy in benzene gave mol. wt. = 166, indicating an association factor of 1·08.[75] However, the constancy of the parachor data over the temperature range 15° to 65°C. thus:

| °C. | Surface tension[344] (dyne cm.$^{-1}$) | Parachor | |
|---|---|---|---|
| 15 | 32·77 | 217·1 | b.p. 108·7°C. at 769 mm. |
| 49 | 28·36 | 217·7 | $d_4^{25}$ = 1·671 |
| 65 | 26·75 | 218·1 | |

and the conformity of the viscosity/temperature relationship with the Andrade[71] exponential formula, indicate[344] that phosphoryl chloride is an essentially normal liquid. Further, the parachor values for the phosphoryl chloride–benzene and for the phosphorus(III) chloride–benzene systems were found[79] to be additive on a mole fraction basis. Molar polarization and dipole moment values for both phosphoryl and thiophosphoryl chlorides, and bond moments for the semipolar $P \rightarrow O$ and $P \rightarrow S$ bonds (see Table X) were obtained[345–6] from dielectric constant measurements of their solutions in benzene together with the available dipole moment data[50] for phosphorus(III) chloride.

The molar diamagnetic susceptibility ($-\chi_m \times 10^6$) was found to be 68·9,[63] 61·8[347] c.g.s. units. Ultrasonic measurements[84] lead to the values of molar sound velocity and adiabatic compressibility shown in Table III.

The ultra-violet absorption spectra (2400 to 1850 A.) for gaseous phosphoryl chloride and phosphorus trichloride have been published.[348] The former shows low

absorption at 2100 A. and a broad maximum at 1960 to 1850 A., while the latter shows strong absorption below 2400 A. with a maximum at 2170 ± 5 A., followed by a minimum at 1960 A. and another increase in absorption which had not reached a maximum at the limits of the instrument at 1850 A.

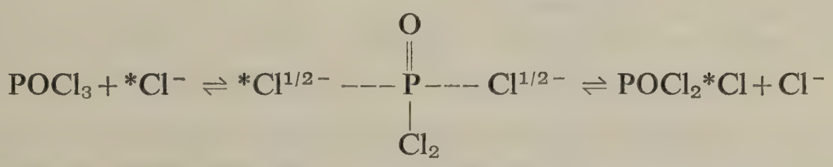
## Chemical Properties

### CHLORINE EXCHANGE

$^{35}Cl$ exchange in the vapour phase using labelled hydrogen chloride is much more rapid with phosphorus(III) chloride than with phosphoryl chloride.[88] Rapid exchange of chloride ion (complete within the time of separation at 20°C.) occurs in dilute solutions of $^{36}Cl$-labelled tetraethylammonium chloride in phosphoryl chloride[349–50]; conductimetry for such solutions showed the solute to be completely dissociated.[349] A kinetic study of the above reaction carried out in chloroform, nitrobenzene or methyl cyanide solvent indicated a bimolecular mechanism, the exchange being of first order with respect to chloride ion and to phosphoryl chloride. It was concluded[349] that the reaction in phosphoryl chloride medium proceeds either through direct formation of $[POCl_4]^-$ according to:

$$POCl_3 + {}^*Cl^- \rightleftharpoons [POCl_3][Cl^*]^- \rightleftharpoons POCl_2{}^*Cl + Cl^-$$

or through a substitution intermediate state[351] written as:



$$POCl_3 + {}^*Cl^- \rightleftharpoons {}^*Cl^{1/2-} --- \overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle Cl_2}{|}}{P}} --- Cl^{1/2-} \rightleftharpoons POCl_2{}^*Cl + Cl^-$$

rather than through self-ionization of the solvent. Exchange between $^{36}Cl$-labelled liquid nitrosyl chloride and phosphoryl chloride solute is slow[352] and is assumed to occur *via* the formation of chloride ions; the concentration of such ions in the solvent was calculated to be $10^{-8}$ g. ion/litre.

### REORGANIZATION IN THE PHOSPHORYL HALIDES

Phosphoryl chloride/bromide or thiophosphoryl chloride/bromide mixtures undergo ligand exchange to form mixed chlorobromides when kept in sealed tubes at elevated temperatures. Quantitative nuclear magnetic resonance methods applied to such mixtures *in situ* have shown[91] that equilibrium is attained at 130°C. within seven days; the compositions then approximate to those predicted for completely randomized ligand exchanges. Such mixtures, originally of 2:1 molar ratios of chloride to bromide, reached equilibrium in a few hours at 200°C. and contained 42 to 46% of mixed phosphoryl or thiophosphoryl halides respectively, isolated by fractionation under reduced pressure. For the mixed systems $POCl_3$–$PBr_3$ and $POBr_3$–$PCl_3$, n.m.r. analysis after 4 weeks at 110° or 1 week at 200°C. shows the presence of all eight possible compounds, viz.: $POCl_3$, $POCl_2Br$, $POClBr_2$, $POBr_3$, $PCl_3$, $PCl_2Br$, $PClBr_2$ and $PBr_3$.[92] Completely randomized interaction is expressed by two equations of each type:

$$\begin{aligned} 2PX_2Y &= PX_3+PXY_2 \\ 2POX_2Y &= POX_3+POXY_2 \end{aligned}$$

for which $K_1=K_2=K_3=K_4=0{\cdot}33$, and one equation of mixed type, for which the general expression:

$$PX_iY_{3-i}+POX_jY_{3-j} \rightleftharpoons PX_nY_{3-n}+POX_{i+j-n}Y_{3-(i+j-n)}$$

gives $K_5=1$. The experimental values for $K_{1-4}$ range from 0·3 to 0·6, with a single value of $K_5=5$. However, numerical significance cannot be attached to the last figure, since the equation used is but one of fourteen possible expressions having widely differing values for departures of $K_{1-4}$ from 0·33.[92]

### HYDROLYSIS OF PHOSPHORYL CHLORIDE

Titrations with standard baryta[353] afforded early evidence that the hydrolysis in ice-water proceeds through dichlorophosphoric acid. Thus neutralization to the thymolphthalein end point required two equivalents initially and, on standing, further increments up to a total of six equivalents, in accordance with:

$$POCl_3 \xrightarrow[+H_2O]{} H[PO_2Cl_2]+HCl \xrightarrow[+2H_2O]{} H_3PO_4+3HCl$$

The latter stage is accompanied by precipitation of all the phosphorus as barium orthophosphate, $Ba_3(PO_4)_2$. Addition of an equimolar quantity of water to phosphoryl chloride at −75°C., followed by melting and careful reaction at −25° to −10°C., gave pure dichlorophosphoric acid,[98] confirmed by analysis of its insoluble nitron and brucine salts. With 2 moles of water to 1 of phosphoryl chloride at temperatures up to 10°C., dichlorophosphoric acid monohydrate, $[PO_2Cl_2]^-[H_3O]^+$, was formed, again with loss of only 1 equivalent of hydrogen chloride. Pure dichlorophosphoric acid was said[354] to be unobtainable from partial hydrolysis of phosphoryl chloride, and a recent paper[355] by the same author gives the percentage of total phosphorus in the form of dichlorophosphoric acid (following addition of stoicheiometric amounts of alkali to ice-water hydrolysates) as:

| Mole ratio NaOH:$POCl_3$ | 1 | 2 | 3 | 4 |
|---|---|---|---|---|
| % Total P as $[PO_2Cl_2]^-$* | 93·1 | 93·3 | 44·4 | Nil |

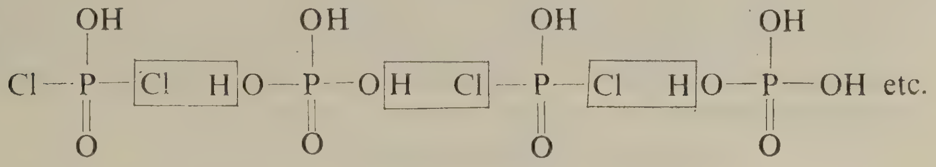
* By precipitation as the nitron salt $C_{20}H_{16}N_4HOPOCl_2$.

This is taken as indicative of 93% conversion to dichlorophosphoric acid in the untreated hydrolysate. Addition of an equimolar quantity of water to pure dichlorophosphoric acid followed by heating at 42°C. for 2 hr. gave a product with atom ratio Cl:P = 1·36; dichlorophosphoric acid (obtained as nitron salt) accounted for 68% of the total phosphorus, and the product contained no condensed phosphates as evidenced by paper chromatography. This is in accord with the composition: $0{\cdot}32H_3PO_4+0{\cdot}68H[PO_2Cl_2]+0{\cdot}36H_2O$. Both sets of results point to the complete absence of monochlorophosphoric acid, the further hydrolysis of which must proceed at a rate faster than its rate of formation. The hydrolysis of phosphoryl chloride is therefore expressed[355] by the two equations:

$$\begin{aligned} POCl_3+H_2O &= H[PO_2Cl_2]+HCl \\ H[PO_2Cl_2]+2H_2O &= H_3PO_4+2HCl \end{aligned}$$

In a similar study, at NaOH:$POCl_3$ mole ratios 1:1 to 0·01:1, only orthophosphate and a trace of pyrophosphate could be detected at the highest ratio. At lower ratios viscous liquid phases were formed, which contained in addition to ortho- and pyrophosphate, higher polyphosphates and trimetaphosphate.[520]

Paper chromatographic evidence following slow addition of an equimolar quantity of water to phosphoryl chloride over 14 days and subsequent evacuation of the hydrogen chloride and phosphoryl chloride at 60°C., showed[356–8] the presence of ortho-, pyro-, cyclic trimeta- and small amounts of polyphosphoric acids. With mole ratio $[H_2O]:[POCl_3]$ between 1:1 and 2:1 and subsequent heating under reflux at 80° to 100°C. for 30 min. or holding at room temperature for 6 months, cyclic trimeta- and polyphosphoric acids containing up to 9 phosphorus atoms were detected.[359] The mechanism was considered to be one of successive condensation between a chlorine atom of the dichlorophosphoric acid first formed (or of a higher condensed product) and a hydroxyl radicle of phosphoric acid (or of higher condensed products) with formation of P–O–P linkage and elimination of hydrogen chloride, according to the general scheme:



$$Cl-\overset{OH}{\underset{O}{P}}-\boxed{Cl\quad H}O-\overset{OH}{\underset{O}{P}}-O\boxed{H\quad Cl}-\overset{OH}{\underset{O}{P}}-\boxed{Cl\quad H}O-\overset{OH}{\underset{O}{P}}-OH \text{ etc.}$$

Using purely nuclear magnetic resonance methods on the products *in situ*, thereby avoiding such condensation and degradation changes as were shown[360] to be inherent in the analytical procedures earlier employed in this field, sealed tube equilibration of phosphoric acid–phosphoryl chloride mixtures (for 60 days at 25°, or 5 days at 110°C.) was shown to give[361] the following products at the listed phosphoryl chloride concentrations:

$>50$ mole %, dichlorophosphoric acid as the main product,
50 mole %, a small amount only of dichlorophosphoric acid,
$<60$ mole %, hydrogen chloride + condensed species containing $O_{1/2}PO(OH)_2$, $O_{1/2}P(OH)Cl$ and $O_{1/2}POCl_2$ end-groups, and $O_{1/2}PO(OH)O_{1/2}$ middle groups,
15–60 mole %, some hydrogen chloride as a separate liquid phase.

The results conform with those expected for a randomly reorganizing system, theory for which predicts essentially pure dichlorophosphoric acid at a mole ratio $POCl_3:H_3PO_4=2$. At the above ratio, as in the products from reaction of equimolar amounts of phosphoryl chloride in ether with water at room temperature, or of equimolar amounts of phosphoryl chloride with water at $-20°$ to $-10°$C., or of equilibration at 250°C. of such mixtures as required by the equations:

$$P_4O_{10}+6H_2O+8POCl_3 \rightarrow 12HO.POCl_2$$

and

$$P_4O_{10}+6PCl_5+5H_3PO_4 \rightarrow 15HO.POCl_2$$

$93 \pm 3\%$ of the total phosphorus was shown[361] to be present as dichlorophosphoric acid, and $7 \pm 3\%$ as condensed products. Hydrolysis rate measurements for both phosphoryl chloride and phosphorus(III) chloride in toluene at 25° and 35°C. were in conformity with pseudo mono-molecular reactions.[362] The data:

| | $K_v$ (sec.$^{-1}$) 20°C. | $K_v$ (sec.$^{-1}$) 35°C. | Activation energy (kcal. mole$^{-1}$) |
|---|---|---|---|
| $POCl_3$ | 0·018 | 0·037 | 8·396 |
| $PCl_3$ | 0·093 | 0·130 | 3·992 |

were taken as indicative of a semipolar P → O bond in phosphoryl chloride.

In the vapour phase at 25°C., hydrolysis of phosphoryl chloride was shown[113] to proceed by a wall reaction for which the rate of adsorption of water vapour on the phosphoric acid deposited on the walls of the vessel is the rate controlling step. With phosphorus(III) chloride vapour under similar conditions no reaction occurs. More recently[363] conductimetric, potentiometric and acid-base titration methods used in conjunction with a 'stopped-flow' procedure, by which separate dioxan solutions of phosphoryl chloride and water introduced simultaneously into a reaction vessel could be conveniently titrated at measured time intervals, have confirmed for the complete hydrolysis in the liquid phase:

(i) an initial fast reaction ($t_{1/2} = 10^{-2}$ sec.) corresponding to the production of two protons for each chloride ion and the formation of dichlorophosphoric acid:

$$\mathrm{H_2O + POCl_3 \rightarrow HO.POCl_2 + HCl}$$

(ii) a succeeding slow reaction ($t_{1/2}$ approx. 250 sec.) with development of one proton for each chloride ion, unaffected by acidity change between pH 4 to 7 and hence considered to involve the dissociated acid. Moreover, since the reaction rate remains unchanged in the presence of sodium phenoxide or nitrite (both reactive towards phosphorylating agents) but is increased by pyridine, the hydrolysis is thought to proceed through a bimolecular mechanism thus:

$$\begin{tikzcd}
\mathrm{HO.POCl_2} \arrow[r, phantom, "\rightleftharpoons"] & \mathrm{Cl_2PO_2^- + H^+} \arrow[rd, "+\mathrm{H_2O}"'] & \\
 & & \mathrm{HCl + HO.PClO.O^-}
\end{tikzcd}$$

The rate of removal of the second Cl-atom is considerably faster than that of the first (in direct contrast to the corresponding fluoro acids), and of the following possible mechanisms:

$$\begin{tikzcd}
\mathrm{H^+ + HO.PClO.O^-} \arrow[r, phantom, "\rightleftharpoons"] \arrow[d, "+\mathrm{H_2O}"] & \mathrm{PClO(O^-)_2 + 2H^+} \arrow[ld, "+\mathrm{H_2O}"'] \arrow[d] \\
\mathrm{H_3PO_4 + HCl} & \mathrm{PO_3^- + Cl^-} \arrow[l, "+\mathrm{H_2O}"]
\end{tikzcd}$$

the route through unstable $PO_3^-$ is considered to be the more probable. At lower water contents, rapid reactions are thought[363] to occur as follows:

$$\begin{tikzcd}
\mathrm{POCl_3 + H_2O} \arrow[r] & \mathrm{HO.POCl_2 + HCl} \arrow[d, shift left] & & \\
 & \mathrm{H^+ + Cl_2PO_2^-} \arrow[u, shift left] \arrow[r, "+\mathrm{POCl_3}"'] & \mathrm{Cl_2PO.OPOCl_2} \arrow[r, "+\mathrm{H_2O}"'] & \mathrm{2HO.POCl_2}
\end{tikzcd}$$

This scheme leads initially to mixtures with dichlorophosphoric acid and pyrophosphoryl chloride as main components. Subsequent slower reactions result from the dissociation of the dichlorophosphoric acid, whence dichlorophosphate anions react with pyrophosphoryl chloride or the undissociated acid thus:

$$\mathrm{Cl_2PO_2^- + Cl_2PO.OPOCl_2 \rightarrow Cl_2PO.OPOCl.OPOCl_2 + Cl^-}$$
$$\mathrm{Cl_2PO_2^- + Cl_2PO.OH \rightarrow Cl_2PO.OPOCl.OH + Cl^-}$$

Further such P–Cl fission reactions, with corresponding release of hydrogen chloride, lead to longer straight chain or to cyclic species in a manner similar to that already described.[356, 359] Five-co-ordinate intermediates, in which the entering oxygen atom is transiently equivalent to the phosphoryl oxygen atom, have been postulated in the hydrolysis of some phosphate esters. However, the hydrolysis of phosphoryl chloride in water enriched with $^{18}O$ gave phosphoric acid containing three quarters of the $^{18}O$ concentration of the original water. Such intermediates can therefore have no part at any stage in the hydrolysis of phosphoryl chloride.[521]

Hydrolysis of phosphoryl chloride in sodium bicarbonate buffer solutions containing sodium phosphite or tetrasodium hypophosphate, has led[110, 364] to the isolation of salts of $P^3$–O–$P^5$ and $P^5$–O–$P^4$–$P^4$ acids, viz.: $Na(HO)PO.OPO(ONa)_2$, isohypophosphoric acid, and $(NaO)_2PO.OPO(ONa).PO(ONa)_2$, respectively (see Section XIX).

MISCELLANEOUS REACTIONS

Passing phosphoryl chloride vapour–hydrogen mixtures through an electrodeless discharge at room temperature gave[1] small amounts of elemental phosphorus and unidentified liquid products. Liquid hydrogen sulphide is slowly oxidized by phosphoryl chloride.[365] Fluorination occurs in liquid sulphur dioxide solution, slowly with nitrosyl fluoride,[366] or more conveniently with potassium fluoride.[122] Fluorination of phosphoryl chloride is discussed under phosphoryl fluoride; typical halogen exchange occurs with ammonium fluoride,[130] benzyl fluoride,[367] etc., and, where conditions permit repeated recycling of intermediate compounds, the product is wholly phosphoryl trifluoride. Phosphoryl chloride dissolves in absolute nitric acid to give a strongly yellow solution, the evaporation of which at 40°C. under reduced pressure was said[368] to afford a convenient preparation for metaphosphoric acid. The following mechanism was proposed:

$$\begin{aligned} POCl_3 + 3HNO_3 &= PO(NO_3)_3 + 3HCl \\ 3HCl + HNO_3 &= 2H_2O + Cl_2 + NOCl \\ PO(NO_3)_3 + 2H_2O &= 3HNO_3 + HPO_3 \\ \hline POCl_3 + HNO_3 &= HPO_3 + Cl_2 + NOCl \end{aligned}$$

Dinitrogen tetroxide in oxygen is strongly absorbed by phosphoryl chloride at −20°C. giving red solutions, which after distillation of gaseous products deposit colourless crystals of composition $P_2O_6NCl_2$.[138] Small amounts of pyrophosphoryl chloride are also formed. The crystals, separable under moisture-free conditions, decompose *in vacuo* at 50°C. leaving a darkish residue of resinous appearance and containing no nitrogen. Reaction with anhydrous ammonia at 70° to 100°C. leads to chlorine-free products consisting of mixtures of phosphoryl triamide, phosphoryl imidoamide and polyphosphorylamide (cf. Mellor, VIII, 1024). Numerous references[369–77] in the patent literature deal with the preparation, purification and subsequent heat treatment of these compounds, and with their application as flameproofing agents for cellulosic materials. Phosphoryl chloride, thiophosphoryl chloride and phosphorus(III) chloride have each been shown[378] to undergo largely similar type condensation reactions with methyl-, ethyl- and *tert.*-butylamines. With phosphoryl chloride, reaction to $PO(NHR)_3$ could be effected at 0°C. in petroleum ether; the methyl compound underwent thermal condensation to the imide $[P_2O_2N_3(CH_3)_3]_n$, but no such compound could be characterized from the *tert.*-butyl derivative.

Phosphoryl chloride is a more active inhibitor of the combustion of carbon than is carbon tetrachloride; comparative threshold concentrations are 1/2000 and 1/100 v/v., respectively.[379] Controlled combustion experiments at 750° to 1100°C. with differing carbons showed an increase in the $CO/CO_2$ ratio and in the oxygen content of the exit gases, when the incoming air-streams contained up to 2 v/v. % of various halide inhibitors. The effect was greatest[380] with phosphoryl chloride and phosphorus(III) chloride, i.e. those substances having a strong affinity for water at high temperatures. Comparative $CO/CO_2$ ratios at 850°C., each with the inhibitor in excess of its threshold concentration, were:

| inhibitor (<1%) | $POCl_3$ | $PCl_3$ | $Cl_2$, $CCl_4$,<br>$CHCl_3$, $SnCl_2$ | $CH_2Cl_2$,<br>HCl |
|---|---|---|---|---|
| mole ratio $CO/CO_2$ | 8·4 | 6·4 | 2·9–2·1 | 1·1 |

High activity has been linked[381] with high polarity, but from the above and similar experiments[380, 382–6] the ability to remove those species which are potential propagators of reaction chains, together with the thermal stability of the end product $(HPO_3)_x$, appear to be important factors. Combustion of coals was inhibited by the presence of approximately 1 v/v. % $POCl_3$ in the air-stream,[387] the net effect being a decrease in the ease of reaction with oxygen, and a short-lived acceleration followed by a depression of the reaction with carbon dioxide to give carbon monoxide. Chemical reaction between inhibitor and the coal surface was postulated. The effect of <2 v/v. % phosphoryl chloride vapour on the gasification of various coals in carbon dioxide was twofold[388]: (i) a reversible effect, initially catalyzing the reaction and almost independent of the nature of the coal, and (ii) an irreversible inhibiting effect, appearing only in strongly graphitized coals. The presence of carbon tetrachloride vapour decreases and that of phosphoryl chloride vapour rapidly increases the minimum partial pressure of oxygen at which chemiluminescence of white phosphorus begins.[389] The upper explosive limit of hydrogen–air mixtures, viz.: 74:26, is reduced to 64:36 in the presence of 5 mm. partial pressure phosphoryl chloride vapour; comparative figures are available for a number of compounds,[390] but the lower limit (11:89) is barely affected by any of them.

### COMPLEX FORMATION

There is a wide range of complex compounds in which phosphoryl chloride acts as a donor molecule towards other inorganic halides.[522] A calorimetric study showed that the heats of solution of acceptor chlorides in phosphoryl chloride were of the order 10–20 kcal./mole, and the heats of solution of the solvates 1–2 kcal./mole. Heats of solvation were found to be 8–23 kcal./mole for one co-ordination position (neglecting heats of vaporization and sublimation) and decreased in the order $SbCl_5 > FeCl_3 > AlCl_3 > \frac{1}{2}TiCl_4 > \frac{1}{2}SnCl_4 > GaCl_3 > BCl_3$.[523] Conductivity measurements in nitrobenzene solution point to the existence of zirconium and hafnium complexes of general formulæ $MCl_4,2POCl_3$ and $MCl_4,POCl_3$.[391] The compositions coincide with maxima at 184·7° and 205°C. (zirconium), 198·3° and 221·8°C. (hafnium), in the respective fusion diagrams.[392–3] Such diagrams failed to provide evidence for the compounds $2ZrCl_4,POCl_3$ and $3ZrCl_4,2POCl_3$ described by other authors.[246, 394–5] The 1:2 compounds begin to decompose above 60°C., the 1:1 compounds sublime at 130°C. and decompose above 145°C.[396] The 3:2 compounds: b.p. 360° (Zr), 355°C. (Hf), vapour pressure ratio 1·14 at the boiling point, heat of vaporization $20{\cdot}5 \pm 0{\cdot}05$ kcal. mole$^{-1}$,[394] were thought,[395] on evidence of non-uniform melting, to be azeotropic mixtures. Thus for the crystallized zirconium complex, melting at 98° to 100° (initial), 170° to 175° (bulk) and 225° to 230°C. (final crystals) was observed, while vapour density measurement at the boiling point indicated an average mol. wt. of about 450. For the 1:1 and 1:2 compounds in nitrobenzene solution, freezing point measurements[397] showed the former compound to be monomeric and the latter to dissociate to the monomer and phosphoryl chloride. Largely similar *X*-ray powder diagrams were obtained for the corresponding 1:1 and 1:2 zirconium and hafnium compounds; each, however, indicated a lower order of symmetry than the respective tetrahalides.[397, 524] Fractionation of the zirconium and hafnium complexes can be effected in multiplate columns,[394, 398] and recovery of the metals from the separated complexes is the subject of numerous patents.[247, 399]

The fusion diagram for the aluminium chloride–phosphoryl chloride system appeared to show a well-defined maximum at 186·5°C. corresponding to the 1:1 compound, and a 1:2 compound ($AlCl_3,2POCl_3$), m.p. 164°C., close to the eutectic between them. Further, by rapid cooling to −70°C. of the glassy non-crystalline material in the composition range 76–90 mole % $AlCl_3$, followed by slow warming to room temperature, leaflet crystals of a 1:6 complex ($AlCl_3,6POCl_3$), m.p. 41° to 42°C.[400–1] were obtained. Later authors have confirmed the existence of the 1:1 compound, m.p. 187–188°[422, 432, 525–7] with a heat of fusion of 14·3 kcal./mole.[533] However, although the 1:2 compound has also been subsequently reported,[526] it seems more likely to have the formula $2AlCl_3,3POCl_3$, and melts, possibly incongruently, at 188°C.[422, 527] No sign of the 1:6 compound could be detected in a thermal analysis of the $AlCl_3$–$POCl_3$ system.[527] $AlBr_3,POCl_3$ (m.p. 142° (decomp.)) is known,[526] as are the complexes $MgBr_2,2POCl_3$ and $MgBr_2,3POCl_3$.[542] Thermal analysis of the antimony(V) chloride–phosphoryl chloride system[402] gave 1:1 and 1:2 compounds, m.p. 150°C. (cf. 116°C.[403]) and 88·5°C. (incongruently with formation of 1:1 compound), respectively. Electrolysis of aluminium chloride or antimony(V) chloride solutions in phosphoryl chloride has shown[404] the presence of $AlCl_4^+$ and $SbCl_6^-$ ions with transport numbers $0{\cdot}04_4$ and $0{\cdot}05_0$, respectively; the relatively high migration velocities can be explained on the basis of chloride-ion transitions between $POCl_3$ molecules and $POCl_2^+$ ions. Raman evidence,[405–6] both from a saturated solution of antimony(V) chloride in phosphoryl chloride and from the crystalline 1:1 complex, confirmed the presence of $SbCl_6^-$ ions, and showed none of the characteristic frequencies for $SbCl_5$ molecules. Single crystal *X*-ray studies[407–8] (crystals prepared by a zone-melting technique in sealed capillaries) show the crystalline 1:1 complex to consist of orthorhombic unit cells of 4 mols., space group *Pmnb*, with $a = 8{\cdot}06$, $b = 16{\cdot}42$ and $c = 8{\cdot}93$ Å. There is octahedral co-ordination around the Sb atom with an O atom from $POCl_3$ at the sixth corner; the approximate tetrahedral structure of the $POCl_3$ molecule is preserved; the angle Sb–O–P is 143·7°. Refined data for this structure, as well as for the isostructural compounds $SbCl_5,OPMe_3$ and $NbCl_5,OPCl_3$, have recently been published.[409] Complex formation with phosphoryl chloride has been proposed[410] for the removal of aluminium chloride from Friedel–Crafts mixtures where separation as aluminium hydroxide is precluded by the presence of easily hydrolyzed chloride in the product, e.g., in the preparation of phenyldichlorophosphine, $PhPCl_2$. The solubility of the 1:2 complex ($AlCl_3,2POCl_3$) in nitrobenzene is given[411] as 5·91, 7·25 and 8·63 g./100 g. at 25°, 30° and 40°C., respectively (but see reference 527). Dissociation to the 1:1 complex and phosphoryl chloride occurs; such solutions show absorption maxima at 6900–7200 Å. which are not observed with the separate components.[412]

Treatment of ferric chloride with excess of phosphoryl chloride at 95°C. and subsequent cooling give water-soluble red crystals of the 2:3 complex ($2FeCl_3,3POCl_3$). These lose phosphoryl chloride at 50°C. *in vacuo* giving yellow-brown crystals of the 1:1 complex. Other data[413] include:

| Complex | m.p. °C. | $\log_{10} p$(mm.) | Heat of dissociation (kcal. mole$^{-1}$) | Apparent mol. wt. in nitrobenzene |
|---|---|---|---|---|
| $2FeCl_3,3POCl_3$ | $98 \pm 0{\cdot}2$ | $11{\cdot}38 – 3225/T$ | 14·56 | 310 |
| $FeCl_3,POCl_3$ | $119 \pm 0{\cdot}2$ | $13{\cdot}53 – 4167/T$ | 18·16 | 344 |

The colour of ferric chloride solutions in phosphoryl chloride increases with concentration thus:

| $1 \times 10^{-5}$ M. | $1 \times 10^{-3}$ M. | 0·1 M. | 0·3 M. |
|---|---|---|---|
| colourless | yellow | dark red | dark brown |

The ultra-violet absorption spectra for $10^{-4}$ M. solutions before and after neutralization with tetraethylammonium chloride were similar to those of ferric chloride in concentrated hydrochloric acid, so indicating the presence of $FeCl_4^-$ ions and providing apparent evidence of self ionization of the solvent[414]:

$$FeCl_3 + POCl_3 \rightleftharpoons FeCl_4^- + POCl_2^+$$

However, electrolysis of a radioactive $^{59}FeCl_3$ complex with phosphoryl chloride showed that iron atoms were present in both cationic and anionic species possibly of the type $(POCl_3)_2FeCl_2^+.FeCl_4^-$, no $POCl_2^+$ ions being detected.[528] This is consonant with other evidence for compounds of the type $(Cl_3PO)_nMCl_x^+.MCl_{x+2}^-$.[422, 444, 529–31] Addition of carbon tetrachloride to the red (while hot) and to the yellow solutions above gives crystals of the 2:3 and 1:1 complexes, respectively. The colour change red → yellow occurs on addition of a chloride-ion donor, e.g. tetraethylammonium chloride, potassium chloride, etc.; for dilute, yellow solutions, the change is reversed on addition of a chloride-ion acceptor, e.g. antimony(V) chloride, or by concentrating.[415] Analogy with the antimony(V), tin(IV) and titanium(IV) chloride complexes shown from *X*-ray,[407–8, 416–7] infra-red[418–9] and Raman[405, 420–1] evidence to be oxygen-co-ordinated, leads to the conclusion[415] that the ferric and aluminium complexes are similarly co-ordinated in the solid state. The amphoteric and high conductance properties of aluminium chloride in phosphoryl chloride medium are explained[422] on the basis of ionization to $[AlCl_2(POCl_3)_2]^+[AlCl_4]^-$. In the presence of polar chlorides, $AlCl_4^-$ ions are formed; but with strong chloride-ion acceptors, solvated $AlCl^{++}$ ions may be present, or insoluble complexes such as $[Al(OPCl_3)_6][SbCl_6]_3$ are precipitated.[423]

Molecular 1:1 and 1:2 compounds (m.p. 104°, 105·7, and 105°C., respectively) have been identified in the titanium(IV) chloride–phosphoryl chloride system[424–5, 524–5, 532] and a 1:2 compound (m.p. 59°, b.p. 117°C.) in the tin(IV) chloride–phosphoryl chloride system[425, 524]; a proposed extraction route for titanium metal consists[426] of causing the 1:1 complex, $TiCl_4,POCl_3$ (formed by refluxing the chlorides together in stoicheiometric proportions) to react with sodium–potassium alloy or with mercury, and distilling the resulting titanium amalgam. The compounds are completely dissociated above 80°C. (above 60°C. for $SnCl_4,2POCl_3$) in the vapour phase, the O–Ti bond energy of the titanium complex being only 6·4 kcal./mole.[532] For $TiCl_4,2POCl_3$, $\log_{10} p_{(mm.)} = 8{\cdot}914 - 2523/T$, specific conductivity at 105°C. (molten state) $= 0{\cdot}138 \times 10^{-2}$ mho cm.$^{-1}$, $d_4^t = 2{\cdot}1027 - 3{\cdot}013 \times 10^{-3}t$ and the molar volume at 100°C. is 275·6 ml. (cf. 319·6 ml. for the components). Molar contraction was also observed for the $SnCl_4,2POCl_3$ complex at 100°C., viz., 315·6 ml. against 327·6 ml. for the components,[425] but parachor considerations[427] showed the latter compound to be largely dissociated in the liquid state. The b.p. (100 mm.) was 70°C., m.p. 54·5°C. and $d_4^t$ $2{\cdot}090 - 0{\cdot}00293t$. It was suggested[425] (in agreement with the conclusions[406] from a Raman study of the compound $SbCl_5,POCl_3$) that these compounds are co-ordination complexes with chlorine acting as the donor atom. However, other considerations,[250, 420, 428] but primarily the shifts in the infra-red P → O stretching frequency resulting from adduct formation[418, 532] and *X*-ray crystal analysis,[417, 429] assign them as oxygen-coordinated in the solid state. The $TaCl_5,POCl_3$ crystal, orthorhombic, space group *Pnma*, $a = 16{\cdot}4$, $b = 8{\cdot}1$, $c = 9{\cdot}0$ A. is isostructural with $SbCl_5,POCl_3$, and the $TiCl_4,2POCl_3$ crystal, orthorhombic, space group *Pnnm*, $a = 13{\cdot}4$, $b = 13{\cdot}5$, $c = 7{\cdot}7$ A. is isostructural with $SnCl_4,2POCl_3$.[417] This stannic 1:2 complex, $a = 14{\cdot}53 \pm 0{\cdot}02$, $b = 14{\cdot}25 \pm 0{\cdot}05$, $c = 8{\cdot}01 \pm 0{\cdot}01$ A., 4 mols./unit cell, has an octahedrally co-ordinated Sn atom with two $POCl_3$ groups (crystallographically different, though preserving their approximately tetrahedral structure) lying in *cis* position, the O-atoms in each group functioning as donor atoms.[429] The 1:1 titanium chloride–phosphoryl chloride crystalline complex is built up of dimeric molecules $(TiCl_4,POCl_3)_2$ with two chlorine bridges between octahedrally co-ordinated titanium atoms, the oxygen atoms in each $POCl_3$ group functioning as donor atoms.[416]

Mixed halide systems containing titanium(IV) chloride and phosphoryl chloride have been described. These include $TiCl_4,NbCl_5,3POCl_3$ (m.p. 96°C.), $TiCl_4,TaCl_5,POCl_3$ (m.p. 113·5°C.),[533–4] and $TiCl_4,SbCl_5,3POCl_3$ (probably $TiCl_3(OPCl_3)_3{}^+SbCl_6{}^-$).[535] Similar mixed halide systems are formed by aluminium chloride, e.g. $AlCl_3,NbCl_5,3POCl_3$ (m.p. 198°) and $AlCl_3,TaCl_5,3POCl_3$ (m.p. 217·5°).[536] Oxyhalides of Groups IVa and Va also form complexes including $TiOBr_2,2POCl_3$,[537] $TiOCl_2,2POCl_3$,[538] $ZrOCl_2,2POCl_3$,[539] $Zr_2OCl_6,4POCl_3$ (probably $ZrCl_3(OPCl_3)_3{}^+ZrOCl_3(OPCl_3)^-$)[540] and $VOCl_3,2POCl_3$.[541]

In the gallium chloride–phosphoryl chloride system 1:1 and 1:2 compounds (m.p. 118·5° and 77°C., respectively) occur[430, 526] and a detailed comparison of physical properties of the former with those of its components at their respective melting points has been made.[430] Thus, at 118·5°C. the molar volume is 179·98 ml. (cf. 192·16 ml. for the components), specific conductivity $= 1{\cdot}26 \times 10^{-3}$ mho cm.$^{-1}$ (ca. $2 \times 10^{-6}$ for components), vapour pressure is $<1$ mm.,

$$d_4^t = 1{\cdot}8281 - [1{\cdot}526 \times 10^{-3}(t - 120)]$$

from 111° to 149°C., and the compound may be sublimed without decomposition.

Approximate values of % ionic dissociation at the melting points derived[430] from the molar conductances for molten gallium 1:1, and also for molten titanium and tin(IV) 1:2 complexes were:

| Complex | m.p. °C. | Molar conductance (mho cm.$^2$ mole$^{-1}$) | Ionic dissociation % |
|---|---|---|---|
| $GaCl_3,POCl_3$ | 118·5 | 0·227 | 0·5 |
| $TiCl_4,2POCl_3$ | 105 | 0·384 | 0·75 |
| $SnCl_4,2POCl_3$ | 55 | 0·025 | 0·05 |

Configurations implying electron donation from a Cl atom of $POCl_3$ to the metal atom were proposed for these compounds,[430] but in view of the later *X*-ray structural work[416–7] (described above) those for the titanium and tin compounds at least, must now be discounted. The measured $\Delta H$ for the reaction:

$$GaCl_3(c) + POCl_3(l) = GaCl_3,POCl_3(c)$$

at 25°C. was $-10·2$ kcal. mole$^{-1}$,[330] and values of $-22·6$ and 280·0 kcal. mole$^{-1}$ were derived for the heat of reaction in the gas phase and for the standard heat of formation from the elements ($\Delta H^\circ_{f_{25}}$), respectively. The complexes $InCl_3,POCl_3$ (m.p. $>250°$) and $TlCl_3,2POCl_3$ have been detected by infra-red and Raman spectroscopy.[526]

Maxima in the fusion diagrams for the respective binary systems correspond to complex formation as follows:

| Complex | m.p. °C. | Ref. |
|---|---|---|
| $AsCl_3,POCl_3$ | $-22$ to $-25$ | 403 |
| $BiCl_3,2POCl_3$ | 37 | 431 |
| $SnCl_4,2POCl_3$ | 55 to 57 | 403 |
| $SbCl_5,POCl_3$ | 115 to 117 | 403 |

but provide no evidence of the tin(IV) 2:1 and 1:1 compounds earlier described.[432] For the arsenic, antimony and bismuth(III) chloride systems, infra-red and Raman shifts vary in a continuous manner with mole ratio; for the tin(IV) and antimony(V) systems, spectra of free and bonded molecules were observed. It was tentatively concluded[421, 431] that the former complexes involve a dipole–dipole and the latter an electron pair interaction, but the true nature of the bonding awaits further structural information.

The 1:1 complexes with niobium or tantalum pentachlorides (m.p. 124·5° and 132·4°C., respectively) lose part of their phosphoryl chloride on heating to form sublimable residues of composition $POCl_3,1·49NbCl_5$ and $POCl_3,1·22TaCl_5$.[433–4, 536] However, they are said to be more stable than $TiCl_4,POCl_3$.[534] Distillation of the respective reaction mixtures used in the preparation of the 1:1 complexes gives similarly composed azeotropes.[435] Rectification of tantalum(V), niobium(V) and zirconium(IV) chloride mixtures in phosphoryl chloride can be effected at atmospheric pressure using a 20-plate fractionating column at reflux ratio = 15:1.[436] Recent *X*-ray structural work[409] shows $NbCl_5,POCl_3$ to be isostructural with both $SbCl_5,POCl_3$ and $SbCl_3,PO(CH_3)_3$; the space group is *Pmnb* with $a = 8·07 \pm 0·01$, $b = 16·23 \pm 0·03$, $c = 8·83 \pm 0·02$ A. Wide variation in the Nb–Cl bond lengths (comparable with that for the non-bridging bonds in $Nb_2Cl_{10}$) was observed.

The tetrasolvate complex $UCl_4,4POCl_3$ is precipitated as pale green tetragonal crystals, m.p. 340°C. (sealed tube), refractive indices $n_e$ 1·645, $n_o$ 1·657, from phosphoryl chloride solutions of uranium tetrachloride on standing. The crystals lose phosphoryl chloride on gentle heating *in vacuo* to give pale blue-green $UCl_4,POCl_3$, refractive indices 1·645, 1·660.[437]

Phosphoryl chloride is a convenient ionizing solvent for the chlorides of non-metals and of many transition elements, the solvo-system being the subject of an extensive literature including several review articles.[259, 428, 438] Self-ionization of the solvent occurs with chloride ion transfer: thus, an acid is defined as a chloride ion acceptor and a base as a chloride ion donor. The equilibrium:

$$2POCl_3 \rightleftharpoons POCl_2^+ + POCl_4^-$$

is temperature dependent, the graph of specific conductance against temperature showing a maximum at $2{\cdot}49\times10^{-6}$ mho cm.$^{-1}$ at 88°C.[343] The molar conductance of 0·001 M. alkali halide solutions in phosphoryl chloride increases with increase in the radius of the solute ions. The data at 20°C. (Table XI) show that these halides exhibit a slight to moderate degree of ionization in this solvent.[439] More recent measurements[324] in an inert atmosphere have given somewhat different results:

*Table XI.—Solubility-conductivity Data for Phosphoryl Chloride Solutions at* 20°*C.*

| Solute | Solubility (g./litre) | Specific conductance (mho cm.$^{-1}$) | Equivalent conductance (mho cm.$^2$ mole$^{-1}$) of 0·001 molal solutions |
|---|---|---|---|
| $POCl_3$ | — | $0{\cdot}155\times10^{-5}$ | — |

In the above concentration range tetraethylammonium chloride behaves as a typical polar compound in a solvent of low dielectric constant; similar results were obtained[499] with tetrapropylammonium chloride, tetrabutylammonium chloride and tetraethylammonium bromide, iodide or perchlorate as solute. Evaluation of the limiting conductivities, dissociation constants, Bjerrum parameters and ionic mobilities from the conductimetric data[499] for these solutions and also for solutions of the tetra- and triethylammonium complexes with ferric chloride, antimony(V) chloride, etc.,[440] permitted treatment in terms of electron pair donor-acceptor and ion-pair equilibria of the Bjerrum type. With triethylamine, $Et_3N$, as solute, the overall equilibrium is expressed[441]:

$$Et_3N + POCl_3 \rightleftharpoons [Et_3NPOCl_2^+.Cl^-] \rightleftharpoons Et_3NPOCl_2^+ + Cl^-$$

the overall dissociation constant has the value $2{\cdot}6\times10^{-5}$. Dilute solutions of triethylammonium chloride in phosphoryl chloride contain approximately equal amounts of $Et_3NH^+$ and $Et_3POCl_2^+$ ions, the co-ordination affinity of protons for triethylamine being close to that of the ion $POCl_2^+$.[422]

Typical of the numerous solvate compounds which have been isolated are $SbCl_5,POCl_3$ and $TiCl_4,2POCl_3$. The former behaves as a monobasic acid and the latter as a dibasic acid in phosphoryl chloride solution.[442] A more recent conductimetric and potentiometric study of such solutions shows[443] that the dissociation:

$$SbCl_5,POCl_3 \rightleftharpoons POCl_2^+ + SbCl_6^- \qquad (K = 4\times10^{-6})$$

is basically dependent upon the equilibrium between chloride ion and the oxygen co-ordinated complex:

$$SbCl_6^- \underset{-POCl_3}{\overset{+POCl_3}{\rightleftharpoons}} Cl_5SbOPCl_3 + Cl^- \qquad (K \leq 10^{-9})$$

Thus, in such coupled equilibria, the co-ordinating tendency of phosphoryl chloride through oxygen exceeds its chloride ion donor strength. Titration of titanium(IV) chloride with tetraethylammonium chloride in phosphoryl chloride media suggests the acceptance of either 1 or 2 chloride ions with formation of $TiCl_5^-$ or $TiCl_6^{--}$. Titrations with ferric chloride or antimonic chloride, however, typify donation of a chloride ion from $TiCl_4$; formulations of type $[TiCl_3(OPCl_3)_3]^+[FeCl_4]^-$ have been suggested for these complexes.[444] Potassium and cæsium chlorides readily dissolve in phosphoryl chloride solutions of antimony(V) or iron(III) chloride, and ebullioscopy[338] in concentrations up to $10^{-3}$ M. shows that the soluble potassium chloride complexes $KSbCl_6$ and $KFeCl_4$ are 60 and 45% dissociated respectively. The degree of dissociation decreases rapidly with increasing concentration, but is somewhat greater than that derived conductimetrically[324, 443] for the salts of the larger tetraethylammonium cation in phosphoryl chloride solutions at room temperature.

Tetraethylammonium chloride, alkali metal chlorides, zinc chloride and phosphorus(V) chloride behave as solvo-bases in phosphoryl chloride solution, e.g.,

$$(CH_3)_4NCl + POCl_3 \rightarrow (CH_3)_4N^+ + POCl_4^- \text{ }^{445}$$

Addition of such solutions to red solutions of tungsten(VI) chloride in phosphoryl chloride gives yellow solvated complexes of the ion $WCl_7^-$, but these are stable only in the presence of the solvent.[446] Solid compounds containing the $POCl_4^-$ ion are not known.[428, 442] The reaction:

$$POCl_2.SbCl_6 + (CH_3)_4NCl \rightarrow (CH_3)_4NSbCl_6 + POCl_3$$

in phosphoryl chloride is typical of neutralization, and the resulting salt (soluble in phosphoryl chloride) is not obtainable directly from tetraethylammonium chloride and antimony(V) chloride.[442] Such neutralization affords a general preparative method for chloro-complexes[244, 445] which, where not insoluble, may be isolated by evaporation or by change of solvent. Thus, a 1:2 pyridine complex, $POCl_3,2C_5H_5N$, slightly soluble in phosphoryl chloride, is precipitated by addition of carbon tetrachloride.[447] Conductivity measurements at 20°C. give the dissociation constant for the equilibrium:

$$POCl_3,2C_5H_5N \underset{-POCl_3}{\overset{+POCl_3}{\rightleftharpoons}} 2[POCl_2,C_5H_5N]^+ + 2Cl^- \text{ as } 1{\cdot}34\times10^{-4}$$

The complex is solvo-basic and forms compounds of the type $[C_5H_5N,POCl_2]^+[MCl_6]^-$ with vanadium, antimony, tantalum or phosphorus pentachlorides. Potentiometric titration using a molybdenum electrode and antimony(V) chloride as titrant,[262] gave the order of basicity for various chlorides in phosphoryl chloride as:

$SbCl_5 < FeCl_3$ (acidic) $< ZrCl_4 < SbCl_3 < POCl_3 < SnCl_4 < TaCl_5 < NbCl_5 < AlCl_3 < PCl_5 < TiCl_4$ (amphoteric) $< (CH_3)_4NCl <$ pyridine $< (C_2H_5)_4NCl$ (basic)

In addition, vanadium(IV) chloride[248] and boron trichloride[448] behave as acids and the alkali chlorides[442] as bases. Typical comparative titrations against tetraethylammonium chloride and antimony(V) chloride followed potentiometrically, conductimetrically and by use of indicators[262] may be summarized:

| In $POCl_3$ solution | $(C_2H_5)_4NCl$ titrant | $SbCl_5$ titrant |
|---|---|---|
| $TiCl_4$ | 1:1 and 1:2 reactions corresponding to the formation of soluble acid and slightly soluble neutral salts, respectively. | 1:1 reaction. Solution deposits yellow crystals of $TiCl_3,SbCl_6,2POCl_3$ on standing. |
| $AlCl_3$ | 1:1 reaction. | 1:1 reaction. |
| $PCl_5$ | no break observed in the titration curves; white, fine crystals of $(C_2H_5)_4NPCl_6$ formed. | 1:1 reaction. |
| $FeCl_3$ | 1:1 reaction; voluminous white 'chloroferrate' precipitated. | no reaction. |

With 0·02–0·04 M. metal chloride solutions as titrants, potentiometric titration of 0·02 M. tetraethylammonium chloride in phosphoryl chloride[449] gave the order of decreasing acid strength as:

$$FeCl_3 > SbCl_5 > NbCl_5 > TaCl_5 > SnCl_4 > AuCl_3 > ZrCl_4 > TiCl_3 > AlCl_3 > TeCl_4 > TiCl_4$$

Each showed a break at the 1:1 equivalence point, weak for titanium, zirconium and tin chlorides, which also showed breaks at the 1:2 $MCl_4:(C_2H_5)_4NCl$ equivalence point. It was concluded[450–1] that the acidic or basic character of the solute is determined by its tendency towards co-ordination with chloride ion (acidic) or with oxygen of a phosphoryl chloride molecule (basic) according to the general equation:

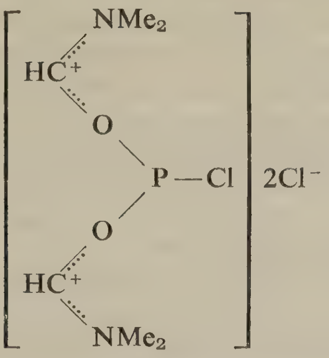
$$(MCl_{n+1})^- + POCl_2^+ \rightleftharpoons Cl_nMOPCl_3 \rightleftharpoons (MCl_{n-1},POCl_3)^+ + Cl^-$$

Spectrophotometric observation (400–600 mμ) of $FeCl_4^-$-ion formation in approximately 0·02 M. ferric chloride solutions has provided further evidence[452–3] of the order of basicity of chloride ion donor compounds in phosphoryl chloride. Thus basicity decreased in the sequence: $(C_2H_5)_4NCl$, KCl, $ZnCl_2$, $AlCl_3$, $AlCl_2^+ > TiCl_4 > PCl_5$, $AlCl^{++} \gg SbCl_6^-$, $HgCl_2 > BCl_3$, $SnCl_4$. Chloride ion transfer from phosphoryl chloride to ferric chloride is also facilitated by pyridine, triethylamine and tetraethylammonium bromide, chlorate or permanganate.[454]

Heat is absorbed on mixing phosphoryl chloride with sulphuryl chloride and observed vapour pressures for the system were higher than the values calculated from individual partial pressures.[455] However, the fusion diagram (eutectic −73·8°C.) provides no evidence of compound formation[456]; boiling point, density and viscosity data (the latter from 15° to 35°C.) are available.[457–8] Phosphoryl chloride is miscible in all proportions with liquid sulphur dioxide[119] and chlorine[329]; thermal analysis of the second system shows the formation of a compound, $2POCl_3,Cl_2$, which forms yellow prismatic crystals, decomposing above −55°C.[329]

Heats of solution for inorganic oxychlorides in chloroform were taken[459] as a measure of C–H ← O bonding. For phosphoryl chloride the heat evolved was 0·48 kcal. mole$^{-1}$, in reasonable agreement with a value of 2 kcal. mole$^{-1}$ estimated from Raman data,[543] and, as a general rule, the presence of halogen in the donor molecule was accompanied by decrease in the bonding strength. Infra-red spectra for such solutions[460] have confirmed the order of hydrogen bonding as $OP(n\text{-}C_4H_9)_3$

$> OP(C_2H_5)_3 > OPCl_3$. A complex of dimethylformamide with phosphoryl chloride, $POCl_3,2DMF$ has been isolated, and assigned the structure[544]



The stability constant and enthalpy of formation of a 1:1 complex between Crystal Violet and phosphoryl chloride have been determined.[545]

Phosphoryl chloride is readily soluble in liquid hydrogen chloride and in such solutions behaves as a base of medium strength, the specific and molar conductance of a 0·48 M. solution being $9{\cdot}35 \times 10^{-5}$ mho $cm.^{-1}$ and 0·20 mho $cm.^2$, respectively. The ionization is believed to be expressed by:

$$POCl_3 + HCl \rightleftharpoons POCl_2^+ + HCl_2^-$$

and conductimetric titration with boron trichloride or trifluoride shows a break at the 1:1 mole ratio. The solid adducts are isolated on evaporation of the solvent (m.p. $POCl_3,BF_3 = -3$°C. with decomposition) and infra-red evidence confirms co-ordination through oxygen to the boron.[263–5, 461] Similar evidence[526] supports the existence of other adducts with the properties shown below:

| Property | Ref. | $BCl_3,POCl_3$ | $BBr_3,POCl_3$ | $BCl_3,POBr_3$ | $BBr_3,POBr_3$ |
|---|---|---|---|---|---|
| m.p. °C. | 526 | 73 | 128 | — | 150 |
| | 546 | 72–75 | 126–129 | 115–118 | 152–154 |
| $\Delta H^{(a)}$ kcal./mole | 546 | $-40{\cdot}2^{(b)}$ | $-50{\cdot}8$ | $-35{\cdot}0$ | $-33{\cdot}7$ |

$^{(a)}$ Defined by the equation $POX_3(g) + BY_3(g) = POX_3,BY_3(c)\ \Delta H$.

$^{(b)}$ A value of 26·1 kcal./mole derived[546] from earlier data[463] suggests the existence of two forms of this complex.

Rapid isotopic exchange between $^{36}$Cl-labelled boron trichloride and excess of phosphoryl chloride at 0°C. is also interpreted[462] in terms of co-ordination through oxygen:

$$POCl_3 \rightleftharpoons POCl_2^+ + Cl^-$$
$$Cl^- + Cl_3^*B.OPCl_3 \rightleftharpoons [Cl_4^*B.OPCl_3]^- \rightleftharpoons Cl^{*-} + Cl_3B.OPCl_3$$

An approximate value for the free energy of dissociation of the last complex is $\Delta G^\circ_{298} = -4{\cdot}6$ kcal. $mole^{-1}$.[463]

Phosphoryl chloride gives slightly conducting solutions in tin(IV) chloride and behaves as a solvo-base in titrations against antimony(V)-, arsenic(III)- and iodine-chloride solvo-acids.[464]

Electrolysis of saturated phosphoryl chloride in triethylammonium chloride solution using platinum electrodes gave[465] chlorine at the anode and a brownish solid of composition $(PO)_n$ at the cathode. The following equations are suggested:

$$POCl_3 \rightleftharpoons POCl_2^+ + Cl^-$$
$$3n[POCl_2]^+ \rightleftharpoons [PO]_n + 2nPOCl_3$$

The solid is insoluble and stable in water. It gives phosphine with alkali, and its composition has been verified by controlled oxidation to phosphorus pentoxide at 300°C.

## PHOSPHORYL CHLOROBROMIDES

The mixed phosphoryl halides are obtained by the reaction of phosphorus(V) dibromotrichloride with acetic acid, or of phosphorus pentachloride–pentabromide mixtures with acetic acid, alcohols or acetone.[466] By equilibrating equimolar phosphorus trichloride–tribromide mixtures at 140°C., cooling and reacting first with bromine and then with phosphorus pentoxide,[467] a product is obtained which can be decanted from unreacted pentoxide and separated into the various mixed halides by fractional distillation at reduced pressure. Small quantities of both chlorobromides also arise during the thermal decomposition of the complex $MgBr_2,3POCl_3$ in the presence of excess phosphoryl chloride.[542]

Phosphoryl dichlorobromide is a water-white liquid, b.p. 52° to 53°C. (39 mm.), 135°C. (758 mm. Hg), giving colourless crystals, m.p. 10° to 11°C. It fumes in moist air and is not decomposed by distillation at normal pressures. The dibromochloride forms as colourless crystals, m.p. 31°C., which rapidly assume a bromine coloration in moist air. Boiling points are 49°C. at 12 mm., 165°C. at 759 mm. Hg.[467] Fluorination proceeds with powdered antimony(III) fluoride at 80°C. (100 mm. pressure) to give small amounts of phosphoryl monofluorochloride, monofluorobromide and fluorochlorobromide condensing at −60°C. The last compound, (POFClBr), has b.p. 79° to 80°C., *d* 1·87, and a Raman spectrum typical of a tetrahedral structure devoid of any symmetry element.[466]

## PYROPHOSPHORYL CHLORIDE, $P_2O_3Cl_4$

### Preparation

Pyrophosphoryl chloride is conveniently prepared by passing chlorine into a boiling suspension of phosphorus pentoxide in phosphorus trichloride diluted with carbon tetrachloride. Phosphorus pentachloride forms *in situ*, and its subsequent reaction can be written:

$$P_4O_{10}+4PCl_5 = 2P_2O_3Cl_4+4POCl_3$$

Maximum yields (30% on the total P) are obtained with a reactant mole ratio $P_4O_{10}:PCl_3 = 1:4$, and experiments using $^{32}P$-labelled phosphorus trichloride have confirmed that the P–O–P linkage originates from the phosphorus pentoxide.[468] The reaction between phosphorus trichloride and nitrogen tetroxide at −10°C. (Mellor, VIII, 1027) has been reinvestigated.[138] The main products (yields based on $PCl_3$) were said to be phosphoryl chloride 58%, pyrophosphoryl chloride 17%, tetraphosphoryl decachloride 6% and colourless crystals of composition $P_2O_6NCl_2$ 14%. A free radicle mechanism was proposed:

$$Cl_3P+ONO \rightarrow Cl_3\dot{P}ONO \rightarrow Cl_2\dot{P}O+NOCl$$

$$Cl_2\dot{P}O+ONO \rightarrow Cl_2PO.O\dot{N}O \xrightarrow{+\dot{P}OCl_2} Cl_2PO.OPOCl_2+NO$$

Yields of 17% and 12%, respectively, can be obtained by controlled addition of 1 mole of water to a vigorously stirred solution of 2 moles of phosphoryl chloride in carbon tetrachloride,[469] or to 1 mole of phosphoryl chloride at 0°C.[470] The last traces of hydrogen chloride, diluent and unreacted phosphoryl chloride are removed at 60° to 90°C. under vacuum. Pyrophosphoryl chloride separates at 110° to 135°C. and is purified by redistillation under high vacuum at 66° to 70°C. Other authors,[98] however, showed that the reaction between 1 mole of water and 1 mole of phosphoryl chloride at −20° to −10°C. gives dichlorophosphoric acid; heating at 100°C. gave an upper layer of phosphoryl chloride, and a lower layer which on further heating gave pyrophosphoryl chloride. A 30% conversion to pyrophosphoryl chloride (based on total P) was achieved[471] from fractional distillation of the products of the sealed tube reaction between phosphoryl chloride and phosphorus pentoxide at 200°C. (optimum mole ratio $POCl_3:P_2O_5 = 3–4:1$). Dichlorophosphoric acid (obtained in 90 to 97% purity either by warming 1 mole of phosphoric acid with 2 moles of phosphoryl chloride,[474] by low temperature hydrolysis of pyrophosphoryl chloride,[354, 472–3, 475] or by reorganization of other suitable mixtures in sealed tube reactions[361] (see page 493) undergoes 35% conversion to pyrophosphoryl chloride, either on addition to excess phosphoryl chloride at 90°C. and vacuum fractionation[474, 476] or by condensation at 100°C. and 12 mm. pressure in a current of hydrogen chloride.[354, 472–3] The above reactions may be expressed:

$$H_3PO_4 + 2POCl_3 \rightarrow 3HOPOCl_2$$
$$HO.POCl_2 + POCl_3 \rightarrow P_2O_3Cl_4 + HCl$$

The dehydration reaction:

$$2HO.POCl_2 \rightarrow P_2O_3Cl_4 + H_2O$$

proceeds only at 300°C. in the absence of hydrogen chloride.[354, 472] Addition of 1 mole of phosphorus(V) chloride to 2 moles of dichlorophosphoric acid followed by vacuum fractionation gives better than 90% conversion to pyrophosphoryl chloride.[477–8, 547] The following mechanism is postulated[477]:

$$PCl_5 + 2HO.POCl_2 \rightarrow Cl_3P(OPOCl_2)_2 + 2HCl$$
$$\hookrightarrow POCl_3 + P_2O_3Cl_4$$

With cyanogen chloride under reflux, the following reaction occurs[479]:

$$2HO.POCl_2 + ClCN \rightarrow P_2O_3Cl_4 + ClCONH_2$$

### Properties

Pyrophosphoryl chloride is a colourless, oily, strongly refractive liquid, $d_4^{15}$ 1·820, b.p. 65°C. at 1 mm., 210° to 215°C. with decomposition at 760 mm. Hg,[138] m.p. $-16{\cdot}5$°C.[471] Raman evidence[480] confirms the presence of two $O{:}PCl_2$ groups connected by an oxygen bridge. The pure liquid is odourless and does not fume in air; it is soluble in inert organic solvents and reacts with amides and alcohols. The hydrolysis reaction with water is vigorous and comparable with that of phosphoric anhydride.[138] Controlled hydrolysis, by dropwise addition of an equimolar quantity of water to pyrophosphoryl chloride at $-70$° to $-60$°C. with stirring, gives dichlorophosphoric acid in a strongly exothermic reaction.[354, 472, 475] With saturated ammonia in ether or chloroform solution at $-25$°C. the products of reaction are dependent upon the availability of water,[481] thus:

(i) in dry solvent:

$$Cl_2PO.OPOCl_2 + 8NH_3 \rightarrow (H_2N)_2PO.OPO(NH_2)_2 + 4NH_4Cl$$

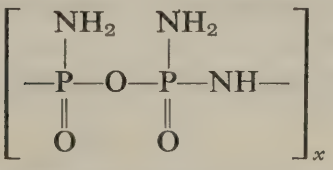
(ii) in the presence of 0·01% $H_2O$:

$$Cl_2PO.OPOCl_2 + 9NH_3 \rightarrow (H_2N)_2PO.NH_2 + HO.PO(NH_2)_2 + 4NH_4Cl$$

(iii) in the presence of 0·05 to 1% $H_2O$

$$Cl_2PO.OPOCl_2 + 10NH_3 + H_2O \rightarrow 2(NH_2)_2PO.ONH_4 + 4NH_4Cl$$

Filtration followed by washing with liquid ammonia until free from chloride ion gives approximately 90% yields for reactions (i) and (iii). Tetramidodiphosphate, product of reaction (i), is also formed by controlled addition of pyrophosphoryl chloride to a stirred excess of dry liquid ammonia.[482–4] Rapid addition, however, gave approximately 70% conversion to a water-soluble amorphous polymer which on isolation had the empirical formula $P_2O_3N_3H_5$ or $P_2O_3N_4H_8$ dependent upon whether the soluble chloride was extracted with ice-water or liquid ammonia. The configuration



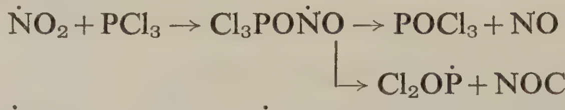
$$\left[ -\overset{\overset{\displaystyle NH_2}{|}}{\underset{\underset{\displaystyle O}{\|}}{P}}-O-\overset{\overset{\displaystyle NH_2}{|}}{\underset{\underset{\displaystyle O}{\|}}{P}}-NH- \right]_x$$

is proposed for the former compound.[481]

Addition compounds with pyrophosphoryl chloride as donor molecule, viz.: $2SbCl_5,P_2O_3Cl_4$ and $SnCl_4,P_2O_3Cl_4$, have been obtained and their infra-red spectra recorded.[485]

## 'TETRAPHOSPHORYL DECACHLORIDE'

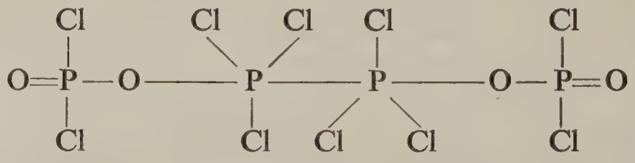
A colourless hygroscopic liquid: b.p. (1 mm. Hg) 105°C., f.p. 37°C., $d_4^{40}$ 2·017, mol. wt. (in camphene) 564, said to be tetraphosphoryl decachloride, $P_4O_4Cl_{10}$, was obtained[138, 486] in 6% yield by fractionation of the products of reaction between liquid dinitrogen tetroxide and phosphorus(III) chloride at −10°C. A free radicle mechanism was proposed:



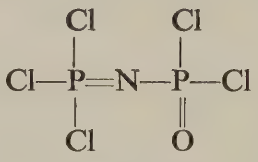
$$\dot{N}O_2 + PCl_3 \rightarrow Cl_3PO\dot{N}O \rightarrow POCl_3 + N\dot{O}$$
$$\hookrightarrow Cl_2O\dot{P} + NOCl$$

$$\dot{P}OCl_2 + POCl_3 \rightarrow \dot{P}_2O_2Cl_5\ (\equiv \tfrac{1}{2}P_4O_4Cl_{10})$$

The crystalline form was colourless, hygroscopic, soluble in organic solvents and gave slightly conducting solutions in thionyl chloride and nitrobenzene, while the formation of a hexachlorotin salt in carbon tetrachloride solution, formulated $(P_4O_4Cl_8)SnCl_6$, was taken[486] as indicating that two chlorine atoms per molecule were appreciably ionic in character. Reaction with water or organic amides was vigorous; the principal hydrolysis products were identified by paper electrophoresis as orthophosphate and hypodiphosphate, said[486] to indicate the presence of both 4 and 5 oxidation-state phosphorus atoms in the original compound. From a comparative study[487] of the infra-red and Raman spectra for phosphoryl chloride, pyrophosphoryl chloride, "$P_4O_4Cl_{10}$" and its phenyl ester, $P_2O_2(OPh)_5$,[488] it was concluded that 'tetraphosphoryl decachloride' was a chain molecule, symmetrically oriented about a direct P–P linkage thus:



and neither resonance[138] nor ring[489] stabilized as previously suggested. More recently[490] the structure of the compound has been identified as:



$$Cl_3P{=}N{-}P(O)Cl_2$$

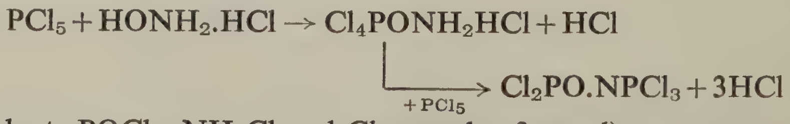
in agreement with the results of complete chemical analysis, and a nuclear magnetic resonance spectrum indicative of two 4-coordinated phosphorus atoms, each bonded in a different manner.

The compound (m.p. 35·7°, b.p. 102°/1 mm., $n_D^{38}$ 1·5256) isolated as above from the reaction between phosphorus trichloride and dinitrogen tetroxide was found[490]to be identical with those prepared from the reactions between phosphorus(V) chloride and:

(i) amidophosphoric acids in tetrachloroethane at 80°C.,[228] e.g.

$$3PCl_5 + H_2N.PO(OH)_2 \rightarrow 2POCl_3 + 4HCl + Cl_3PNPOCl_2$$

(ii) hydroxylamine hydrochloride in tetrachloroethane on heating up to 100°C.,[230] probably by:



$$PCl_5 + HONH_2.HCl \rightarrow Cl_4PONH_2HCl + HCl$$
$$\xrightarrow[+PCl_5]{} Cl_2PO.NPCl_3 + 3HCl$$

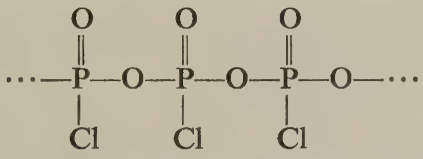
(side products $POCl_3$, $NH_4Cl$ and $Cl_2$ are also formed).

**Refs. p. 508**

(iii) ammonium chloride in nitrobenzene at 40° to 60°C. followed by reaction with sulphur dioxide, when $P_3NCl_{12}$ first formed (believed to be $[Cl_3P{:}NPCl_3^+][PCl_6^-]$) decomposes to $POCl_3 + Cl_3P{:}NPOCl_2$.[491]

## POLYPHOSPHORYL AND CYCLIC PHOSPHORYL CHLORIDES

The sealed tube reaction at 200° to 230°C. between phosphoryl chloride–phosphorus pentoxide mixtures with Cl:P atom ratio between 1·24 and 3 gives viscous single-phase liquids which can be fractionated (12 mm. Hg) to give phosphoryl chloride (b.p. 29°C.), pyrophosphoryl chloride (b.p. 90°C.) and a glassy residue of composition $PO_2Cl$.[471, 360] The latter, thought[471] on paper chromatographic evidence to contain cyclic trimetaphosphoryl chloride and linear polyphosphoryl chlorides of general formula $P_nO_{2n-1}Cl_{n+2}$, where $n = 4$ to 6, was said to lose pyrophosphoryl and trimetaphosphoryl chlorides on more prolonged distillation up to 130°C. (12 mm. Hg), and to leave a solid residue containing cross-linked phosphoryl chlorides. A compound of similar composition has been obtained by the action of dinitrogen tetroxide on phosphorus(III) chloride,[548] and in purer form by the action of dichlorine monoxide on trimeric phosphonitrilic chloride.[549] It is a colourless plastic solid, insoluble in the normal organic solvents. Very hygroscopic, it reacts violently with water giving hydrogen chloride and metaphosphoric acid. Its infra-red spectrum shows broad absorptions characteristic of a polymeric structure[549] such as:



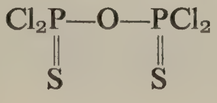
$$\cdots-\underset{\displaystyle Cl}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}-O-\underset{\displaystyle Cl}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}-O-\underset{\displaystyle Cl}{\overset{\displaystyle O}{\overset{\|}{\underset{|}{P}}}}-O-\cdots$$

Nuclear magnetic resonance examination coupled with high vacuum distillation and thermal diffusion techniques have permitted analysis of the system $POCl_3$–$P_2O_5$ *in situ*[360] without the necessity for withdrawal of samples or of an intermediate hydrolysis step. The nuclear magnetic resonance spectra showed four peaks only, which were assigned to $POCl_3$ 'isolated', $POCl_2.O_{1/2}$ 'end', $O_{1/2}POCl.O_{1/2}$ 'middle' and $O_{1/2}PO.O_{1/2}.O_{1/2}$ 'branched' structural units; and for the equilibrium defined by the two equations:

$$POCl_2.O_{1/2} + O_{1/2}PO.O_{1/2}.O_{1/2} \rightleftharpoons 2O_{1/2}POCl.O_{1/2}$$
$$POCl_3 + O_{1/2}POCl.O_{1/2} \rightleftharpoons 2POCl_2.O_{1/2}$$

values of the equilibrium constants were found to be 0·42 and 0·64, respectively. These are considered to be reasonably close to 0·33, the theoretical value for ideally random reorganization. Thus, chlorine and bridging oxygen atoms were considered to exchange sites on the phosphorus atom in an approximately random manner. At Cl:P atom ratio = 2:1, 12% of the total phosphorus at equilibrium was present as pyrophosphoryl chloride, cf. 15% calculated for ideally random reorganization. The phosphoryl and pyrophosphoryl chlorides may be fractionated at room temperature (1 and $10^{-4}$ mm. Hg, respectively) without further reorganization of the mixture; above 65°C., however, appreciable further reorganization occurs during the distillation.[360]

In a similar series of experiments, phosphoryl chloride–phosphorus pentoxide–thiophosphoryl chloride–phosphorus pentasulphide mixtures with atom ratio Cl:P from 1·5 to 2 gave homogeneous liquid products only when the atom ratio S:P was unity. Such products were mainly mixed thionophosphoryl chlorides, i.e. with sulphur replacing the non-bridging oxygen atom. High vacuum distillation again gave phosphoryl and pyrophosphoryl chloride fractions, while some thionopyrophosphoryl chloride,



$$Cl_2\underset{\displaystyle S}{\underset{\|}{P}}-O-\underset{\displaystyle S}{\underset{\|}{P}}Cl_2$$

separated at $10^{-5}$ mm. over the temperature range 0° to 35°C. At higher temperatures appreciable further reorganization occurred.[360]

Dichlorophosphoric acid, $d_4^{25}$ 1·6878, m.p. $-28$°C.,[475] is miscible with water at room temperature, undergoing gentle hydrolysis to phosphoric and hydrochloric acids.[361] Addition to phosphoryl, thionyl, sulphuryl or trimethylsilane chloride followed by rapid distillation gave[474] dichlorophosphoric anhydrides thus:

$$\begin{array}{lll} & & \text{Yield} \\ HPO_2Cl_2 + POCl_3 & = OPCl_2.OPOCl_2 + HCl & 35\% \\ HPO_2Cl_2 + SOCl_2 & = OPCl_2.OSOCl + HCl & \multirow{2}{*}{\Big\}\ 15 \text{ to } 19\%} \\ HPO_2Cl_2 + SO_2Cl_2 & = OPCl_2.OSO_2Cl + HCl & \\ HPO_2Cl_2 + Me_3SiCl & = OPCl_2.OSiMe_3 + HCl & 90\% \end{array}$$

The pyrolysis products of dichlorophosphoric acid have been variously identified as pyrophosphoryl chloride and trimetaphosphoryl chloride at 100°C.,[475] phosphoryl and pyrophosphoryl chlorides and condensed phosphoric acids at 100° to 380°C.,[98] and as hydrochloric and condensed phosphoric acids.[361] It was shown[360] that the characterization of polyphosphoryl chloride mixtures by chromatographic methods involves major errors arising from possible degradation and condensation reactions inherent in the hydrolysis step. A wider application of nuclear magnetic resonance techniques must lead to a better understanding in this field.

## SECTION XV

# PHOSPHORUS BROMIDES

BY R. H. TOMLINSON

## PHOSPHORUS TRIBROMIDE

### Preparation

Reaction between liquid bromine and white phosphorus is vigorous and in practice is moderated by carrying it out in phosphorus(III) bromide as solvent.[1] On the laboratory scale, independent investigators[2–3] commend a similar process, adding dropwise not more than 75% of the theoretical quantity of bromine to dried red phosphorus contained in refluxing phosphorus(III) bromide, thereby minimizing both the vigour of the reaction and the formation of phosphorus(V) bromide. Distillation gives 94% yields based on the bromine. A similar procedure giving phosphorus(III) bromide of high quality has been described more recently.[83] Other diluents, e.g. benzene, may be used, and provide similar yields[4] after separative distillation. Tagged phosphorus tribromide was obtained[5] by bromine exchange, on shaking phosphorus(III) bromide with excess of neutron-irradiated ethyl bromide at room temperatures and separating on the steam bath. Exchange of bromine in phosphorus tribromide with tagged bromine in carbon tetrachloride solution at 20°C. is also rapid, and presumably occurs by intermediate formation of pentabromide.[6]

### Physical Properties

The density, $d_4^t$, from 0° to 158°C. is given[7] by:

$$2{\cdot}9231 - 2{\cdot}458\,.\,10^{-4}t + 3{\cdot}78\,.\,10^{-7}t^2 - 2{\cdot}81\,.\,10^{-9}t^3$$

Extrapolation from density measurements at −79°C. gave[8] the molar volume at 0°K. = 76·1 ml. Vapour pressure and related data are:

| Range °C. | $\log_{10} p_{(\text{mm.})}$ | b.p. °C. | Latent heat of vaporization at the b.p. (kcal.) | Ref. |
|---|---|---|---|---|
| 40–173 | $7{\cdot}6787 - 2137{\cdot}9/T$ | 172·8 | 9·77 | 9 |
| 70–185 | $7{\cdot}498 - 2061/T$ | 173·3 | 9·42 | 10 |

The heat of hydrolysis ($\Delta H_{\text{obs.}}$) for the reaction: $PBr_3 + 3H_2O = H_3PO_3 + 3HBr$ is $-67{\cdot}2 \pm 0{\cdot}6$ kcal./mole, from which the value $-46{\cdot}5$ kcal./mole was obtained[11] for the heat of formation ($\Delta H^\circ_{f_{25}}$) of phosphorus(III) bromide from its elements. A value of $-41{\cdot}6$ kcal./mole is based[12] on the best data for phosphorus(III) chloride (see Section XIV, page 466) and the derived value therefrom (viz., $-227{\cdot}1$ kcal./mole) for the heat of formation of phosphorous acid. Values of standard heat ($\Delta H^\circ_f$), free energy ($\Delta F^\circ_f$) and equilibrium constant ($\log K_f$) of formation for phosphorus(III) bromide vapour at 25°C. are given[13–5] as: $-35{\cdot}9$, $-41{\cdot}2$ (in kcal./mole) and 30·19, respectively. Later values of the standard enthalpy of formation of phosphorus(III) bromide vapour, liquid, and crystalline solid at 298°K. have been given as $\Delta H^\circ_f(\text{g}) = -30{\cdot}7$, $\Delta H^\circ_f(\text{l}) = -41{\cdot}7$, and $\Delta H^\circ_f(\text{c}) = -45{\cdot}2$ kcal./mole, respectively.[90] Enthalpy, free energy and standard entropy functions for the vapour state between

298·1° and 800°K. have been derived[14, 16]; and a selection of the data is given in Table I.

*Table I.—Thermodynamic Properties of Phosphorus(III) Bromide*[14]

| Temperature °K. | $-\frac{G^\circ - H^\circ}{T}$ g.-cal./mole/deg. | $H^\circ - H^\circ_0$ g.-cal./mole | $S^\circ$ g.-cal./mole/deg. |
|---|---|---|---|
| 298·1 | 68·89 | 4,250 | 83·15 |
| 350 | 71·28 | 5,210 | 86·17 |
| 400 | 73·31 | 6,160 | 88·71 |
| 500 | 76·82 | 8,060 | 92·94 |
| 600 | 79·72 | 9,980 | 96·35 |
| 700 | 82·32 | 11,930 | 99·36 |
| 800 | 84·64 | 13,890 | 102·00 |

Heat capacities in the vapour state over the same temperature range are expressed[17] by $C^\circ_p = 18{\cdot}154 + 0{\cdot}002045T - 15300/T^2$.

Dipole moment values, 0·61[18] and 0·52,[19] were derived from dielectric constant measurements in carbon tetrachloride or benzene solution. The viscosity from −15° to +60°C. is given by $\eta_{(\text{poise})} = c/(\nu - \omega)$, where $c = 0{\cdot}000521$ and $\omega = 0{\cdot}3205$.[20–1] Ultrasonic measurements[22] have provided the data given in Table III, Section XIV, page 469. The molar susceptibility of phosphorus(III) bromide is $89{\cdot}3 \times 10^{-6}$ e.m.u. and that of phosphoryl bromide $93{\cdot}9 \times 10^{-6}$ e.m.u. The exaltation due to the phosphoryl group is almost exactly that found for the corresponding chlorides.[84]

Raman spectra measurements have shown reorganization in phosphorus(III) halide mixtures $PBr_3$–$PCl_3$[23] and $PBr_3$–$PI_3$[24] at room temperature with formation of mixed phosphorus(III) bromohalides. The micro-wave spectrum for phosphorus(III) bromide is recorded[25]; the far infra-red absorption spectrum was measured,[26] vibrational fundamentals being assigned and force constants calculated. The $^{31}P$ nuclear magnetic resonance spectrum of phosphorus(III) bromide[85] compared with that in a series of other halides and pseudohalides shows that Br is less electronegative than Cl, NCO or NCS (see also Section XIV, page 468).

## Chemical Properties

The aqueous hydrolysates of phosphorus(III) bromide showed strongest absorption in the ultra-violet–visible range when the hydrolysis had been freshly carried out under controlled conditions at pH 5·7 and 0°C.[27–8] The absorption was thought[27] to indicate maximum yield of an unstable "α-form" of phosphorous acid, $P(OH)_3$. Paper chromatographic analysis of the hydrolysate following dissolution of phosphorus(III) bromide in sodium bicarbonate suspension at 0°C. showed[29] the presence of orthophosphate and phosphite, trisodium diphosphite, hypophosphate and isohypophosphate, and also an unidentified product believed to contain P–O–P and P–P bonds; some phosphine is also formed. Similar products are obtained from the hydrolysis of phosphorus(III) bromide in cold aqueous sodium hydroxide[86] (see also Section XIV, page 471). The reaction of phosphorus(III) bromide with phosphorous acid is reversible, and because of the solubility of hydrogen bromide in the reaction medium lower yields of pyrophosphorous acid are obtained than in the analogous reaction of phosphorus(III) chloride.[87]

If phosphorus tribromide is caused to react under reflux with potassium chlorate, oxidation to phosphoryl bromide proceeds to 80% in 3 hr.[30] Oxidation in the vapour phase is catalyzed by dinitrogen tetroxide (not by $NO_2$ or NO) over a limited range of temperatures and oxygen pressures. The velocity constants up to 100°C. are proportional to the partial pressure of $N_2O_4$; outside defined limits the reaction is explosive, and the products include phosphorus pentoxide and bromine[31] (cf. Mellor, VIII, 1032).

**Refs. p. 525**

In the vapour phase with hydrogen under electrodeless discharge some reduction to phosphorous acid and an unidentified liquid impurity occurred.[32] Dropwise addition of phosphorus(III) bromide to powdered magnesium in refluxing absolute ether is said[33] to give red phosphorus of 99% purity. Reduction also occurs at temperatures between −115° and 0°C. with lithium hydride, aluminium hydride, or lithium aluminium hydride in dry ether[34]; the products are phosphine and a yellow solid of composition $(PH)_x$, the relative proportions of which vary with the temperature and reductant used.

Thermal analysis provides no evidence of compound formation in $PX_3$–iodine systems (where X is chlorine or bromine) and the electrical conductivity of each system is lower than that of molten iodine.[35] Addition of $PX_3$ to iodine chloride is exothermic; the systems show eutectics at 10 mole-% $PCl_3$ and 33 mole-% $PBr_3$, respectively, have high specific conductances (up to $4 \times 10^{-2}$ mho cm.$^{-1}$) and give rise to compounds of composition $PX_6I$, identical with those precipitated from saturated solutions of $PX_5$ with IX in carbon disulphide or carbon tetrachloride,[36] or isolatable from the $PX_5$–iodine[37] or $PX_5$–iodine chloride[38] systems. The reaction: $PX_3 + 2\,IX = PX_5 + I_2$ therefore, is thought to be reversible, complex formation with $PX_5$ occurring in the presence of IX. The high electrical conductance of these systems is explained on the basis of ion formation according to $PX_6I \rightleftharpoons [PX_4]^+ + [IX_2]^-$, while a more general study of ionization in molten iodine bromide[39] (specific conductance at 55°C. $= 7 \times 10^{-6}$ mho cm.$^{-1}$) showed $PBr_6I$ to be solvo-basic in that solvent. The maximum in the thermal diagram for the phosphorus(V) bromide–iodine system (Fig. 1) is attributed[37] to formation of $PBr_6I$ according to the scheme outlined above. The overall equation may be written: $3PBr_5 + I_2 = PBr_3 + 2PBr_6I$. A spectrophotometric study in the 300 to 600 mμ region confirms[40] the dissociation of $PX_6I$ solutions in polar and non-polar solvents as ionic and molecular, respectively:

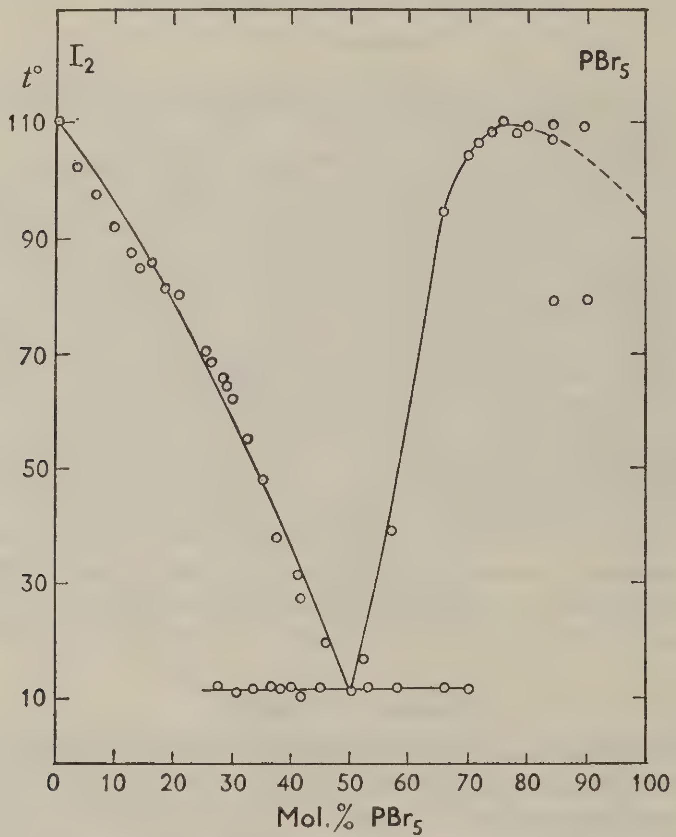

FIG. 1.—Thermal analysis of the system $PBr_5$–$I_2$

$$PX_4^+ + IX_2^- \underset{\text{in MeCN}}{\rightleftharpoons} PX_6I \underset{\text{in } CCl_4,\ C_2H_4Cl_2 \text{ or } CS_2}{\rightleftharpoons} PX_5 + IX$$

Refs. p. 525

While phosphorus(V) chloride shows no tendency towards further dissociation in non-polar solvents, phosphorus(V) bromide undergoes approximately 50% dissociation according to $PBr_5 \rightleftharpoons PBr_3 + Br_2$, the dissociation constants in carbon tetrachloride or ethylene dichloride solution being[41] of the order 2 to $3 \times 10^{-3}$. The compound $PBr_5,2CCl_4$ slowly hydrolyzes in moist air, has no sharp m.p., decomposes at 86°C. and forms as an orange-yellow precipitate on mixing equimolar carbon tetrachloride solutions of phosphorus(III) bromide and bromine,[40] or deposits from saturated phosphorus(V) bromide solutions in carbon tetrachloride.[42] The compound $2PCl_5,CCl_4$ is similarly obtained[42] from phosphorus(V) chloride solutions in carbon tetrachloride. Addition of phosphorus(III) bromide to phosphorus(V) chloride gives liquid phosphorus(III) chloride and red crystals of composition $PCl_3Br_4$; with more phosphorus(III) bromide, yellow crystals of composition $PClBr_4$ are formed.[43] The relative electrical conductances of $PBr_5$, $PClBr_4$ and $PCl_3Br_4$ in nitrobenzene solution are respectively[43] 1:1·5:10. Fluorination of phosphorus(III) bromide occurs in the gas phase with calcium fluoride at 140°C. or with powdered antimony(III) fluoride and bromine as catalyst at 70° to 170°C.; the products are phosphorus(III) fluoride and mixed fluorobromides.[44–5]

A cryoscopic and ebullioscopic investigation of mutual solutions of the halides of the elements belonging to the 4th and 5th groups of the Periodic Table[46] has indicated ready halogen exchange between the titanium and tin tetra-, and phosphorus, arsenic and antimony trihalides; well crystallized complexes of composition $TiCl_4,PCl_3$ and $TiBr_4,2PBr_3$ were also isolated. Fusion curves for each of the systems $PBr_3$–$SbBr_3$, $PBr_5$–$S_2Br_2$ and $PCl_3$–$SnCl_4$ show one branch only, whilst those for $PBr_3$–$SnBr_4$ and $PBr_5$–$AsBr_3$ show eutectics at −50°C. (84 mole-% $PBr_3$) and 23·5°C. (17·5 mole-% $PBr_5$) respectively; the curve for the system $PBr_3$–$AsBr_3$ shows a continuous series of solid solutions.[47–8] Phosphorus(III) and (V) bromides are readily soluble in molten antimony tribromide giving red solutions.[49]

Addition of gaseous trimethylamine to liquid phosphorus(III) bromide at 0°C. gives[50] crystals of the 1:1 complex for which the heat of dissociation (calculated from vapour pressure measurements at 0° to 28°C.) is 19·9 kcal./mole. The heat of solution ($Me_3N$ gas in $PBr_3$ liq.) is −9·5 kcal./mole, which together with the latent heat of vaporization $Me_3N$(l.), viz., 6·4 kcal./mole, provides an estimated P–N bond energy of 3·1 kcal.; the value 6·4 kcal. was obtained for the P–N bond in the corresponding phosphorus(III) chloride complex $Me_3N,PCl_3$ (Section XIV, page 475). Such complexes may be examples of triply connected phosphorus behaving as an electron pair acceptor in $\sigma$-bond formation.[50] Formation of a boron tribromide complex $PBr_3,BBr_3$ (cf. Mellor, VIII, 1033) was confirmed[51]; the product, m.p. 61° to 62°C., remains unchanged *in vacuo* at room temperature. It is also formed by the action of excess of boron(III) bromide on diphosphorus tetrachloride[88] or by the interaction of boron(III) bromide and phosphorus(III) bromide in carbon disulphide at −40°.[89] The yellow compound $PBr_3,BI_3$, m.p. 50° (decomp.), has been prepared similarly,[89–90] and thermodynamic data for these and allied compounds given as follows (units kcal./mole)[90]:

| Compound | $PI_3,BI_3$ | $PI_3,BBr_3$ | $PBr_3,BI_3$ | $PBr_3,BBr_3$ |
|---|---|---|---|---|
| $\Delta H^{\circ\,(a)}$ | −21·8 | −69·9 | −37·8 | −15·2 |
| $\Delta H_1{}^{(a)}$ | −55·8 | −96·6 | −64·3 | −34·4 |
| $\Delta H(c \rightarrow g)^{(b)}$ | 34·0 | 31·3 | 30·0 | 27·3 |
| $D(P–B)^{(c)}$ | 21·8 | 65·3 | 34·3 | 7·1 |

(a) Enthalpy change of the reactions
$PX_3(\text{standard state}) + BY_3(\text{standard state}) \rightarrow PX_3,BY_3\ (c)$ $\Delta H^\circ$
$PX_3(g) + BY_3(g) \rightarrow PX_3,BY_3\ (c)$ $\Delta H_1$
(b) Enthalpy of sublimation.
(c) P–B bond dissociation energy.

A vigorous exothermic reaction occurs between ruthenium tetroxide and phosphorus(III) bromide in carbon tetrachloride solution; distillation *in vacuo* of the phosphoryl bromide from the product left a black residue thought[52] to be a mixture of $RuO_2$ and $RuO_2,PBr_3$.

Phosphonitrilic bromides (which are unstable in air, and hydrolyzed by boiling water, soften at 23° to 40°C. and give elastomeric solids at 195°C. *in vacuo*) are obtained by causing phosphorus(III) bromide to react (i) with sodium azide at 162° to 167°C.[53] according to:

$$PBr_3 + NaN_3 \rightarrow (Br_2PN)_n + N_2 + NaBr$$

or (ii) with ammonium bromide + bromine in *sym.*tetrachloroethane at 110° to 150°C. over 7 days.[54] The latter reaction, starting from differing phosphorus halide–ammonium halide–bromine mixtures, leads[55] to phosphonitrilic bromochlorides, viz.:

| | | |
|---|---|---|
| $P_3N_3Cl_5Br$ | m.p. | 122·5° to 123·5°C. |
| $P_3N_3Cl_4Br_2$ | ,, | 134·5° to 136·5°C. |
| $P_3N_3Cl_2Br_4$ | ,, | 165·5° to 167·0°C. |

and, by stopping the reaction at 110° to 120°C., the addition compound $PNBr_2,PBr_5$ is obtained.[54]

Tetrakistribromophosphine nickel, $Ni(PBr_3)_4$, forms as small, pale-yellow thermochromic crystals (deep orange at room temperature) on treating $Ni(PCl_3)_4$ with excess of phosphorus(III) bromide at 70°C., removing phosphorus(III) chloride *in vacuo* and cooling to $-38$°C.[56]

Polymerization of white to red phosphorus in the presence of phosphorus(III) chloride or bromide or iodine as catalyst gives a product containing halogen, variously considered to be incorporated as a mixed polymer,[57] or as terminal atoms in the general polymeric structure.[58] A similar yellow amorphous involatile polymeric product of the empirical formula $P_2BBr_3$ is obtained by reaction of boron(III) bromide with white phosphorus in chloroform.[91]

Comparative solubilities (g./100 g.) of various phosphorus halides in liquid sulphur dioxide under pressure[59] may be summarized thus:

| | $POCl_3$ | $PCl_3$ | $PBr_3$ | $PI_3$ |
|---|---|---|---|---|
| 0°C. | miscible in all proportions | | 12 | — |
| 25°C. | ,, | ,, | 20 | 0·3 |

However, phosphorus(III) bromide and *iso*thiocyanate have been shown to react with liquid sulphur dioxide, slowly at the boiling point and quite rapidly at 50° under pressure, according to the equation:

$$3PX_3 + SO_2 \rightarrow PSX_3 + 2POX_3$$ [92]

Formation of the compound $PBr_3,3C_6H_5CHO$ in the phosphorus(III) bromide–benzaldehyde system is indicated[60] by the shape of the density, viscosity and surface tension isotherms at 30° and 50°C. Phosphorus(III) bromide, unlike phosphorus(III) chloride, reacts with tetraethyl silicate giving ethyl bromide and a polymer containing phosphorus, oxygen and silicon.[93]

## PHOSPHORUS PENTABROMIDE

The preparation of phosphorus(V) bromide by slow addition of bromine to yellow phosphorus in carbon disulphide solution, initially a violent reaction, is described.[61] Purification is effected by recrystallization from nitrobenzene and washing with absolute ether, the last traces of which are removed in a stream of nitrogen. The substance may also be conveniently prepared by reaction of equimolecular quantities of phosphorus(III) bromide and bromine at 30–35°C. in an anhydrous inert solvent, such as a lower aliphatic polyhalide, in which the product is insoluble.[94]

**Refs. p. 525**

## Physical Properties

From exchange studies with labelled chlorine or bromine in carbon tetrachloride solution,[62–3] it has been concluded that all the five halogen atoms in phosphorus(V) chloride or bromide are equally reactive. Later (see Section XIV) it was shown[64–5] that the three equatorial chlorine atoms of $PCl_5$ exchange much more rapidly with tagged chlorine than do the two apical chlorine atoms. Absorption spectra in the 300 to 600 m$\mu$ region for solutions of phosphorus(V) bromide in non-polar solvents, although closely similar to those of bromine solutions, were shown[41] to be due in large part to undissociated $PBr_3,Br_2$, the degree of dissociation being about 50%. Conductivity and transport experiments with solutions of phosphorus(V) bromide in acetonitrile have confirmed the presence of $PBr_4^+$ and $PBr_6^-$ ions, while conductimetric titration of phosphorus(III) bromide in the same solvent with bromine gives a break at the 1:1 mole ratio only.[66] In contrast with acetonitrile, nitrobenzene solutions of phosphorus(V) bromide have low conductivity:

| solvent | acetonitrile | | | | nitrobenzene |
|---|---|---|---|---|---|
| moles $PBr_5$/l. | 0·0152 | 0·0195 | 0·0296 | 0·0729 | 0·147 |
| molar conductance (mho cm.$^2$ mole$^{-1}$) | 13·95 | 14·25 | 12·26 | 7·86 | 0·224 |

Cryoscopic data for the $PBr_3$–$Br_2$ system in nitrobenzene were interpreted[66] in terms of two equilibria involving $PBr_5$ and to a lesser extent $PBr_7$ species. There appeared to be about 90% dissociation, and the structure of the entities was not decided. The crystal structure of phosphorus(V) bromide differs completely from that of phosphorus(V) chloride (Section XIV, page 477) being orthorhombic with $a$, $b$ and $c = 5{\cdot}62 \pm 0{\cdot}03$, $16{\cdot}91 \pm 0{\cdot}03$ and $8{\cdot}29 \pm 0{\cdot}03$ A., respectively.[67] There are 4 molecules per unit cell, the space group is $D_{2h}^{11}$–$Pbcm$ with all the phosphorus atoms crystallographically and chemically equivalent. The structure consists of tetrahedral $[PBr_4]^+$ groups together with $Br^-$ ions; the P–Br bond length is 2·2 A. and the shortest P to $Br^-$ distance = 4·3 A. A Raman investigation[68] confirms the ionic structure and gives force constants (Urey–Bradley field) $K_1 = 2{\cdot}19$, $K_2 = 0{\cdot}18$ and $\gamma_3 = 0{\cdot}028$, each $\times 10^5$ dynes/cm.

Vapour pressure measurements[61] between 75° and 83·5°C. are expressed within ±1% by $\log_{10} p_{\text{mm.}} = 10{\cdot}7867 – 3020{\cdot}3/T$. At higher temperatures the plot of $T \log_{10} p$ versus $t$°C. was curved and cut the lower straight line portion at 83·8°C., which is thought to be the maximum sublimation temperature of dissociating phosphorus(V) bromide. At this temperature the originally 2-phase system becomes 3-phase with the appearance of the liquid form of phosphorus(III) bromide. Vapour pressure measurements over the temperature range 32·5° to 75°C.[69] are expressed by $\log_{10} p_{(\text{mm.})} = 10{\cdot}1713 – 2895{\cdot}7/T$. The observed vapour density[69] is constant from 65° to 180°C. and corresponds to a molecular weight one-half that of phosphorus(V) bromide. Thus the equilibrium is of the type: solid ⇌ gas + gas. Writing the total pressure as $P_{(\text{atmospheres})}$, the equilibrium constant $K_p$ becomes $P^2/4$ and $\log_{10} K_p = 13{\cdot}979 – 5791{\cdot}4/T$. The heat of the dissociation: $PBr_5(s) \rightleftharpoons PBr_3(g) + Br_2(g)$ is therefore 26·5 kcal./mole. From the heat of hydrolysis of phosphorus(V) bromide a value of $\Delta H_f^\circ = -54{\cdot}6 \pm 1{\cdot}2$ kcal./mole has been deduced for the standard enthalpy of formation of crystalline $PBr_5$ at 298°K.[95]

## Chemical Properties

Slow addition of arsenic(III) fluoride to a stirred suspension of phosphorus(V) bromide in carbon tetrachloride or disulphide at 30° to 50°C. gives white tetrabromophosphonium hexafluorophosphate, $[PBr_4][PF_6]$[70] (see Section XIII, page 454).

Addition of iodine chloride to phosphorus(V) bromide in carbon tetrachloride solution gives red needle crystals of composition $PBr_5,ICl$, m.p. 112·5°C. and stable on storage in a sealed tube.[71] Solutions in benzene or carbon tetrachloride are non-conducting and cryoscopic values agree with the theoretical molecular weight.

Electrical conductance in nitrobenzene is greater than that of an equimolar solution in iodine chloride; the formulation: $[PBr_4][BrICl]$ is suggested.

On heating phosphorus(V) bromide with dihydroxydifluoroboric acid the following reaction occurs[72]:

$$3H_3BO_2F_2+3PBr_5 = BPO_4+2POBr_3+2BF_3+9HBr$$

Phosphorus(V) bromide–chloride mixtures or phosphorus(V) bromochlorides react with acetic acid, alcohols or acetone to give phosphoryl chlorobromides.[73] The reaction between phosphorus(V) bromide and acetic acid:

$$CH_3COOH+PBr_5 \rightarrow POBr_3+HBr+CH_3COBr$$

(more conveniently in *tert.*-butanol or dry *iso*propanol–ether) gives 85% yields of phosphoryl bromide on distillation.[74] The reaction between acetic anhydride and phosphorus(V) chloride:

$$(CH_3CO)_2O+PCl_5 \rightarrow 2CH_3COCl+POCl_3$$

has been recently noted.[75]

## PHOSPHORUS POLYBROMIDES

Thermal analysis of the phosphorus–bromine system[76] shows the existence of two polybromides of composition $PBr_7$ and $PBr_{17}$ besides the normal phosphorus(III)and (V) bromides. The heptabromide is obtained as red crystals, decomposing into two liquid layers at 106·5°C.; the polybromide $PBr_{17}$ melted at 14·5°C. The former compound was thought to arise from disproportionation of the pentabromide at 99°C. according to:

$$2PBr_5 \rightleftharpoons PBr_3+PBr_7$$

## PHOSPHORYL BROMIDE

The preparation from phosphorus(III) bromide, bromine and phosphorus pentoxide has been described in detail[77]; the solid phosphorus(V) bromide first formed is mixed with phosphorus pentoxide in the mole ratio 3:1, gently heated until liquid, then more strongly, and finally distilled to give an 80% yield of phosphoryl bromide based on the phosphorus tribromide used. Redistillation at 12 mm. Hg and fractionation under high vacuum at 100° to 120°C. has yielded[78] pure phosphoryl bromide for determination of the atomic weight of phosphorus. (Hydrolysis in cold aqueous ammonia followed by precipitation with silver nitrate gave the value $30{\cdot}973 \pm 0{\cdot}003$.) Pure phosphoryl bromide, m.p. 56·4°C., has also been obtained[79] by repeated fractional freezing until the product is cryoscopically homogeneous. Bromination of phosphoryl chloride with gaseous hydrogen bromide proceeds to 99% in the presence of 0·5% of aluminium chloride or bromide as catalyst at 80°C.[80] Other formative methods to which earlier reference has been made include the reactions between: phosphorus(III) bromide vapour[31] or liquid[96] and oxygen with nitrogen tetroxide as catalyst, phosphorus(III) bromide liquid and potassium chlorate at 170° to 180°C.[30] (page 519) and phosphorus(V) bromide and acetic acid, acetone,[73] tertiary butanol in absolute ether[74] or difluoroboric acid[72] (page 524).

### Physical Properties

The molar volume at 0°K. = 82·8 c.c.[8] Vapour pressure measurements between 150° and 205°C.[81] are expressed within ±1% by $\log_{10}p_{(\mathrm{mm.})} = 7{\cdot}875 - 2323{\cdot}2/T$; b.p. = 192·0°C. and latent heat of vaporization = 10·9 kcal./mole. The heat of hydrolysis ($\varDelta H_{\mathrm{obs.}}$) for the reaction:

$$POBr_3(c)+(n+3)H_2O(l) \rightarrow H_3PO_4+3HBr \text{ in } nH_2O(l)$$

with solid phosphoryl bromide at 25°C. is −80·8 ± 0·5 kcal./mole, from which the derived values of standard heat of formation ($\Delta H^\circ_{f_{25}}$) for (c) and (g) phases were −110·1 and −95·1 kcal./mole, respectively[11]; the last figure incorporates an estimated heat of sublimation = 15 ± 1 kcal./mole. Densities from 62° to 130°C. are expressed by $d^t_4 = 2{\cdot}8335 - 0{\cdot}002487(t-55)$, surface tension from 55° to 100°C. by $\gamma = 41{\cdot}2 - 0{\cdot}167(t-55)$ dynes/cm. and free surface energy ($\gamma . V_M^{2/3}$ where $V_M$ is molar volume) by $\omega = 895 - 3{\cdot}22(t-55)$; the mean parachor is 255·3,[79] cf. 254·3.[82] The plot of log viscosity against $1/T$ is slightly curved, values at 54·5° and 93·1°C. being 2·729 and 1·655 centipoise, respectively; the activation energy of viscous flow decreases from 3·21 kcal./mole at the m.p. to 2·85 kcal./mole at 90°C.[79] The molar susceptibility of phosphoryl bromide has been determined[84] (see page 519). Infra-red and Raman spectroscopic data have also been recorded.[97]

### Chemical Properties

The specific conductance of phosphoryl bromide is $< 4 \times 10^{-8}$ mho cm.$^{-1}$ The fusion diagram for the gallium bromide–phosphoryl bromide system[79] establishes the formation of a 1:1 compound having m.p. 154°C.; it is, however, less stable than the analogous $GaCl_3,POCl_3$ complex. A comparison of the conductivity data at their respective melting points bears out the analogy.

| | $GaBr_3,POBr_3$ (m.p. 154°C.) | $GaCl_3,POCl_3$ (m.p. 118·5°C.) |
|---|---|---|
| Specific conductance (mho cm.$^{-1}$) | $1{\cdot}0 \times 10^{-3}$ | $1{\cdot}26 \times 10^{-3}$ |
| Molar conductance (mho cm.$^2$ mole$^{-1}$) | 0·21 | 0·227 |
| Reduced conductivity ($\mu . \eta$ mho cm.$^2$ centipoises) | 1·0 | 0·442 |

The Raman spectra for the molten gallium chloride–phosphoryl chloride complex indicates an ionic formula $POCl_2^+,GaCl_4^-$. At 161·2°C. the density of the gallium bromide–phosphoryl bromide complex was 2·875 g./c.c. and the viscosity 4·921 centipoises; the specific conductance increased from $1{\cdot}0 \times 10^{-3}$ mho cm.$^{-1}$ at zero time to a constant value of $2{\cdot}3 \times 10^{-3}$ mho cm.$^{-1}$ after 3 hr.[79]

Similar considerations support the existence of compounds of phosphoryl bromide with sulphur trioxide, tin(IV) bromide and chloride, aluminium(III) chloride, lithium bromide, and nitrogen bases such as quinoline, pyridine or dimethyl formamide.[98] The compounds $BCl_3,PBr_3$, $BBr_3,POBr_3$ (m.p. 150°C.), $AlCl_3,POBr_3$ (m.p. ca. 100° (decomp.)), $AlBr_3,POBr_3$ (m.p. 183°C. (decomp.))[99] and $TiOBr_2,2POBr_3$,[100] were identified in other investigations. Thermochemical studies[101] of the four compounds $POX_3,BY_3$ (X, Y = Cl or Br) have been reported in Section XIV, page 503.

## SECTION XVI

# PHOSPHORUS IODIDES

BY R. H. TOMLINSON

## PHOSPHORUS DI-IODIDE

Phosphorus di-iodide (diphosphorus tetraiodide), $P_2I_4$, forms as unstable, red needle crystals, m.p. (heated quickly in a preheated bath) 125·5°C., from stoicheiometric mixtures of yellow phosphorus and iodine in carbon disulphide solution. The preparation originally described[1] (Mellor, VIII, 1038) has been modified[2] with respect to detail. The crystals[2] underwent considerable decomposition on storage, both in sealed ampoules and in stoppered flasks over calcium chloride. Preparation of phosphorus thioiodide, $P_4S_3I_2$, from its elements in carbon disulphide solution is described.[3] Its formation, from sulphur impurity in the carbon disulphide used, was considered[1] to account for the low m.p. reported for phosphorus di-iodide by earlier workers. *X*-Ray crystallography[4] shows the thioiodide to consist of two 5-member rings of 3 P and 2 S atoms joined by a common P–S–P linkage, the iodine atoms being bonded to the remaining P atom in each ring. A possible alternative explanation for impurities in phosphorus di-iodide is the disproportionation into phosphorus(III) iodide, which is discussed below.[15, 34]

Mixtures of solid iodine with red phosphorus, having atom ratios (I:P) between 1·33:1 and 3:1, undergo exothermic reaction on initiation by gentle heat. At the lower ratio, after stirring the reaction product for a further 1 hr. at 180° to 190°C. and taking up in chlorobenzene, a 40% yield of phosphorus di-iodide crystals (m.p. 126° to 127°C.) was obtained.[5] At the 3:1 ratio, crystallization of the reaction product from dichloroethylene gave dark-red phosphorus(III) iodide crystals (m.p. 60° to 61°C.) in 65% yield. Reaction between excess of red phosphorus and iodine or phosphorus(III) iodide in refluxing butyl iodide,[5] or between yellow phosphorus and phosphorus(III) iodide or methyl tetraiodophosphorane in carbon disulphide solution at room temperature, also results[6] in appreciable yields of the di-iodide. Phosphorus di-iodide with iodine also arises from the catalytic decomposition of phosphorus(III) iodide by ether.[35]

The reaction between yellow phosphorus and iodine in carbon disulphide has been reported to yield phosphorus di-iodide via several iodide intermediates, without breaking and reforming the P–P bond.[36] However, later workers have shown by $^{31}P$ nuclear magnetic resonance and ultra-violet spectrophotometry that there is an initial rapid reaction to form phosphorus(III) iodide which is followed by a slower reaction with excess of phosphorus, where present.[37]

### Physical Properties

Phosphorus di-iodide crystallizes in the triclinic system, its space group is $P\text{–}\bar{1}$ and there is one molecule per unit cell. The P–P and P–I distances are 2·21 (standard deviation 0·06) and 2·475 (standard deviation 0·028) A., respectively, with each phosphorus atom linked to two iodine atoms. The molecular symmetry is $2/m$, the two $PI_2$ groups being in the *trans* position to each other[7] as shown diagramatically in Fig. 1.

Ebullioscopy in carbon disulphide solution confirms the molecular formula $P_2I_4$. Dielectric constant measurements in the same solvent[8] gave values of 0·45 and

0·34 D. for the dipole moments of phosphorus di- and tri-iodides, respectively. A value of 0·24 D. was obtained for the dipole moment of the P–I bond; it was concluded[8] (in contrast to the *trans* configuration indicated above for the crystalline form) that the two $PI_2$ groups of the isolated molecule in solution are rotated about the P–P bond at an angle of approximately 85°. The infra-red spectrum of carbon disulphide solutions also appeared to support this staggered (*gauche*) configuration of $C_2$ symmetry for dissolved phosphorus di-iodide molecules.[38–9] However, it now seems probable that the compound in fact has the *trans* $I_2P{-}PI_2$ structure with $C_{2h}$ symmetry in both solid state and solution. This opinion is based on the absence of coincidences between the Raman and infra-red spectra, the similarity between the solid and solution spectra, and the fact that only two infra-red active and three Raman active fundamentals (two depolarized and one polarized) are observed.[40–1] Infra-red absorption bands seen at 303 and 328 cm.$^{-1}$ are assigned to phosphorus(III) iodide which, together with phosphorus, has been shown to arise by the dismutation of pure phosphorus di-iodide in carbon disulphide solution.[34] The presence of phosphorus(III) iodide, demonstrated by its $^{31}P$ nuclear magnetic resonance and ultraviolet spectra, may also account for the dipole moment observed by previous workers.[8] The $^{31}P$ nuclear magnetic resonance spectra for phosphorus di-iodide (in carbon disulphide solution) and for phosphorus tri-iodide (liquid) show chemical shifts, referred to aqueous phosphoric acid, of $-170 \pm 10$ and $-178 \pm 4$ p.p.m., respectively.[9] The density of the di-iodide at 20°C. is $4{\cdot}178 \pm 0{\cdot}002$ g./c.c.[8]

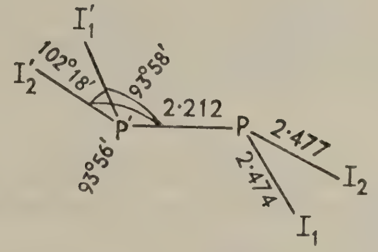

FIG. 1.—Molecular dimensions of $P_2I_4$. Non-bonded distances are, in A., $I_1I_2$, 3·856; $I_1P'$, 3·341; $I_2P'$, 3·434

## Chemical Properties

The products of hydrolysis of phosphorus di-iodide at 0°C. are hydrogen iodide, phosphine, hypophosphorous, phosphorous and phosphoric acids; while oxidation of the hydrolysate with hydrogen peroxide at an alkaline pH gave[10] up to 24% conversion into hypophosphoric acid ($H_4P_2O_6$). The presence of various P–P bonded phosphoric acids in the products of oxidative hydrolysis of either phosphorus di-iodide or of the lower phosphorus sulphides ($P_4S_3$, $P_4S_5$ or $P_4S_7$) has been reported.[11] In basic solution and the absence of oxidants the hydrolysis, like that of $P_2Cl_4$ (*q.v.*), appears to go according to the equations:

$$2P_2X_4 + 2H_2O \rightarrow P_2H_4 + P_2(OH)_4,$$
$$P_2(OH)_4 + H_2O \rightarrow H_3PO_2 + H_3PO_3$$

followed by:

$$4H_3PO_3 \rightarrow 3H_3PO_4 + PH_3$$ [42]

Phosphorus di-iodide solutions in carbon disulphide at 20°C. absorb 0·6 to 1 mole of oxygen per mole of $P_2I_4$ to give an amorphous yellow polymer, the reaction being approximately represented[12] by:

$$7P_2I_4 + 6O_2 \rightarrow 2/n(P_3I_2O_6)_n + 8PI_3$$

Refs. p. 532

With sulphur in boiling benzene or carbon disulphide solutions in the absence of daylight, the following reactions are reported[13]:

$$7P_2I_4+\tfrac{7}{4}S_8 = 2P_4S_7+6PI_3+5I_2$$
$$2P_2I_4+\tfrac{7}{8}S_8 = P_4S_7+4I_2$$

while from phosphorus tri-iodide with sulphur in carbon disulphide solution at 10° to 15°C., also in the absence of daylight, unstable thiophosphoryl iodide, $PSI_3$, has been crystallized.[14] The thioiodides: $P_4S_3I_2$, $P_2S_2I_4$ and $P_2SI_4$ (m.p., each with decomposition, 118°, 90° to 93° and 105° to 110°C., respectively), may be obtained by crystallization from carbon disulphide solutions of the elements in stoicheiometric proportions after standing in the dark for several days at room temperature.[3, 13] Crystals of the less stable thiophosphoryl iodide (m.p. 46° to 48°C. with decomposition) are obtained in a similar manner, but after 3 to 4 hr. standing at 10° to 15°C.[14] There is some evidence that an unstable complex, $P_2I_4,4S_8$, may be an intermediate in these reactions.[43]

In a study of various phosphorus halide–iodine systems,[15] it was shown that molten phosphorus di-iodide–iodine mixtures containing greater than 33 mole-% of phosphorus di-iodide gradually transform to phosphorus tri-iodide and iodine. The action of bromine on phosphorus di-iodide yields a mixture of the four halides $PBr_nI_{3-n}$ $(n=0-3)$.[44] Like other phosphorus halides, phosphorus di-iodide forms complexes, though these have been little studied. Thus it reacts with boron tribromide and tri-iodide (but not with the weaker Lewis acids $BF_3$ and $BCl_3$) and the unstable yellow complex $P_2I_4,2BBr_3$ has been isolated.[38] With aluminium(III) iodide three products are formed:

(1) A red amorphous solid, insoluble in carbon disulphide with an I:P ratio of approximately unity, and a P:Al ratio approximately 5:1.
(2) A small amount of the complex $2PI_3,AlI_3$.
(3) A major proportion of impure $P_2I_4,AlI_3$ (red-brown crystals, m.p. 122–5°C.).

Products (1) and (2) presumably arise from the partial disproportionation of $P_2I_4$ in the sense:

$$P_2I_4 \rightarrow (\text{–PI–})_n+PI_3$$ [45]

## PHOSPHORUS TRI-IODIDE

Phosphorus(III) iodide, m.p. 61°C., forms as hygroscopic, red tabular crystals from carbon disulphide solutions of iodine with an equivalent amount of yellow (or suspended red) phosphorus,[1, 37] or by recrystallization from dichloroethylene of the product of the exothermic reaction between stoicheiometric amounts of red phosphorus and solid iodine.[5] Its formation has also been noted in the reaction between phosphorus and iodine vapours at ordinary temperatures[16]; the position of the deposit of solid tri-iodide is dependent upon such factors as tube shape, total pressure and the admission or otherwise of hydrogen or wood charcoal. Other reactions by which it arises include the decomposition of $P_2I_4$ by heat,[34] iodine,[15] or bromine.[44]

### Properties

The complete Raman spectrum for phosphorus(III) iodide was obtained[17] using He 6678·2 A. radiation; the fundamental frequencies were assigned, and force constants: $K=1{\cdot}21$, $K'=0{\cdot}06$, $H=0{\cdot}18$ and $H'=0{\cdot}03$ dynes $\text{cm.}^{-1}\times 10^5$ evaluated, using an assumed pyramidal angle of 102°. Raman methods have also shown[18] the presence of mixed phosphorus(III) halides in mixtures of phosphorus(III) iodide and chloride, while Hg 4358 A. radiation in about 15 hr. produces change of the type: $PClI_2+PCl_3=2PCl_2I$ with loss of colour, the reaction being reversible on removal of the light source. Mixed bromoiodides have been demonstrated similarly.[44]

The enthalpy of formation of phosphorus(III) iodide was determined by aqueous hydrolysis.[46] The value obtained, $-10{\cdot}7$ kcal./mole, was in good agreement with previous values.[47]

Published values for the dipole moment of phosphorus tri-iodide (from observations in carbon disulphide solution) are 0·0[19] and 0·34 D.[8]

Hydrolysis at 0°C. in sodium bicarbonate buffered solutions gives phosphine and salts of a number of reduced acids (see Section XIV, page 471) as well as ortho- and pyrophosphates.[20] Sodium hydroxide hydrolysis yields similar results, though no phosphine can be detected.[48]

Conductivity and cryoscopic methods have indicated[21] that the association factor of phosphorus(III) iodide in molten iodine (at 111°C.) increases with increasing $PI_3$ concentration. Conductivity data for the system at 130° and 140°C.[22–3] plotted against concentration show a negative temperature coefficient, with maximum specific conductance $1{\cdot}24 \times 10^{-4}$ mho cm.$^{-1}$ at 9·7 mole-% $PI_3$. An electrolytic dissociation of associated iodide molecules of the type:

$$(MI)_n \rightleftharpoons (M_nI_{n-m})^{m+} + mI^-$$

rather than formation of polyiodide is suggested.[23] Specific gravity[24] and viscosity[25] changes for the system are reported, a maximum in the viscosity–composition curve coinciding[25] with the minimum in the specific gravity–composition curve.

Double decomposition reactions with elimination of the more volatile phosphorus(III) chloride occur on heating phosphorus(III) iodide with bismuth, lead, arsenic, antimony, tin, titanium[26] and germanium[27] chlorides; but no reaction was observed[28] with zirconium or thorium tetrachlorides. With aliphatic alcohols in carbon disulphide solution at or below 25°C., alkyl iodides are formed.[29] With silver *iso*cyanate in nitromethane solution the reaction:

$$PI_3 + 3AgNCO \rightarrow P(NCO)_3 + 3AgI$$

commencing at room temperature and complete under reflux is reported.[30] The solubility of phosphorus(III) iodide in liquid sulphur dioxide at 25°C. is 0·3 w./w. %.[31] On heating phosphorus(III) iodide with dihydroxydifluoroboric acid, the main reaction was thought[32] to be:

$$3H_3BO_2F_2 + 2PI_3 = [B_2O_3.P_2O_3] + 6HI + BF_3 + 3HF$$

Small amounts of iodine, elementary phosphorus and an unidentified liquid product (b.p. 76°C.) were also present. With tetrasilane in a sealed tube at 100°C., a colourless spontaneously inflammable liquid of unknown composition (evolving iodine vapour on combustion) is formed.[33]

Diethyl ether on the other hand has been reported[35] to catalyze the reaction:

$$2PI_3 \rightarrow P_2I_4 + I_2$$

Phosphorus(III) iodide forms complex compounds with boron(III) bromide and iodide, but not with the less acidic fluoride and chloride.[38] The reaction with boron (III) bromide in carbon disulphide at $-40°$ yields $Br_3B,PI_3$, yellow, decomp. 50°,[49] m.p. 159–160° (decomp.).[38, 52] Similarly boron(III) iodide yields $I_3B,PI_3$, yellow or orange, decomp. below 250°,[38, 50, 52] subl. (*in vacuo*) 100°.[49] The infra-red spectrum of $I_3B,PI_3$ has been recorded,[38, 51] and is compatible with a P–B bond stretching force constant of 1·0 millidyne/A., and a P–B dissociation energy of ~16 kcal./mole.[51] Further thermodynamic data for both compounds are tabled[52] in Section XV, page 521. The compound is slightly soluble in carbon disulphide or benzene, hydrolyzed by water or atmospheric moisture with evolution of hydrogen iodide, and oxidized, slowly by dry air or rapidly by nitric acid, liberating iodine. It decomposes to cubic boron phosphide at 900°C.[50] Aluminium(III) iodide on the other hand reacts with phosphorus(III) iodide in carbon disulphide to give the dark brown solid complex $2PI_3,AlI_3$, m.p. 127–130°C., which is rapidly decomposed by polar solvents or atmospheric moisture. The complex is probably monomeric, with a trigonal bipyramidal structure (symmetry $D_{3h}$), corresponding to the unusual co-ordination number of 5 at the aluminium atom.[45] Little is known of organic co-ordination compounds of phosphorus(III) iodide except the 1:1 complex with 2-thioamidopyridine (TP) which appears to ionize in ethanolic solution[53]:

$$PI_3(TP) \rightleftharpoons [PI_2TP^+]+I^-$$

## SECTION XVII

# THE THIOPHOSPHORYL HALIDES

BY A. F. CHILDS

## THIOPHOSPHORYL FLUORIDE AND MIXED HALIDE FLUORIDES

### Thiophosphoryl Fluoride, $PSF_3$

PREPARATION

The formation of thiophosphoryl fluoride by the action of lead(II) fluoride on tetraphosphorus decasulphide (Thorpe and Rodger, Mellor, VIII, 1071) has been confirmed, and an apparatus suitable for carrying out the reaction has been described.[1–2] A more generally applicable preparation, which can also be used to obtain mixed fluorides, is the fluorination of thiophosphoryl chloride[3] or bromide,[4–5] by antimony(III) fluoride. In the case of thiophosphoryl chloride, antimony(V) chloride is added as a catalyst, and the reaction is carried out at 75–80°C. The fluorinated products issue through a reflux head and, by controlling the temperature of reflux and the pressure within the apparatus, the proportion of the various products can be varied. The best yield of thiophosphoryl fluoride is obtained at atmospheric pressure, using solid carbon dioxide/acetone in the reflux head. The product can be purified by fractional distillation through a spiral nichrome column in a nitrogen atmosphere. The fluorination of thiophosphoryl bromide is carried out at 60–70°C.

Thiophosphoryl fluoride has also been prepared by fluorination of thiophosphoryl chloride using sodium fluoride in a polar solvent (tetramethylene sulphone, acetonitrile[6–7]) or potassium fluorosulphinate, $KSO_2F$.[8] The yield in both reactions is just over 50% of the theoretical quantity. In all cases moisture and oxygen must be strictly excluded from the apparatus in which thiophosphoryl fluoride is being prepared or handled.

PHYSICAL PROPERTIES

Thiophosphoryl fluoride is a colourless gas which can ignite spontaneously in air. It condenses to a colourless, highly refractive liquid, b.p. $-52{\cdot}3 \pm 0{\cdot}05$°C.[3] (cf. $-52{\cdot}6$°C./760 mm.[2]), and on further cooling forms a white solid, f.p. $-148{\cdot}8 \pm 0{\cdot}5$°C.[3,9] It forms a eutectic, f.p. $-152{\cdot}1 \pm 0{\cdot}5$°C., with pure boron trifluoride, but unlike phosphoryl chloride shows no evidence of compound formation.[9] The vapour pressure of the liquid is given by the relation $\log p = 7{\cdot}5882 – 1038{\cdot}8/T$ ($T$ in °K.) and the latent heat of vaporization (kcal. mole$^{-1}$) is 4·684,[3] 4·73.[2] The liquid has a normal Trouton constant (21·2,[3] 21·4[2]) and the substance is not associated in the vapour phase.[2] The critical temperature and pressure are 72·8°C. and 37·7 atm., respectively. From the measured linear Stark components in the microwave spectrum the dipole moment has been calculated to be $0{\cdot}633 \pm 3\%$ relative to carbon oxysulphide.[10]

The tetrahedral structure of symmetry $C_{3v}$ established for thiophosphoryl fluoride by electron diffraction[11] has been confirmed and refined by microwave spectroscopy.[5] The most probable values of bond lengths and angles in thiophosphoryl fluoride and other thiophosphoryl halides of which the structure is known are shown in Table I.

The P–S and P–F bond lengths observed in $PSF_3$ are significantly shorter than in other $X_3PS$ compounds, presumably due to contributions from ionic structures. Attempts have been made to relate in greater detail the variation of structure of the

thiophosphoryl halides to the electronegativity of the substituent halogens,[14] but further more accurate structure determinations are required to confirm the validity of these conclusions.

The Raman spectrum of liquid thiophosphoryl fluoride shows the six lines (three polarized and three depolarized) expected for a molecule of symmetry $C_{3v}$.[15] A normal co-ordinate treatment based on the values of potential constants for similar molecules gave calculated values of the absorption frequencies agreeing to within 1% with those observed.[16] Force constants (dynes/cm. × $10^5$) $f_D = 4{\cdot}500$, $f_d$ 4·774, $f_\alpha$ 0·219, $f_\beta$ 1·425, $f_{d\alpha}$ 0·273 and $f_{\alpha\alpha}$ 0·144 have been derived similarly.[17] The infra-red spectrum of thiophosphoryl fluoride has been recorded[113] and discussed, together with the spectra of $SPF_2Cl$ and $SPF_2Br$, from the point of view of the effect of substituents on the P = S stretching frequency in the molecules.[114] The nuclear magnetic resonance data for these compounds, recorded below, can also be explained by the differing polarities of the $\sigma$ bonds and differing degrees of $\pi$ bonding.[115]

### CHEMICAL PROPERTIES

The aqueous hydrolysis of thiophosphoryl fluoride is slow, being only 3·3% complete after 4·5 hr. at room temperature.[1] The first product of alkaline hydrolysis is a salt of phosphorodifluoridothioic acid, $HOPSF_2$, which can be precipitated as its insoluble nitron salt. Further hydrolysis gives phosphorothioic acid, $H_3PSO_3$, and finally (in acid or neutral medium) phosphoric acid. No phosphorofluoridothioic acid can be isolated.[2]

Reactions with metals, where they occur, lead to the formation of sulphides (or fluorides) and trivalent phosphorus compounds.[1] The gas has no action on mercury or nichrome in the cold, but slightly attacks copper.[3]

## Diphosphorus Tetrasulphur Tetrafluoride, $P_2S_4F_4$

This compound, b.p. 58–60°/10 mm., is prepared by bromine oxidation of the anion $S_2PF_2^-$, obtained by the action of alkali metal fluorides on tetraphosphorus decasulphide in acetonitrile (see Section XI. Its infra-red and nuclear magnetic resonance spectra are consistent with the structure $F_2(S)PSSP(S)F_2$. It reacts with *cyclo*hexene to give $C_6H_{10}[SP(S)F_2]_2$, a colourless liquid, moderately stable to hydrolysis.[116]

### Thiophosphoryl Chlorofluorides

Thiophosphoryl chlorodifluoride, $PSF_2Cl$, and thiophosphoryl dichlorofluoride, $PSFCl_2$, are obtained as intermediates in the preparation of thiophosphoryl fluoride as described above.[3, 8] They are colourless compounds, with the physical properties given in Table II. Thiophosphoryl chlorodifluoride has also been obtained in 80% yield by the action of anhydrous hydrogen chloride on *N*,*N*-diethylphosphorodifluoridothionic amide, $F_2P(S)NEt_2$.[114]

*Table II.—Physical Properties of Thiophosphoryl Chlorofluorides*

The observed boiling points agree closely with those calculated by the method of Maslov.[18–9] The molecular structure of the thiophosphoryl chlorofluorides has not been determined, but the Raman spectrum of liquid thiophosphoryl chlorodifluoride shows the nine frequencies expected from a molecule of symmetry $C_{1h}$.[15] The spectrum of thiophosphoryl dichlorofluoride on the other hand shows only eight absorptions, the deformation frequencies somewhat resembling those of a $C_{3v}$-type molecule, possibly because of the similarity in mass between the sulphur and chlorine atoms.[20] The infra-red spectrum of the dichlorofluoride has been determined. Absorptions at 476 and 565 cm.$^{-1}$ were assigned to P–Cl vibrations and one at 900 cm.$^{-1}$ to the P–F vibration.[21] A study of the infra-red spectra of phosphoryl and thiophosphoryl mixed halides, showed that whereas the frequency of the phosphoryl absorption depends additively on the electronegativities of the substituent halogens, simple inductive effects will not explain the behaviour of the thiophosphoryl absorption.[117]

Like thiophosphoryl fluoride, the chlorofluorides hydrolyze slowly in aqueous potassium hydroxide, or in moist air. The chlorodifluoride will also explode spontaneously in air at certain concentrations, but this behaviour has not been observed with the dichlorofluoride. The latter compound attacks mercury when hot, but neither chlorofluoride has any action on mercury or nichrome in the cold.[3] Thiophosphoryl dichlorofluoride reacts with the lower alcohols to give colourless alkyl phosphorochloridofluoridothionates, which by further treatment with sodium alkoxide yield dialkyl phosphorofluoridothionates:

$$\mathrm{PSFCl_2 + ROH \rightarrow ROPSFCl \xrightarrow{RONa} (RO)_2PSF}$$

Analogous reactions are observed in the case of primary and secondary amines, and the products are claimed to be powerful insecticides[22]:

$$\mathrm{PSFCl_2 + RR'NH \rightarrow PS(NRR')FCl \xrightarrow{R''ONa} R''OPS(NRR')F}$$

### Thiophosphoryl Bromofluorides

Thiophosphoryl bromodifluoride, $PSF_2Br$, and thiophosphoryl dibromofluoride, $PSFBr_2$, have been prepared by the fluorination of thiophosphoryl bromide by antimony(III) fluoride. Fluorination takes place smoothly and exothermically at 60–70°C., no catalyst being required. The product varies with pressure, $PSF_2Br$ being the main product at 40 mm. and $PSFBr_2$ at 15 mm.[4] In a similar way the action of antimony(III) fluoride on thiophosphoryl dibromochloride at 80–100°C. and 20–40 mm. yields a high proportion of thiophosphoryl bromochlorofluoride, PSFClBr. The same product is also obtained, in admixture with thiophosphoryl dichlorofluoride, by fluorination of thiophosphoryl bromodichloride.[20]

The three bromofluorides are colourless fuming liquids, with the physical properties given in Table III.

*Table III.—Physical Properties of Thiophosphoryl Bromofluorides*

| Reference | 25 | 25 | 22 |

The molecular structure which has been established by electron diffraction for thiophosphoryl dibromofluoride and bromodifluoride[12] (see Table I) conforms with the observed Raman spectra[15, 20] of these substances, which show the nine absorption frequencies expected for molecules of symmetry $C_{1h}$. The Raman spectrum of thiophosphoryl bromochlorofluoride also shows nine absorptions, but two are polarized showing that the molecule tends towards a $C_{1h}$ structure (possibly because of the similarity of Cl and S in mass) rather than the expected $C_1$ symmetry.[20]

Thiophosphoryl dibromofluoride is unaffected by standing for 24 hr. at room temperature over water or dilute potassium hydroxide solution, and reacts only slowly at the boiling point. It is miscible without reaction with acetone, carbon tetrachloride and paraffin wax. It does not react with lead, tin, zinc, nichrome or sulphur in the cold. Iron is corroded giving a white, and silver a yellow, solid respectively. Copper is severely attacked to form white, red and black solids, probably fluorides and sulphides. Mercury reacts at 70°C. to give unspecified products. Sodium iodide gives a red colour with thiophosphoryl dibromofluoride, presumably due to liberation of iodine.

Thiophosphoryl bromodifluoride is somewhat more reactive, hydrolyzing slowly in cold potassium hydroxide and vigorously in hot sodium hydroxide solution, and attacking mercury slightly at 35–40°C.[4]

## THIOPHOSPHORYL CHLORIDE AND MIXED HALIDE CHLORIDES

### Thiophosphoryl Chloride, $PSCl_3$

PREPARATION

Many of the methods described in the earlier literature (Mellor, VIII, 1074) have been developed further for the laboratory or commercial preparation of thiophosphoryl chloride. The most generally applicable of these is the addition of sulphur to phosphorus trichloride. The second order reaction between the pure materials is slow at 100°C., and even under increased pressure at 200°C. requires 7–8 hr. for its completion.[24–5] To avoid the use of increased pressure it has been proposed to bubble phosphorus trichloride vapour through a heated solution of sulphur in an inert solvent of high boiling point.[26] However, the reaction is better carried out at lower temperatures using a catalyst, of which the best is probably aluminium chloride.[27] The presence of only 1–2 moles % of this substance leads to complete reaction of sulphur with phosphorus trichloride in 10 min. at 100°C. and atmospheric pressure. A useful laboratory preparation of thiophosphoryl chloride, based on this procedure, has been reported[28] and variants of it have been patented[29–30] including the use of ferric chloride or aluminium bromide as catalysts.[31–2] Other catalysts which have been suggested include metals,[33] activated carbon,[34–5] sodium sulphide[24] and sulphur monochloride.[36]

The thiohydrolysis of phosphorus pentachloride first described by Sérullas (Mellor, VIII, 1074) has been studied both in liquid hydrogen sulphide[37] and in carbon disulphide solution,[38] the yield of thiophosphoryl chloride in the latter case being only 70%:

$$PCl_5 + H_2S \rightarrow PSCl_3 + 2HCl$$

The interaction of carbon tetrachloride and tetraphosphorus decasulphide is also claimed to give thiophosphoryl chloride in 60% yield[39]:

$$3CCl_4 + P_4S_{10} \rightarrow 4PSCl_3 + 3CS_2$$

This reaction is interesting in being the complement of that described by Carius (Mellor, VIII, 1074):

$$2PCl_5 + CS_2 \rightarrow CCl_4 + 2PSCl_3$$

The two together lead to the overall reaction:

$$6PCl_5 + P_4S_{10} \rightarrow 10PSCl_3$$

which has received little attention since its discovery by Weber (Mellor, *loc. cit.*), although it has been suggested as a laboratory preparation.[40] (The reaction will also yield condensed thiophosphoryl halides under suitable conditions.[109]) Thiophosphoryl chloride, amongst other products, has also been claimed to result from the reaction of sulphur monochloride, either with ferrophosphorus[41]:

$$Fe_2P + 3\tfrac{1}{2}S_2Cl_2 \rightarrow 2FeCl_2 + PSCl_3 + 6S$$

with phosphorus trichloride and tetraphosphorus decasulphide[42]:

$$18PCl_3 + P_4S_{10} + 6S_2Cl_2 \rightarrow 22PSCl_3$$

or with calcium phosphate, silica and carbon at 1000°C.[43] A procedure which involves elements of several of the above consists in causing sulphur, phosphorus and chlorine to react directly in a heel of thiophosphoryl chloride, using wood charcoal as catalyst.[44] Thiophosphoryl chloride is also obtained by the interaction of thiophosphoryl nitride with hydrogen chloride[118]:

$$PNS + 4HCl \rightarrow PSCl_3 + NH_4Cl$$

Several preparations of radioactive thiophosphoryl chloride have been described. Thus $^{31}P^{35}SCl_3$,[45–6] $^{32}P^{32}SCl_3$[47–8] and $^{32}P^{35}SCl_3$,[49] have all been prepared by interaction of appropriately labelled sulphur and phosphorus trichloride. Neutron irradiated phosphorus trichloride contains $^{31}P^{35}SCl_3$ and $^{32}P^{35}SCl_3$, the radioisotopes being formed by the $^{31}P(n,\gamma)^{32}P$ and $^{35}Cl(n,p)^{35}S$ reactions.[50–1] Less than 2% exchange takes place in $S/P^{35}SCl_3$ and $S_2Cl_2/P^{35}SCl_3$ mixtures,[51] but 60% exchange of $^{32}P$ takes place between $H^{32}PO_4$ and $PSCl_3$ in 60 hr. at 150°C.[52]

## PHYSICAL PROPERTIES

Thiophosphoryl chloride exists in two solid forms. When warmed the $\alpha$-form, f.p. $-40{\cdot}8 \pm 0{\cdot}2$°C., is transformed with evolution of heat to the $\beta$-form, f.p.

$-36{\cdot}2 \pm 0{\cdot}2$°C.[3] A redistilled specimen of the liquid had b.p. 125·0°C., $n_D^{25}$ 1·5432, $d_4^{25}$ 1·6271.[53] Other values ($n_D^{20}$ 1·5554, $d_4^{20}$ 1·6369[54]) seem in better accord with previous determinations (Mellor, VIII, 1074, 1075) and lead to a value of $MR_L$ 33·25 close to that obtained by summing the bond refractivities P–Cl = 8·856, P=S = 6·866.[55] The observed (263·63) and calculated (259·97) bond refraction constants, $MR_E$,[55–6] are also in good agreement.

Values of the density and viscosity of thiophosphoryl chloride at various temperatures are tabulated below:

| $d_4^t$ (g./c.c.) | $t$ (°C.) | $\eta$ (centipoise) |
|---|---|---|
| 1·734 | −30·4 | 2·627 |
| 1·703 | −20·4 | 2·102 |
| 1·687 | −10·0 | 1·741 |
| 1·679 | −5·4 | 1·605 |
| 1·673 | 0·0 | 1·496 |
| 1·621 | +25·0 | 1·017 |
| 1·590 | +45·0 | 0·806 |
| 1·559 | +65·0 | 0·665 |
| 1·542 | +75·0 | 0·611 |
| 1·531 | +85·0 | 0·569 |
| 1·513 | +98·5 | 0·519 |

The complex viscosity behaviour of the chloride near its melting point is surprising, in view of the simple behaviour of $PCl_3$ and $POCl_3$ under similar conditions. The ratio of the energy of vaporization to the activation energy for viscous flow is anomalously high at higher temperatures, and it has been suggested that both these phenomena can be explained by evoking an easy flow process for the approximately spherical $PSCl_3$ molecule in the "normal" region.[119]

The relative molar magnetic rotivity[57] of thiophosphoryl chloride $[\Omega]_M$ for light of wave-length 5460 A. at 20°C. is $676 \times 10^{-2}$ min. and the corresponding molar magnetic rotation ($[\rho]_M$) is $944 \times 10^{-2}$ min. The contribution of the sulphur atom to magnetic rotation, $\Delta[\rho]_M = \rho PSCl_3 - \rho PCl_3$ is positive ($157 \times 10^{-2}$ min.).[54]

Liquid thiophosphoryl chloride is miscible with benzene, carbon tetrachloride, carbon disulphide and chloroform.[40] Although its donor properties towards antimony(V) chloride and tin(IV) chloride are inferior to those of phosphoryl chloride,[58] it is nevertheless a powerful solvent for Lewis acids as can be seen from Table IV.

*Table IV.—Solubility of Inorganic Halides in Thiophosphoryl Chloride*

| Halide | Solubility* | Colour of solution |
|---|---|---|
| $AlCl_3$ | 30·65 | light yellow |
| $SnCl_4$ | miscible | colourless |
| $SbCl_3$ | 125·3 | colourless |
| $TiCl_4$ | miscible | yellow |
| $FeCl_3$ | 7·26 | greenish-red |
| $AsCl_3$ | miscible | colourless |
| $BiCl_3$ | 0·52 | colourless |
| $BCl_3$ | miscible | colourless |
| $SbCl_5$ | moderate | — |
| $ZrCl_4$ | slight | — |
| $TeCl_4$ | slight | — |

* g./100 g. $PSCl_3$ at 35°C. where known.

The compounds $AlCl_3$,$PSCl_3$ (yellowish, m.p. 115°C. (decomp.)) and $SbCl_3$,$PSCl_3$ (red-brown, m.p. 101°C. (decomp.)) separate from saturated solution. Lithium, sodium, potassium, ammonium and barium chlorides are all soluble to less than 0·1%.

Dimethylaniline and γ-picoline are very soluble in the solvent, quinoline, pyridine and α- and β-picoline moderately soluble. By neutralization of the appropriate solvo-acids and bases the complexes shown in Table V were obtained.[59] The authors assume from this that thiophosphoryl chloride ionizes in the sense:

$$PSCl_3 \rightleftharpoons PSCl_2^+ + Cl^-$$

This is supported by a study of the electrolysis of solutions of radioactive iron(III) chloride in thiophosphoryl chloride. Unlike phosphoryl chloride where a complex iron-containing cation was observed, thiophosphoryl chloride ionized ferric chloride in the sense[120]:

$$PSCl_3 + FeCl_3 \rightarrow [PSCl_2^+][FeCl_4^-]$$

*Table V.—Complexes Resulting from Reactions in Thiophosphoryl Chloride*

| Complex | Colour | m.p. °C. (uncorr.) |
|---|---|---|
| $(C_9H_7NPSCl_2)(SbCl_6)$ | brown | 150–3 |
| $(C_5H_5NPSCl_2)(SbCl_6)$ | brown | 120–2 (decomp.) |

| $(\alpha\text{-}C_6H_7N)_2PSCl_3SnCl_4$ | pale yellow | 160–2 |
| $(\gamma\text{-}C_6H_7N)_2PSCl_3SnCl_4$ | white | 180 |
| $C_9H_7NPSCl_3TiCl_4$ | orange red | 210–5 |
| $(C_5H_5N)_2PSCl_3TiCl_4$ | yellow | 175–9 (decomp.) |

The structure of the thiophosphoryl chloride molecule has been determined by electron diffraction[13] and microwave spectroscopy,[5] the results being given in Table I. The $C_{3v}$ symmetry exhibited by the molecule is in accord with the Raman spectrum which has been observed by several authors. These observations have been collated and used to calculate values of the heat content, entropy, free energy and heat capacity for the ideal gaseous state at 1 atm. pressure[16] (see Table VI). These are in broad agreement with previous data,[60–1] based on an earlier structure determination.[13]

*Table VI.—Thermodynamic Data for Thiophosphoryl Chloride*

| $T$°K. | $\dfrac{H^\circ - E^\circ}{T}$ | $-\dfrac{G^\circ - E^\circ_0}{T}$ | $S^\circ$ | $C^\circ_p$ |
|---|---|---|---|---|
| 200 | 12·78 | 59·48 | 72·53 | 18·57 |
| 250 | 14·12 | 62·75 | 76·87 | 20·28 |

| 1000 | 21·58 | 87·95 | 109·54 | 25·31 |

A thermochemical study of the aluminium chloride catalyzed addition of sulphur to phosphorus(III) chloride led to a value of −79·2 kcal./mole for the heat of formation of liquid thiophosphoryl chloride at 25°C. From this a value of 61–70 kcal./mole was deduced for the heat of dissociation of the P═S bond, a value significantly lower than those suggested by earlier workers.[121]

The infra-red spectrum of thiophosphoryl chloride has also been reported by several authors.[24, 62–3] The three fundamental frequencies, 430, 540 and 753 cm.$^{-1}$, are in good agreement with the corresponding Raman values[16] and in the vapour spectrum two of the fundamentals show contours characteristic of the 'parallel' bands of a 'symmetrical-top' molecule.[62]

The infra-red absorption spectrum of a mixture of thiophosphoryl chloride and carbon disulphide exhibits a system of bands due to simultaneous transitions with some frequencies of both molecules. This molecular 'simultaneous transition spectrum' is analogous to the Raman spectrum but shifted to higher frequencies by the 1515 cm.$^{-1}$ of the $\nu_3$ carbon disulphide band. It is limited by the transparency region of carbon disulphide (1500–2100 cm.$^{-1}$) to molecular frequencies between *ca.* 160 and 500 cm.$^{-1}$ The three simultaneous transition frequencies observed for thiophosphoryl chloride[64] (168, 249, 430 cm.$^{-1}$) agree well with Raman data[16] (169, 247, 431 cm.$^{-1}$).

The polarization of thiophosphoryl chloride in benzene or heptane solutions at infinite dilution is 74·3 and the dipole moment of the molecule 1·41 D., whence the P–S bond moment is calculated as 2·5 D.[53] (2·23 D.[65]). The force constant of the P–S bond has been calculated as $5{\cdot}36 \times 10^5$ dynes/cm.[66–7] (see also reference 68). On the basis of Raman data the P–S bond order is calculated as 1·57[69] from the equation: Bond order $(N) = 0{\cdot}61(f_N/f_1) + 0{\cdot}37$, where $f_1$ is given by the 'Product rule'.[70]

The $^{31}$P nuclear magnetic resonance spectrum of thiophosphoryl chloride shows a chemical shift of −28·8 p.p.m. referred to 85% phosphoric acid[71–2]; earlier workers[73–4] reported slightly higher values.

### CHEMICAL PROPERTIES

Thiophosphoryl chloride does not attack nichrome or mercury at room temperature, but reacts with mercury when heated. It is stable in moist air, but hydrolyzes slowly in potassium hydroxide solution. Antimony(III) fluoride causes successive replacement of the chlorine atoms by fluorine.[3] Other inorganic fluorides (sodium fluoride, potassium fluorosulphinate) have also been used[6–8] (see page 534), although nitrosyl fluorosulphinate does not react.[75] The action of dry oxygen on thiophosphoryl chloride was negligible over 26 years, as measured by pressure decrease or sulphur deposition.[76] Sulphur trioxide oxidizes the chloride with liberation of sulphur.[59]

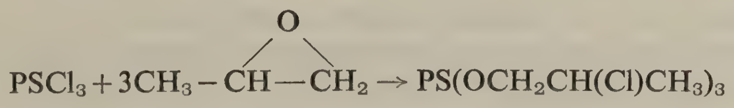
Thiophosphoryl chloride reacts with most aliphatic alcohols giving alkyl phosphorodichloridothionates[77]:

$$PSCl_3 + ROH \rightarrow ROPSCl_2 + HCl$$

The reaction can also be applied to unsaturated alcohols (allyl alcohol[38]), but the interaction of 1,3-dichloropropan-2-ol and thiophosphoryl chloride at 150°C. gives no recognizable products.[78] In the presence of sodium hydroxide,[79] or by the use of aluminium alkoxides,[80] dialkyl phosphorochloridothionates are obtained:

$$2ROH + PSCl_3 + 2NaOH \rightarrow (RO)_2PSCl + 2NaCl + 2H_2O$$
$$3PSCl_3 + 2Al(OR)_3 \rightarrow 3(RO)_2PSCl + 2AlCl_3$$

Olefin oxides react with thiophosphoryl chloride to give tris-2-chloroalkyl phosphorothionates,[81] e.g.



$$PSCl_3 + 3CH_3-\overset{O}{CH-CH_2} \rightarrow PS(OCH_2CH(Cl)CH_3)_3$$

Certain tervalent phosphorus compounds, such as phenyldichlorophosphine, triaryl phosphites, diaryl phosphorochloridites[82] or aryl phosphorodichloridites,[83] will abstract the sulphur from thiophosphoryl chloride yielding the corresponding thionate esters and phosphorus trichloride, e.g.:

$$(PhO)_3P + PSCl_3 \rightarrow (PhO)_3PS + PCl_3$$

Certain alkyl esters of pentavalent phosphorus, on the other hand, undergo dealkylation[84]:

$$(R_2N)_2POOR' + PSCl_3 \rightarrow (R_2N)_2POOPSCl_2 + R'Cl$$

The reaction of Grignard reagents with thiophosphoryl chloride unexpectedly gives tetra-alkyldiphosphine disulphide[85] together with traces of trialkylphosphine sulphide and other materials.[86]

### USES OF THIOPHOSPHORYL CHLORIDE

The uses of thiophosphoryl chloride have been reviewed.[87] It is an intermediate in the manufacture of organophosphorus insecticides, especially parathion (diethyl *p*-nitrophenyl phosphorothionate). Lubricant[88–9] and fuel additives[90] based on thiophosphoryl chloride have also been proposed, and its reaction products with polystyrene are claimed as ion exchange resins.[91] The vapour of thiophosphoryl chloride is very effective in reducing the velocity of propagation of laminar flames of hydrogen or hydrocarbon–air mixtures.[92]

## Thiophosphoryl Bromochlorides

Thiophosphoryl bromodichloride, $PSCl_2Br$, and thiophosphoryl dibromochloride, $PSClBr_2$, are formed by the equilibration of mixtures of thiophosphoryl bromide and chloride at temperatures around 200°C. for several hours.[25, 63, 72] A quantitative study of the system by nuclear magnetic resonance spectroscopy shows that its behaviour approaches that calculated for completely random reorganization. The system can be defined by two equations:

$$2PSCl_2Br \rightleftharpoons PSCl_3 + PSClBr_2 \qquad (1)$$

$$2PSClBr_2 \rightleftharpoons PSBr_3 + PSCl_2Br \qquad (2)$$

for which equilibrium constants $K_1$ and $K_2$ can be written:

$$K_1 = \frac{[PSCl_3][PSClBr_2]}{[PSCl_2Br]^2}$$

$$K_2 = \frac{[PSBr_3][PSCl_2Br]}{[PSClBr_2]^2}$$

For the completely random reorganization of a mixture of bromide and chloride in which the Cl/Br atomic ratio is $p/q$ (where $p+q=1$) the probability of a phosphorus atom being attached to $n$ chlorine and $3-n$ bromine atoms is

$$P_{3(n)} = \frac{3!}{n!(3-n)!}\, p^n q^{3-n}$$

By substitution in the equation for $K_1$ and $K_2$ above, $p$ and $q$ are eliminated, giving

$$K_1 = K_2 = \tfrac{1}{3}$$

The experimentally observed values were $K_1 = 0{\cdot}297$, $K_2 = 0{\cdot}419$.

The optimum yields of bromodichloride or dibromochloride are obtained by heating thiophosphoryl chloride and thiophosphoryl bromide in a 2:1 or 1:2 mole ratio, respectively, according to the equations:

$$2PSCl_3 + PSBr_3 \rightleftharpoons 3PSCl_2Br \qquad (3)$$

$$PSCl_3 + 2PSBr_3 \rightleftharpoons 3PSClBr_2 \qquad (4)$$

The corresponding equilibrium constants of formation, $K_{PSCl_2Br}$ and $K_{PSClBr_2}$ are related to $K_1$ and $K_2$:

$$K_{PSCl_2Br} = \frac{1}{K_1{}^2K_2}$$

$$K_{PSClBr_2} = \frac{1}{K_2{}^2K_1}$$

i.e. in the ideal case the formation constant should have the value 27. From the experimental values for $K_1$ and $K_2$, $K_{PSCl_2Br} = 27{\cdot}5$ and $K_{PSClBr_2} = 20{\cdot}8$, i.e. relatively the bromodichloride is stable and the dibromochloride unstable with respect to trichloride and tribromide. Equilibrated mixtures corresponding to equations (3) and (4) above contain 46% of thiophosphoryl bromodichloride and 42% of thiophosphoryl dibromochloride respectively.[72] Later work by the same authors[93] has shown that similar reorganization occurs in heated mixtures of phosphoryl bromide and thiophosphoryl chloride to give all the eight possible phosphoryl/thiophosphoryl bromide/chlorides. The equilibrium constants derived are in satisfactory agreement with the earlier values. Similar results are obtained by the addition of sulphur to a mixture containing phosphorus dibromochloride and bromodichloride,[63] or by heating phosphorus trichloride and tribromide with sulphur at 190°C. for 5 hr.[25] An alternative, less attractive, method of preparation is the action of hydrogen sulphide on a heated mixture of phosphorus pentachloride and pentabromide.[25]

Thiophosphoryl bromodichloride and dibromochloride are isolated from such mixtures by fractional distillation (under reduced pressure to avoid decomposition). They are oily fuming liquids, with the properties given in Table VII.

*Table VII.—Physical Properties of Thiophosphoryl Bromochlorides*[63]

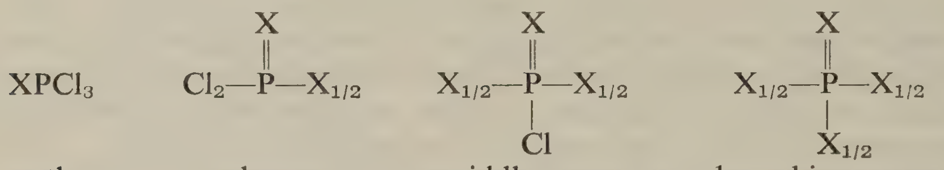
| | $PSCl_2Br$ | $PSClBr_2$ |
|---|---|---|
| Colour | colourless | pale yellow |
| B.p. (°C.) | 154–6°/731 mm.<br>45°/13 mm. | 170–175°/755 mm. (decomp.)<br>67°/13–14 mm.<br>61°/11–12 mm. |
| $d_4^{20}$ | 2·037 | 2·407 |
| $n_D^{20}$ | 1·6107 | 1·6660 |
| $^{31}P$ NMR chemical shifts* | +14·5 | +61·4 |

* p.p.m. referred to 85% $H_3PO_4$.[72]

The structure of the thiophosphoryl bromochlorides has not been determined. The Raman spectrum of thiophosphoryl bromodichloride shows only seven absorptions: as in the case of thiophosphoryl dichlorofluoride the similarity in mass of chlorine and sulphur leads to a pseudo-$C_{3v}$ symmetry where the deformation vibrations are concerned. For similar reasons the nine absorption frequencies exhibited by thiophosphoryl dibromochloride have an arrangement suggesting $C_{2v}$ rather than $C_{1h}$ symmetry.[25] The infra-red spectra,[63] with their three fundamental frequencies respectively at 740, 531 and 490 cm.$^{-1}$ ($PSCl_2Br$) and 730, 506 and 436 cm.$^{-1}$ ($PSClBr_2$), are in good agreement with the Raman data. The $^{31}P$ nuclear magnetic resonance chemical shifts are given in Table VII.[72]

## Polythiophosphoryl Chlorides

Apart from the thiopyrophosphoryl chloride, $P_2O_2SCl_4$, described by Besson (Mellor, VIII, 1023), there has been little study of compounds in which one or more of the oxygen atoms of pyrophosphoryl chloride are replaced by sulphur. A considerable advance was made by the demonstration of dithionopyrophosphoryl chloride, $Cl_2P(S)OP(S)Cl_2$, amongst the products obtained by heating together phosphoryl and thiophosphoryl chlorides, phosphorus pentoxide and tetraphosphorus decasulphide in various proportions.[100] The theory of 'random reorganization', first developed to explain the behaviour of phosphate melts,[108] can be applied to the halide system.[100] It states that, at a sufficiently high temperature, the groups attached to a given phosphorus atom exchange with those attached to other phosphorus atoms, each phosphorus retaining its co-ordination number of 4. The system can be described in terms of four elementary structures:

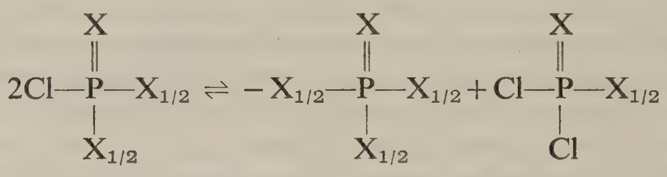


$$\mathrm{XPCl_3} \qquad \mathrm{Cl_2{-}\overset{\overset{X}{\|}}{P}{-}X_{1/2}} \qquad \mathrm{X_{1/2}{-}\underset{\underset{Cl}{|}}{\overset{\overset{X}{\|}}{P}}{-}X_{1/2}} \qquad \mathrm{X_{1/2}{-}\underset{\underset{X_{1/2}}{|}}{\overset{\overset{X}{\|}}{P}}{-}X_{1/2}}$$

ortho | end group | middle group | branching group

*o* | *e* | *m* | *b*

(where X in this case represents either oxygen or sulphur) and be completely defined by the two equilibria:

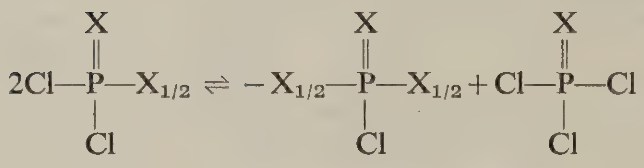


$$\mathrm{2Cl{-}\underset{\underset{X_{1/2}}{|}}{\overset{\overset{X}{\|}}{P}}{-}X_{1/2}} \rightleftharpoons \mathrm{-X_{1/2}{-}\underset{\underset{X_{1/2}}{|}}{\overset{\overset{X}{\|}}{P}}{-}X_{1/2} + Cl{-}\underset{\underset{Cl}{|}}{\overset{\overset{X}{\|}}{P}}{-}X_{1/2}}$$

$$2m = b + e$$

$$\left(K_1 = \frac{[b][e]}{[m]^2}\right)$$

and



$$\mathrm{2Cl{-}\underset{\underset{Cl}{|}}{\overset{\overset{X}{\|}}{P}}{-}X_{1/2}} \rightleftharpoons \mathrm{-X_{1/2}{-}\underset{\underset{Cl}{|}}{\overset{\overset{X}{\|}}{P}}{-}X_{1/2} + Cl{-}\underset{\underset{Cl}{|}}{\overset{\overset{X}{\|}}{P}}{-}Cl}$$

$$2e = m + o$$

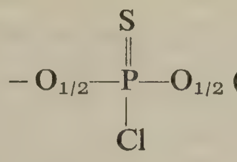
$$K_2 = \frac{[m][o]}{[e]^2}$$

Obviously the molecular complexity of the system depends on the ratio of chlorine to phosphorus atoms, $[Cl]/[P] = R$. Thus in the simple oxygen system (viz., $P_4O_{10}/POCl_3$), when $R = 3$, only orthophosphoryl chloride molecules, $POCl_3$, are present. By reorganization of mixtures having progressively decreasing values of $R$ some pyrophosphoryl chloride is first formed, followed by straight chain, branched chain and cyclic polymers of increasing molecular weight, until at $R = 1{\cdot}20$ a rubbery high polymer finally results.

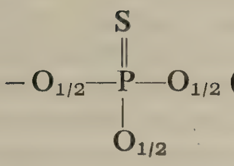
As might be expected, the behaviour of the mixed sulphur/oxygen system is more complex. Equilibration of mixtures of $POCl_3$, $PSCl_3$, $P_4O_{10}$ and $P_4S_{10}$ ($R = 1{\cdot}50$ to $2{\cdot}00$) in sealed tubes at 230°C. for ca. 65 hr. gave homogeneous liquid products only when the molar ratio of sulphur to phosphorus was 1. Compositions containing higher or lower proportions of sulphur were solid–liquid mixtures. The liquid portions of such mixtures were examined by nuclear magnetic resonance spectroscopy. When only oxygen was present ($[S]/[P] = 0$) four main $^{31}P$ NMR absorptions were observed, having chemical shifts in the range $-2$ to $+56$ p.p.m. relative to 85% $H_3PO_4$. As oxygen was progressively replaced by sulphur this group of absorptions diminished in intensity and was supplanted by a group in the range $-30$ to $+2$ p.p.m., the change being complete at $[S]/[P] = 1$. At still higher sulphur contents, the second group of absorptions was in its turn supplanted by a third group in the range $-30$ to $-65$ p.p.m. Some of these absorptions were assigned to individual structural units.

Thus a resonance at ca. −29 p.p.m. due to $PSCl_3$[71] was overlain by one at ca. −28 p.p.m., thought to be due to the end group $Cl_2P(S)-O_{1/2}$. Other tentative assignments included:

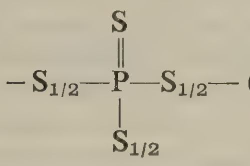
$Cl_2P(O)-S_{1/2}$ (−10 p.p.m.),



$-O_{1/2}-\underset{\underset{Cl}{|}}{\overset{\overset{S}{\|}}{P}}-O_{1/2}$ (−20 p.p.m.),



$-O_{1/2}-\underset{\underset{O_{1/2}}{|}}{\overset{\overset{S}{\|}}{P}}-O_{1/2}$ (−2 p.p.m.), and



$-S_{1/2}-\underset{\underset{S_{1/2}}{|}}{\overset{\overset{S}{\|}}{P}}-S_{1/2}-$ (−60 p.p.m.)[100],

By high vacuum distillation of a mixture having S/P mole ratio = 1 and Cl/P mole ratio 1·8, dithionopyrophosphoryl chloride, $Cl_2P(S)OP(S)Cl_2$, was isolated. The NMR spectrum of the distillate showed that 99% of the total phosphorus was present in a structure resonating at ca. −28 p.p.m. and the analysis and molecular weight determinations were in reasonable agreement with the structure postulated.[100] A subsequent attempt to make dithionopyrophosphoryl chloride by the interaction of tetraphosphorus hexaoxytetrasulphide with phosphorus pentachloride or with phosphorus trichloride and chlorine gave only the monothiono compound (see later), but dithionopyrophosphoryl chloride resulted in 5–10% yield from the interaction of commercial phosphorus pentasulphide (which contains some oxygen) with 10 molar proportions of thiophosphoryl chloride or 1 molar proportion of phosphoryl chloride at 200–240°C. for 2–3 days.[109]

The redistilled chloride had b.p. 35–38°C./0·2 mm., $n_D^{25}$ 1·5810, $d_4^{25}$ 1·731, $MR_L$ 54·3 (cf. dithionopyrophosphoryl chloride 55·4, thiolothionopyrophosphoryl chloride ($Cl_2P(O)SP(S)Cl_2$) 56·4. The infra-red absorption spectrum was assigned as follows: 935, 908 cm.$^{-1}$ (P–O–P), 764, 758 cm.$^{-1}$ (P=S), 567, 472 cm.$^{-1}$ (Cl in $-PSCl_2$). Weak absorptions at 1320 and 610 cm.$^{-1}$ were possibly due to the presence of some thionopyrophosphoryl chloride. A strong absorption at 805 cm.$^{-1}$ was unexplained. The NMR spectrum showed a single resonance at −28·4 p.p.m.[109] Thionopyrophosphoryl chloride, $Cl_2P(O)OP(S)Cl_2$, has been prepared in a similar manner, by the reorganization of mixtures of phosphorus pentoxide and thiophosphoryl chloride[109–10], of tetraphosphorus decasulphide and phosphoryl chloride[109] or of tetraphosphorus hexaoxytetrasulphide and phosphorus pentachloride.[109] The compound is distilled off under high vacuum ($10^{-3}$ mm.), and can then be redistilled with little or no decomposition at somewhat higher pressure (b.p. 34–37°C./0·2 mm., 93°C./11 mm., 99–100°C./15 mm.). It is a colourless oily liquid $n_D^{20}$ 1·5369,[110] $n_D^{25}$ 1·5340, $d_4^{25}$ 1·742.[109] A molecular weight determination shows it to be non-associated in benzene solution. The infra-red spectrum shows absorptions at 1315 cm.$^{-1}$ (P=O), 751 cm.$^{-1}$ (P=S), 934, 912 cm.$^{-1}$ (P–O–P), 652 cm.$^{-1}$ ((S)P–Cl) and 608 cm.$^{-1}$ ((O)P–Cl).[110] In another preparation the spectrum was similar except that a doublet was observed at 764 and 758 cm.$^{-1}$ and a strong unexplained absorption at 805 cm.$^{-1}$ [109] The NMR spectrum of a substantially pure specimen of thionopyrophosphoryl chloride showed two strong resonances at +10·8 p.p.m. and −30·3 p.p.m.[109] approximating to values previously assigned[100] to the $Cl_2P(O)O$ and $Cl_2P(S)O$ groups, respectively. Thionopyrophosphoryl chloride is soluble in benzene, *cyclo*hexane, carbon tetrachloride, chloroform, carbon disulphide, ether, and in other phosphorus halides. It is converted by ethanol and pyridine to the known tetraethyl thionopyrophosphate,

$$(C_2H_5O)_2P(S)OP(O)(OC_2H_5)_2$$ [110]

A compound analyzing approximately for dithiotetraphosphoryl hexachloride ($P_4O_5S_2Cl_6$) has been claimed as a by-product in the preparation of thionopyrophosphoryl chloride. A value of 477 (calc. 481) was given for the molecular weight.

The colourless viscous liquid had b.p. 82°C./$10^{-3}$ mm. (decomp.), $n_D^{20}$ 1·5533, and the infra-red spectrum gave evidence for the presence of P=O, P=S, P–Cl and P–O–P groups. However, no clearly defined organic derivatives could be isolated[110] and since a repetition of the work gave a mixture with a varying refractive index,[109] further study is required before the existence of dithiotetraphosphoryl hexachloride can be regarded as definitely established.

The thiolopyrophosphoryl chloride, $Cl_2P(O)SP(O)Cl_2$, described by Besson (*loc. cit.*) also needs further investigation. The reaction of phosphoryl chloride under reflux with hydrogen sulphide or zinc sulphide, or in a sealed tube at 150–200°C. with zinc or barium sulphide, gave none of the required product. Phosphoryl chloride reacted with hydrogen sulphide in an autoclave (100°C. for 8 days) to give mixtures of varying proportions of thionopyrophosphoryl chloride, pyrophosphoryl chloride and higher condensed chlorides.[109] The preparation of thiolopyrophosphoryl chloride has been claimed by other authors[100] but no details were given, and in view of the statement in the same paper that 'sulphur preferentially locates in the non-bridging position in poly(phosphoryl–thiophosphoryl) chloride equilibrium mixtures' it seems likely that thiolopyrophosphoryl chloride, even if it exists, will readily decompose on distillation. This is in accord with the observation that tetra-alkyl thiopyrophosphates exist in the thiono- and not in the thiolo- form.[111] Attempts to isolate trithiopyrophosphoryl chloride by the reaction of tetraphosphorus decasulphide with thiophosphoryl chloride have been similarly unsuccessful.[109] To summarize, therefore, it seems that all condensed thiopyrophosphoryl chlorides, even the mono- and dithiono- compounds which are the best established, readily decompose or rearrange on heating, yielding a wide range of products in mobile equilibrium with one another.

## THIOPHOSPHORYL BROMIDES

### Thiophosphoryl Bromide, $PSBr_3$

PREPARATION

The interaction of phosphorus pentabromide and tetraphosphorus decasulphide (Mellor, VIII, 1076) has been recommended for the laboratory preparation of thiophosphoryl bromide.[23] The product is purified by distillation under reduced pressure and washing with very dilute aqueous potassium bromide. The bromination of tetraphosphorus trisulphide or heptasulphide, however, yields a mixture of thiophosphoryl bromide, diphosphorus hexathiodibromide and diphosphorus pentathiotetrabromide[99, 107] (see pages 547–8). Later workers claim that the addition of excess sulphur to phosphorus tribromide is a superior procedure. The reaction is carried out under nitrogen at 130°C. and the distilled product recrystallized from dry ligroin at −30°C.[63] Aluminium bromide has been claimed to catalyze the addition.[94] Thiophosphoryl bromide also results from the thiohydrolysis of phosphorus pentabromide[12]:

$$PBr_5 + H_2S \rightarrow PSBr_3 + 2HBr$$

and, in small quantities, from the reorganization of mixtures of phosphoryl bromide and thiophosphoryl chloride.[93] $^{32}P^{32}SBr_3$ has been prepared by the addition of bromine to a suspension of red phosphorus ($^{32}P$), sulphur and aluminium chloride, in carbon disulphide.[95]

PHYSICAL PROPERTIES

Thiophosphoryl bromide is a pale yellow crystalline solid with a pungent odour, m.p. 38·2°C., b.p. 212°C. (decomp.), 125–130°C./25 mm., 95–96°C./18 mm.[23, 63] The crystals are cubic with $a = 11{\cdot}03$ A. and there are 8 molecules in the unit cell. The space group is $T_h^6$-*Pa*3 and the general structure is similar to that of tin(IV) iodide, with P and S lying on 3-fold axes. The measured density is 2·97 (calc. 2·99) g./c.c.[96] The vapour pressure of the solid between 0 and 36·2°C. is given by the relation $\log p = -(3196{\cdot}2/T) + 10{\cdot}105$ mm. and that of the liquid between 40·4 and 80·6°C.

by $\log p = -(2614{\cdot}9/T) + 8{\cdot}3383$ mm.[97] Values for the heat content, standard free energy and standard entropy changes involved in various phase transitions, and quoted by the same authors, are given in Table VIII.

*Table VIII.—Thermodynamic Data for Phase Changes in Thiophosphoryl Bromide*

| Phase change | $\Delta H$ kcal./mole | $\Delta G$ g.-cal./mole | $\Delta G_{298{\cdot}1}$ kcal./mole | $\Delta S_{298{\cdot}1}$ kcal./mole |
|---|---|---|---|---|
| $[PSBr_3]_s \rightarrow PSBr_3$ | 14·62 | 14621–46·208 $T$ | 0·850 | 46·20 |
| $[PSBr_3]_l \rightarrow PSBr_3$ | 12·09 | 12089–38·155 $T$ | 0·715 | 38·15 |
| $[PSBr_3]_s \rightarrow [PSBr_3]_l$ | 2·53 | 2532–8·053 $T$ | 0·135 | 8·05 |

The liquid dissolves sulphur and is itself soluble in phosphorus trichloride, chloroform, ether, carbon disulphide or ligroin. The solid may be recrystallized from the last two solvents.

The molecular arrangement in crystalline thiophosphoryl bromide is described above, and the structure of the molecule itself, as deduced from *X*-ray and electron diffraction measurements, is given in Table I.[12, 96] The Raman spectrum[25] shows the six frequencies corresponding to the expected $C_{3v}$ symmetry. The three fundamental infra-red absorptions,[63] 723, 472 and 321 cm.$^{-1}$, occur at a higher frequency than the respective Raman absorptions (718, 438 and 299 cm.$^{-1}$). Later authors place the six fundamental absorptions at 726, 431, 299, 175, 165 and 133 cm.$^{-1}$, and hence deduce values for reduced enthalpy, reduced free enthalpy, entropy and molar heat capacity at 100° intervals from 200–2000°K.[122] The $^{31}$P chemical shift in the nuclear magnetic resonance spectrum is 111·8 p.p.m. referred to 85% phosphoric acid.[71–2]

The dielectric constants of pure thiophosphoryl bromide are $\epsilon = 3{\cdot}7$ (solid 18–38°C.) and $\epsilon = 6{\cdot}2$ (liquid 38–48·8°C.),[98] and the dipole moment 1·58 D. whence the moment of the P–S bond is calculated to be 2·00 D.[65]

### CHEMICAL PROPERTIES

Thiophosphoryl bromide reacts readily with ethanol, yet is only slightly attacked by cold water, and may even be steam distilled (with considerable loss).[23] The hydrate of composition $PSBr_3,H_2O$ reported by Michaelis[101] has been shown from its analysis and *X*-ray study to be impure thiophosphoryl bromide. The melting-point diagram of the system $PBr_3/PSBr_3$ shows no evidence of the compound $P_2SBr_6$.[102] It decomposes when heated but in contrast to earlier reports (Mellor, VIII, 1077) only phosphorus tribromide and sulphur are formed.[99] Thiophosphoryl bromide undergoes a ready exchange of sulphur or halogen when heated with certain other phosphoryl or thiophosphoryl halides.[72, 93] Cryoscopic measurements gave no evidence of interaction of thiophosphoryl bromide with tetraphosphorus decasulphide[99] though rearrangement is claimed to occur at higher temperatures.[100]

The action of antimony(III) fluoride on thiophosphoryl bromide yields a mixture of bromofluorides[4] (see page 534). Magnesium reacts with the bromide to give a sulphide $(PS)_n$ of indeterminate structure[103] (see page 419).

## Other Phosphorus Thiobromides

The thiobromides $P_2S_3Br_4$, $P_2SBr$ and $P_2SBr_6$, reported by Michaelis[101] (Mellor, VIII, 1077) have been reinvestigated.[102, 99] The melting-point diagrams of the systems $PBr_3/PSBr_3$ and $P_2S_5/PSBr_3$ show no evidence of the compounds $P_2SBr_6$ or $P_2S_3Br_4$.[102] However, the bromination of tetraphosphorus heptasulphide in cold carbon disulphide yields, besides phosphorus tribromide and thiophosphoryl bromide, two new crystalline thiobromides, diphosphorus hexathiodibromide, $P_2S_6Br_2$, and diphosphorus pentathiotetrabromide, $P_2S_5Br_4$. These are isolated by distilling off the carbon disulphide and taking up the residue in ether. Needle-like crystals of

$P_2S_6Br_2$ separate first, followed more slowly by nodules of $P_2S_5Br_4$. All operations must be carried out in a dry inert atmosphere.

The two thiobromides can be recrystallized unchanged from carbon disulphide, and their molecular weights have been determined ebullioscopically in this solvent. Diphosphorus hexathiodibromide, $P_2S_6Br_2$, has m.p. 118°C. (decomp.), density 1·82 g./c.c., mol. wt. 360 (calc. 414), and diphosphorus pentathiotetrabromide, $P_2S_5Br_4$, m.p. 90°C. (decomp.), density 1·99 g./c.c., mol. wt. 583 (calc. 542). The densities are lower even than those of the phosphorus sulphides (2·03–2·19 g./c.c.) and make an ionic structure improbable. The infra-red spectra show absorptions in the ranges 650–680 cm.$^{-1}$ and 450–520 cm.$^{-1}$, attributed to P=S and P–S–P structures, respectively.

An *X*-ray diffraction study shows that the crystal of $P_2S_6Br_2$ is tetragonal with space group $P\bar{4}2_1c$, $a=b=9{\cdot}79$ A., $c=11{\cdot}51$ A., $D_m=2{\cdot}53$ g./c.c. (flotation), $d_{calc}=2{\cdot}58$ g./c.c. The molecules contain a new type of 6-membered $P_2S_4$ ring with two S–S links (Fig. 1). The ring has a skew 'boat' configuration with P–Br = 2·07, P=S = 1·98, P–S = 2·10 and S–S = 2·03 A.[123]

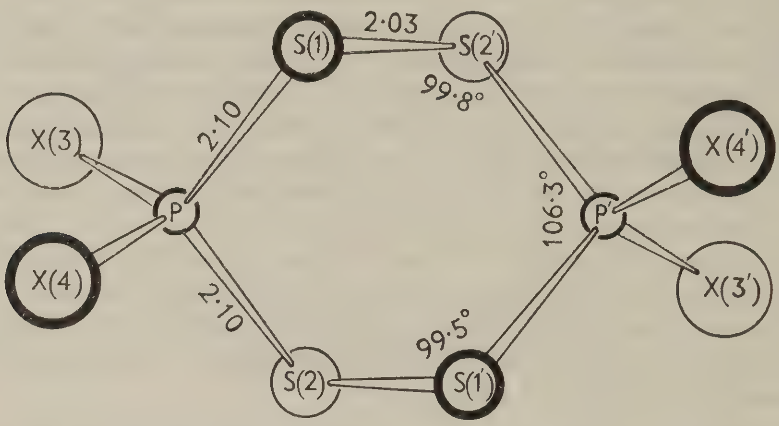


FIG. 1.—The molecule $P_2S_6Br_2$ as it appears in its averaged crystal setting, dimensions of the ring portion being shown. A crystallographic twofold axis relates primed with unprimed atoms. X represents a multiple atomic site ($\frac{1}{2}$Br + $\frac{1}{2}$S)

The thiobromides are decomposed at room temperature by polar solvents, such as acetonitrile, into thiophosphoryl tribromide and an insoluble residue of unknown composition. Thermal decomposition yields the same products together with phosphorus tribromide.[99]

## THIOPHOSPHORYL IODIDES

Thiophosphoryl iodide, $PSI_3$, is made by the slow reaction of phosphorus(III) iodide and sulphur in carbon disulphide at 10–15°C., or from phosphorus, sulphur and iodine (P:S:3I) in the same solvent at 0°C. Both reactions must be carried out in an inert atmosphere, and in the absence of light. In boiling carbon disulphide or benzene the former method yields tetraphosphorus heptasulphide and iodine.

Thiophosphoryl iodide crystallizes from carbon disulphide in brick-red or brownish red leaflets, m.p. 46–48°C. (decomp.). The compound is soluble in carbon disulphide, fairly soluble in aromatic hydrocarbons, carbon tetrachloride, and ether, and dissolves sparingly with decomposition in chloroform, 1,2-dichloroethane and petroleum ether. It is decomposed by light in a few hours at room temperature, with the formation of iodine, phosphorus(III) iodide and tetraphosphorus heptasulphide, but can be kept for longer periods in the dark at −20°C. Moisture also decomposes the compound, forming $H_2S$ and HI.

Raman and infra-red measurements give the characteristic frequencies 309, 321 and 673 cm.$^{-1}$: the symmetry is probably $C_{3v}$.[124]

Of the three phosphorus thioiodides described by Ouvrard and Dreschel (Mellor, VIII, 1079) tetraphosphorus trithiodi-iodide, $P_4S_3I_2$, and diphosphorus thiotetraiodide, $P_2SI_4$, have been confirmed by later workers.[104, 112] The interaction of equi-atomic proportions of phosphorus, sulphur and iodine does not give phosphorus dithiodi-iodide, $P_2S_2I_2$, but a mixture of tetraphosphorus trithiodi-iodide and phosphorus tri-iodide, $PI_3$, together with smaller amounts of tetraphosphorus heptasulphide, $P_4S_7$, red phosphorus and diphosphorus tetraiodide, $P_2I_4$.[104] Diphosphorus thiotetraiodide and diphosphorus dithiotetraiodide, $P_2S_2I_4$, are claimed as products under other conditions.[112] Tetraphosphorus trithiodi-iodide is also formed instead of the dithiodi-iodide by the action of hydrogen sulphide on phosphorus tri-iodide; tetraphosphorus heptasulphide is again a by-product. No reaction occurs between a melt of composition $P_4S_6$ and either iodine or phosphorus tri-iodide, under the mild conditions said by Ouvrard to yield diphosphorus dithiodi-iodide and diphosphorus thiotetraiodide, $P_2SI_4$.

Of the reactions previously claimed to give diphosphorus trithiodi-iodide, the thiohydrolysis of diphosphorus tetraiodide gives a product containing red phosphorus and phosphorus sulphides, while the action of iodine on tetraphosphorus trisulphide yields a mixture of heptasulphide and the trithiodi-iodide. The combination of the elements in the proportions 4P:3S:2I, however, gives an almost quantitative yield of the trithiodi-iodide. After recrystallization from carbon disulphide, the orange-yellow product has m.p. 120·5°C. (decomp.). At the temperature of liquid air it becomes pale yellow.

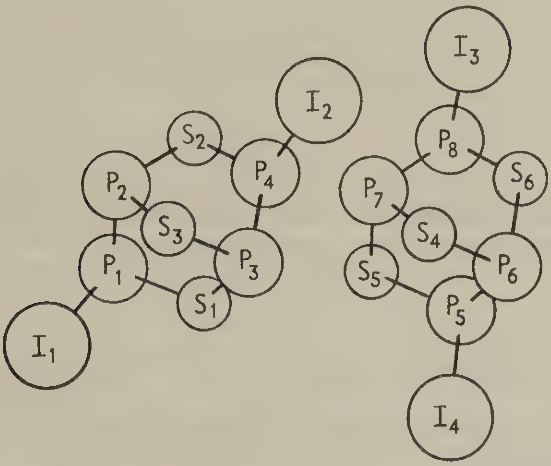

FIG. 2.—The molecular configuration of $P_4S_3I_2$ showing the two enantiomorphous molecules of the asymmetric unit

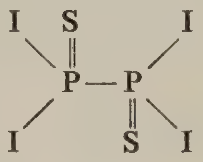
The structure of tetraphosphorus trithiodi-iodide has been determined by *X*-ray diffraction.[105] The crystals are triclinic with $a = 7{\cdot}31 \pm 0{\cdot}01$, $b = 7{\cdot}35 \pm 0{\cdot}01$, $c = 19{\cdot}61 \pm 0{\cdot}03$ A.; $\alpha = 94°\ 24'$, $\beta = 90°\ 10'$, $\gamma = 90°\ 55'$ (all $\pm 10'$). The observed density is $3{\cdot}0 \pm 0{\cdot}1$ g./c.c. (calculated for 4 molecules/unit cell 3·04 g./c.c.). The molecular structure, a remarkable one, is shown in Fig. 2.

The phosphorus and sulphur atoms are arranged in two 5-membered rings having a common P–S–P angle. In each ring there are two phosphorus atoms bonded together, the two pairs of phosphorus atoms being joined by three sulphur atoms. The iodine atoms, bonded to phosphorus atoms in different rings, are in a *cis* configuration with respect to the $P_4S_3$ skeleton. The average bond lengths are P–I $2{\cdot}48 \pm 0{\cdot}032$ A., P–P $2{\cdot}20 \pm 0{\cdot}04$ A. and P–S $2{\cdot}10 \pm 0{\cdot}04$ A.; the bond angles are S–P–S 105°, P–S–P 104° and P–P–S 102°, 91°. The small value of the last angle, of the type $P_1P_2S_2$, between the two 5-membered rings, gives rise to non-bonded approaches of the type $P_1S_2$ of 3·1 A., 0·6 A. lower than the sum of the van der Waals radii.[106] A further interesting feature of this structure is that the formation of tetraphosphorus trithiodi-iodide from tetraphosphorus trisulphide involves not only the breaking of a P–P bond, but also an exchange of position between phosphorus and sulphur atoms in the $P_4S_3$ molecule.

Little is known of the chemistry of tetraphosphorus trithiodi-iodide. It evolves hydrogen sulphide in moist air, though it is not visibly altered by exposure. Treatment with an excess of iodine decomposes it to tetraphosphorus heptasulphide and phosphorus tri-iodide,[107] a further example of the P–P and P–S bond mobility in such molecules.

A brief communication[112] describes the formation of diphosphorus dithiotetraiodide, $P_2S_2I_4$ (orange-red, m.p. 90–93°C. (decomp.)) and diphosphorus thiotetraiodide, $P_2SI_4$ (brick-red, m.p. 105–110°C. (decomp.)) by interaction of the elements in carbon disulphide with exclusion of light. Both thioiodides decompose on standing with formation of tetraphosphorus heptasulphide, phosphorus iodides and iodine, while with oxygen they yield a polymeric oxyiodide of empirical formula $P_3I_2O_6$. The preparation of diphosphorus dithiotetraiodide (orange, m.p. 93–94°C.) has been repeated, both by the above technique, and by the reaction of diphosphorus tetraiodide with sulphur in carbon disulphide. The preparation, isolation and determination of the melting point and infra-red spectrum, were carried out in the dark under dry helium. The infra-red spectrum was compatible with the structure



and this was confirmed by the $^{31}P$ nuclear magnetic resonance spectrum, which showed a single absorption at $-106$ p.p.m. (85% $H_3PO_4$).[125]

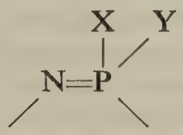
SECTION XVIII

# PHOSPHONITRILIC DERIVATIVES

BY N. L. PADDOCK

Phosphonitrilic derivatives contain the formally unsaturated grouping



The class comprises both linear and cyclic members, and X and Y may be the same or different radicals. Several reviews of phosphonitrilic chemistry are available.[1–6, 158, 170, 185–6, 217] Phosphonitrilic derivatives are so named because complete hydrolysis of the halides gives ammonium phosphate, analogous to the formation of the ammonium salts of organic acids by the hydrolysis of their nitriles. The name is somewhat misleading, however, because monomers containing the P≡N group have not yet been isolated. According to the 1957 IUPAC rules,[7] these substances should be regarded as nitrides, but such a name gives no clue to their structure. They have been more recently described as phosphazenes,[34] which at least implies unsaturation, and recognizes the relation of the series to organic ring systems. The older nomenclature will be used here, as being more widely understood.

## FORMATION OF LINEAR AND CYCLIC SYSTEMS

Some phosphonitrilic chlorides are formed in the reaction with chlorine of phosphorus nitrides[8–9] or thionitride[199] at 800°, and the cyclic trimeric and tetrameric fluorides $(PNF_2)_{3,4}$ can be prepared[10] by the action of nitrogen trifluoride or trifluoromethyl sulphur pentafluoride on the phosphorus nitride, $P_3N_5$, at 700°. The trimeric chloride is also a product of the reaction between sulphur nitride, $S_4N_4$, thionyl chloride and phosphorus trichloride.[11]

The use of azides to prepare phosphonitrilic compounds is comparatively recent.[158] The general reaction is:

$$R_2PX + MN_3 \rightarrow \tfrac{1}{n}(NPR_2)_n + N_2 + MX$$

where X is a halogen and M is an alkali metal, preferably lithium. In published examples R = Br, Ph, Cl,[159, 254] or $CF_3$[160]; the substituents on the phosphorus atom can be different and the method is probably widely applicable. Thus the reaction of sodium azide with a mixture of diphenylchlorophosphine and phenyldichlorophosphine gives an appreciable yield of hexaphenyldichlorophosphonitrile tetramer.[254] Other routes, which have not so far found wide application, include the dehydrofluorination of iminofluorophosphoranes, such as:

$$(Ph_2PF(NH))_n\,^{236} \quad \text{and} \quad (Ph_2PF(NH))_n \xrightarrow[\text{in } Me_2SO]{CsF} (Ph_2PN)_3$$

the pyrolytic decomposition of dimethylhydrazino aryl phosphines, such as:

$$Ph_2PNHN(CH_3)_2,^{255} \qquad Ph_2PNHN(CH_3)_2 \xrightarrow[200°]{\text{Decomp.}} (Ph_2PN)_3$$

or of dialkyldiaminophosphonium chlorides[263]:

$$R_2PNH_2 + NH_2Cl \rightarrow [R_2P(NH_2)_2]Cl \xrightarrow[200^\circ]{\text{Decomp.}} (R_2PN)_3 + NH_4Cl$$

and the reaction of iminobis(aminodiphenylphosphorane) halides with P(V) halides.[281]

The most general method for the preparation of phosphonitrilic derivatives is the ammonolysis of phosphorus pentachloride or its derivatives, the procedure in most cases being based on that devised by Schenck and Römer (Mellor, VIII, 722). Phosphorus pentachloride in an inert solvent is allowed to react with ammonium chloride according to the equation:

$$PCl_5 + NH_4Cl \rightarrow \tfrac{1}{n}(PNCl_2)_n + 4HCl$$

The usual solvent is 1.1.2.2-tetrachloroethane, but carbon tetrachloride, chlorobenzene and *o*-dichlorobenzene can also be used.[12] The product is a mixture of cyclic and linear chlorides,[13] the latter having the general formula $(PNCl_2)_n,PCl_5$. The ratio of the two types of product can be varied by altering the reaction conditions; high yields of the lower cyclic chlorides are obtained by the slow addition of phosphorus pentachloride to a suspension of ammonium chloride in refluxing tetrachloroethane,[13, 15, 17] whereas if an excess of phosphorus pentachloride is used, the product is mainly linear.[13, 17] The highest yields of cyclic trimer ($>70\%$) are obtained if the ammonium chloride is finely divided ($<5\mu$).[256] The reaction is catalyzed by metallic chlorides with acceptor properties,[19] such as ferric, aluminium and magnesium chlorides, or by lithium chloride[232] and also proceeds in the absence of a solvent.[20, 237] or even (in nitrobenzene solution) in the presence of aqueous sodium hydroxide.[257]

The mechanism of the reaction has not been studied in detail. It is probable[2, 17] that ammonium hexachlorophosphate is formed as an intermediate, which breaks down into the unknown trichlorophosphinimine, $PCl_3{:}NH$. Strong indirect evidence to support the production of the first of these intermediates has been produced,[160] and evidence consistent with the hypothesis of phosphinimine formation has been reviewed.[161] In polar solvents at low temperatures phosphorus pentachloride and ammonium chloride react[187, 218] to give a compound $P_3NCl_{12}$, shown by its N.M.R. spectrum to have the structure $[PCl_3{:}N{:}PCl_3]^+PCl_6^-$ (which cation has also been isolated as the tetrachloroborate[228]). The suggested reaction path[188, 282] involves the nucleophilic attack of $NH{:}PCl_3$ on $PCl_4^+$:

$$PCl_4^+PCl_6^- + NH{:}PCl_3 \rightarrow [PCl_3{:}N{:}PCl_3]^+PCl_6^- + HCl$$

At 150° this salt reacts with more $NH{:}PCl_3$ to give[189, 231] another cation,

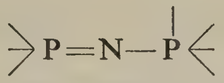
$$[PCl_3{:}N{:}PCl_3]^+ + NH{:}PCl_3 \rightarrow [PCl_3(NPCl_2)_2Cl]^+ + HCl$$

found in solution as its hexachlorophosphate. This latter compound had been previously prepared from sulphur nitride and phosphorus trichloride, or from phosphorus pentachloride and trimeric phosphonitrilic chloride under controlled conditions, and was thought to have the structure $PCl_4^+NPCl_3^-$.[21] The later structure is supported by its electrical conductivity, molecular weight, and especially by its N.M.R. spectrum. The infra-red and Raman spectra of the two compounds have been recorded[289] and an homologous cation with the formula

$$[Cl_3P{-}N{=}P(Cl){-}(N{=}PCl_3)_2]^+$$

has been prepared by the action of phosphorus pentachloride on thiophosphoramide.[249]

An orange bromo-derivative with the empirical formula $P_2NBr_7$ has also been isolated, and is an intermediate in the reaction leading to the formation of the phosphonitrilic bromides.[22] On heating it gives a mixture of small amounts of the trimer and tetramer, and larger quantities of higher homologues. The related compound $C_{24}H_{24}P_2N_3Cl$ (m.p. 245–246·5°) is a principal product[24] of the reaction of ammonia with diphenyl trichlorophosphorane, $Ph_2PCl_3$. While their detailed structures are unknown, it is likely that all these compounds contain the grouping



The phenyl compound gives mainly the cyclic tetrameric phenyl-phosphonitrile on pyrolysis.[24] It is possible that it may be a salt, $[NH_2.PPh_2{:}N.PPh_2.NH_2]^+Cl^-$, like many other phosphonitrilic intermediates.[161]

Ill-defined oily mixtures of linear chlorides of formula $(PNCl_2)_n,PCl_5$, or more probably $[PCl_3(NPCl_2)_{2n}.Cl]^+PCl_6^-$,[161] where $n>1$, can be obtained from the product of incomplete reaction of phosphorus pentachloride and ammonium chloride[12–3] and from the high-temperature reaction of cyclic phosphonitrilic chlorides with phosphorus pentachloride.[25] They are distinguished from the cyclic chlorides by their insolubility in petroleum ether, their ready hydrolysis, their high polarity (dielectric constant about 14) and the ease with which they polymerize to a rubber-like solid in such solvents as refluxing tetrachloroethane.[13] Polymerization in the absence of a solvent is often very slow.

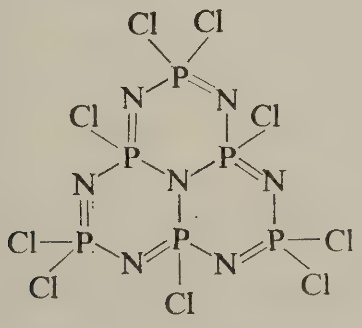
Another series of linear phosphonitrilic derivatives, in which the end-groups are formed from the elements of hydrogen chloride, has been postulated[2, 17] and recognized as a product of the partial ammonolysis of phosphorus pentachloride.[26] The cyclic chlorides may well be formed from this series of derivatives by intramolecular elimination of hydrogen chloride,[161] or from the series previously discussed by the reaction[235]:

$$(PNCl_2)_n.PCl_5 \rightarrow (PNCl_2)_{n-p}.PCl_5 + (PNCl_2)_p$$

The difference between the end-groups of the two series has been demonstrated by nuclear magnetic resonance spectroscopy.[13, 26] Although such linear derivatives are recognized as classes, properly characterized compounds are few; the anilide[12] $P_3N_2Cl_2(NHPh)_7$, the phenyl derivative[27] $Ph(P\,Ph_2N)_3H,HClO_4$ (needles, m.p. 181°) and the fluoride[28] $F(PF_2N)_3H,HF,2H_2O$ (m.p. 32·5°) are known. Other linear derivatives of alkyl and aryl phosphonitriles have also been obtained.[29] Phosphonitrilic chloride chains can be terminated with the elements of other acid chlorides, either by direct addition,[21, 190, 230] or by reaction of hydroxylamine hydrochloride with phosphorus pentachloride[191] and in other ways.[192–3] The compound $PCl_3{:}N.POCl_2$ has been isolated[191–3] and its structure proved by its N.M.R. spectrum.[194]

Cyclic derivatives are better known. The series of cyclic chlorides described by Stokes (Mellor, VIII, 721) has been extended to the octamer, and improved values obtained for their physical properties.[13] The lower members of the series have been separated[30] by vapour-phase chromatography on an analytical scale; their large-scale separation, depending on differences in base strength, has been described in detail.[13, 31] Individual procedures for the confirmed separation of trimer and tetramer chlorides (the most readily formed and commonly used members of the series) have been described.[162, 258]

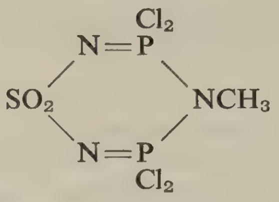
A polycyclic structure



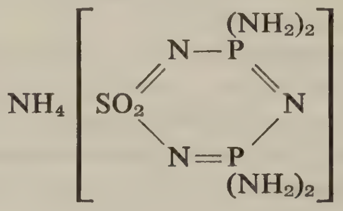
has been proposed[130] for a compound $P_6N_7Cl_9$ which was found by Stokes (*loc. cit.*)[23] with the simple cyclic chlorides. The compound

$$Cl_3P{=}N{-}SO_2{-}N{=}PCl_3$$

obtained by the interaction of phosphorus pentachloride with sulphuryl amide, reacts with heptamethyl disilazane to form a white crystalline derivative, which is formulated[222] as:



and with ammonia to give the analogous salt:



The relation of these to the cyclic phosphonitrilic derivatives is obvious.

The trimeric and tetrameric phosphonitrilic bromides have been prepared from phosphorus pentabromide and ammonium bromide,[22, 33–4] the chief improvement[22, 266] on the original experiments[33] being the maintenance of a comparatively low temperature up to the complete formation of the intermediate $PNBr_2,PBr_5$, or the exclusive use of fractional crystallization in the working-up procedure.[248] In the latter way the pentameric bromide has been isolated. Mixed trimeric chlorobromides have also been obtained[35, 234]; the monobromide pentachloride from phosphorus pentachloride, ammonium bromide and bromine, a dibromide-tetrachloride from phosphorus tribromide, phosphorus pentachloride and excess of ammonium chloride, and a tetrabromide-dichloride from phosphorus trichloride, bromine and ammonium bromide. These compounds together with the trichloride-tribromide are also formed[234] by the reaction of phosphorus pentachloride and ammonium bromide in tetrachloroethane, though there is evidence that the tetrabromide-dichloride of Rice *et al.*[35] is a 1:1 mixture of pentabromide–chloride and tribromide–trichloride.[267] Mixed tetrameric chlorobromides were also detected. The physical properties of the phosphonitrilic halides are given in Tables I–V.

Reaction of ammonium chloride with dimethyl-trichlorophosphorane, followed by treatment with triethylamine, gives the trimeric and tetrameric dimethylphosphonitriles[36]; the base is required for cyclization. The corresponding ethyl derivatives have been prepared[29, 37] by the action of liquid ammonia on diethyltrichlorophosphorane, followed by heating at 220–250°, while dimethyl, diethyl and di-*n*-butyl phosphonitriles are formed by the pyrolysis of the corresponding dialkyldiaminophosphonium chlorides.[263] The lower alkyl phosphonitriles are soluble in water. Similarly, diphenyl-trichlorophosphorane reacts with ammonium chloride, or preferably with ammonia, to give a good yield of tetrameric diphenyl-phosphonitrile and a smaller amount of the trimer.[38] Monophenyl-tetrachlorophosphorane, on ammonolysis, gives three of the four possible stereo-isomers of the tetrameric compound $P_4N_4Cl_4Ph_4$, each phosphorus atom carrying one phenyl group and one chlorine atom.[39, 195] The *cis* (m.p. 191–2°) and *trans* (m.p. 158–9°) isomers of 2,4,6-triphenyl-2,4,6-trichlorotriphosphonitrile[196, 286] can also be isolated under suitable conditions. Analogous bromo-derivatives have been described.[197] For the properties of alkyl and aryl derivatives, see Table VI. Octamethyl tetraphosphonitrile reacts almost quantitatively with molybdenum hexacarbonyl to give a yellow solid,

Table I.—Physical Properties of Phosphonitrilic Halides(a)

| Compound | M.P. (°C.) | $d_4^{20}$ (g.c.c.$^{-1}$) | Crystallographic Data | | | | | P–N stretching frequency(c) (cm.$^{-1}$) | Phosphorus NMR chemical shift(d) (p.p.m.) |

The critical temperatures of the lower phosphonitrilic fluorides are $(PNF_2)_3$, 187·7°; $(PNF_2)_4$, 223·2°; $(PNF_2)_5$, 250·8$_{\text{dec.}}$.[287]

(a) Each reference number relates to all data following the previous number in the same row.

(b) See Ref. 13 for other polymorphic forms.

(c) Where all the halogen atoms in a molecule are identical, this refers to an E′ mode in trimeric, Eg mode in tetrameric molecules, to which the P–N stretching motion is an important contributor.[112] If the halogens are mixed, the degeneracy may be lifted and the band may split.

(d) Relative to $H_3PO_4$(85%). Determined by R. F. M. White, and reported in Ref. 13.

(e) For *X*-ray powder diffraction data, see Ref. 126.

| $P_4N_4Ph_4Cl_4$(IV)(c) | 148 | 1308, 1292, 1275[39] |

(a) (I) and (II) may be configurational isomers. Only the higher-melting form has been found in later work.[38]

(b) (I) and (II) are position isomers. Two phosphorus atoms carry two phenyl groups each.

(c) (III) and (IV) are stereo-isomers. Each phosphorus atom carries a phenyl group and a chlorine atom.

(d) For derivatives, see Table VIII.

## SUBSTITUTION AND ADDITION REACTIONS OF THE PHOSPHONITRILIC CHLORIDES

Most cyclic derivatives have been prepared by substitution reactions from the chlorides. The majority of the reactions appear to be nucleophilic displacements. The simplest group of such reactions is that in which chlorine is replaced by fluorine or by a pseudo-halogen group, if we except the exchange process of radioactive chloride ion and the homologous chlorophosphonitriles $(NPCl_2)_{3-6}$, in acetonitrile solution, which was shown[229] to be of second order. The order of reactivity in this case was shown to be $(PNCl_2)_4 > (PNCl_2)_5 > (PNCl_2)_6 > (PNCl_2)_3$.

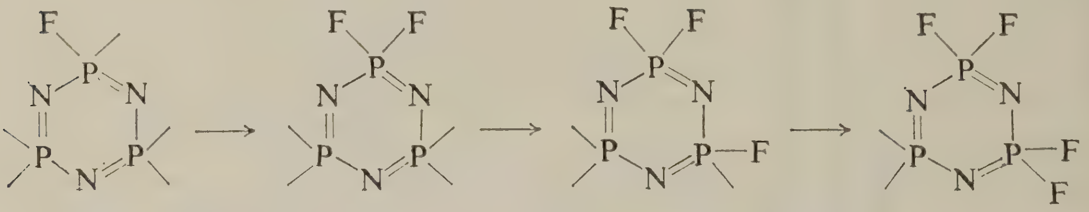
(b) 80–90° petrol.

Fluorination of the trimeric chloride with lead fluoride leads to the tetrameric chlorofluorides[28] $P_4N_4Cl_2F_6$ and[40] $P_4N_4Cl_4F_4$; both compounds polymerize on heating, and depolymerize at higher temperatures, with the formation[40] of the trimeric chloride–fluorides $P_3N_3Cl_2F_4$ and $P_3N_3Cl_4F_2$. The simple trimeric and tetrameric fluorides have been obtained by the action of potassium fluorosulphite, $KSO_2F$, on the corresponding chlorides[41–2]; the trimeric chloride had evidently been obtained in earlier work, but was not then recognized.[43] The orientation of the substituents in these reactions has been established by infra-red and N.M.R. spectroscopy, and geminal substitution[163–5] takes place almost exclusively,



though one of two trimeric fluoride chlorides described some years ago[40] does not fall into this pattern. It therefore seems that redistribution reactions may occur at high temperatures.

Potassium fluorosulphite in the above preparation can be replaced by a mixture of sulphur dioxide and potassium fluoride,[44–5] which reacts readily with a mixture of the cyclic chlorides at 100–110°C.[45] The existence of a series of cyclic polymers up to at least $(PNF_2)_{17}$ has been demonstrated.[45] Acetonitrile[204] and nitrobenzene[205] are suitable media for the reaction with simple fluorides, which is catalyzed by water and hydrogen fluorides.[205] Silver fluoride has also been used[46]; see also Ref. 10 for a preparation from a phosphorus nitride, and Tables I–IV for the properties of the phosphonitrilic fluorides and chloride–fluorides.

The phosphonitrilic fluorides are all very volatile, resembling the *n*-fluoroparaffins in this respect, and in their poor and anomalous solvent properties; for example the pentameric fluoride is immiscible with ethyl iodide at room temperature. The phosphonitrilic fluorides differ from the fluoroparaffins in being very flexible molecules, the liquids having both low viscosities and low temperature-coefficients of viscosity. The viscosity of the pentameric fluoride, $(PNF_2)_5$, is given by

$$\log_{10} \eta(\text{centipoises}) = 556/T - 1{\cdot}728$$

over the range $t = 20$–$80$°C. Its activation energy for viscous flow is 2·54 kcal. mole$^{-1}$, and that of the nonameric fluoride is 2·75 kcal. mole$^{-1}$. The molar volumes of the series can be expressed by the equation $V_m = 43{\cdot}753n + 8{\cdot}19$ c.c., with an average deviation of 0·27 c.c., and the molar refractivities by $[M]_D = 10{\cdot}103n - 1{\cdot}86$ c.c., with an average deviation of 0·06 c.c., where $n$ is the degree of polymerization.[45]

The trimeric phosphonitrilic azide $P_3N_3(N_3)_6$ has been prepared[47] from sodium azide and the trimeric chloride, and the amide–azide $P_3N_3(NH_2)_2(N_3)_4$ (white needles, m.p. 81–82°) from the diamide-tetrachloride.[48] The trimeric[49] and tetrameric[50] *iso*thiocyanates have been prepared similarly. The trimer (white crystals) melts at 41–42°, is very soluble in carbon tetrachloride and is insoluble in water. 100 g. of ether, *n*-heptane and acetone dissolve 20·9 g., 5·23 g. and 5·14 g. of the trimer, respectively. The solubilities of the tetramer in 100 g. of each of the four solvents, carbon tetrachloride, ether, *n*-heptane and acetone are 11·2 g., 0·7 g., 0·26 g. and 0·1 g. It is insoluble in water. The infra-red spectra of the thiocyanates show that the ring-systems are retained. The *iso*thiocyanate group reacts normally with amino-, hydroxy- and hydrazino-compounds. (For m.p. of derivatives, see Tables VII, VIII.)

The *iso*cyanate group cannot be introduced so simply, but an aminotetrachloro-*iso*cyanato triphosphonitrile has been prepared by the action of carbonyl chloride on 1,3-diaminotetrachloro-triphosphonitrile in chlorobenzene. The compound, m.p.

105°C., showed infra-red absorption bands at 3290 cm.$^{-1}$ ($-NH_2$), 2275 cm.$^{-1}$ ($-NCO$) and 1210 cm.$^{-1}$ (P–N ring stretch), and was converted to the corresponding ethyl urethane, m.p. 132°C.[261]

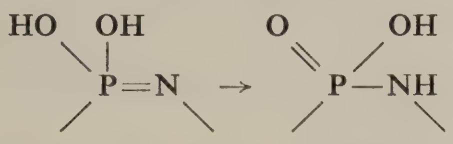
(a) Two modifications.

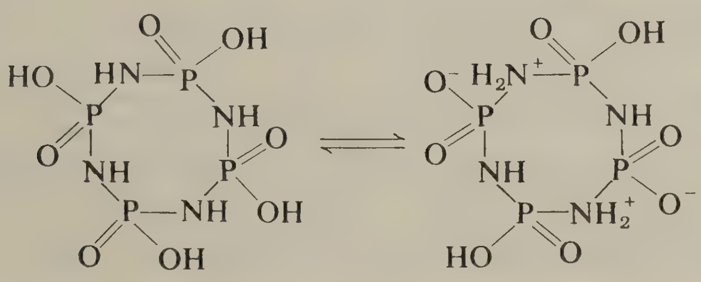
For further data see reference 264.

## Hydrolysis

The phosphonitrilic chlorides can be hydrolyzed to the corresponding acids, though slowly. Kinetic data for hydrolysis and other electrophilic substitution reactions of phosphonitrilic chlorides have been assembled and discussed.[161, 275] In general, the phosphonitrilic acids rearrange to the tautomeric metaphosphimic acids which have one replaceable hydrogen atom in each repeating unit[203]:



Exceptionally, the tetrameric acid is dibasic on rapid and tetrabasic on slow titration[53] suggesting a slow equilibration of the normal and zwitterionic structures:



The acid is normally isolated as the dihydrate; it is orthorhombic[54] space group $P_{2_1 2_1 2}$, $Z=2$. The eight-membered rings have at least a two-fold axis of symmetry. The di-potassium and di-rubidium salts are isomorphous with the acid, in which the water molecules are presumably present as $H_3O^+$ cations. The cell constants are given below. The diammonium salt has a similar structure.[54]

| | *a* (A.) | *b* (A.) | *c* (A.) |
|---|---|---|---|
| $P_4N_4(OH)_8,2H_2O$ | 13·92 | 8·34 | 5·05 |

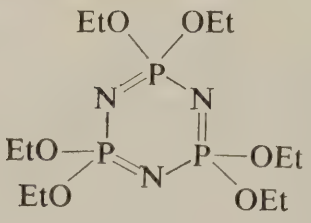
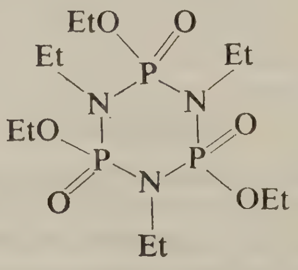
| $P_4N_4(OH)_6(ORb)_2$ | 14·03 | 8·24 | 5·06 |

The preparation of the sodium and potassium salts of triphosphonitrilic acid has also been described.[51] The infra-red spectra of a number of salts of the trimeric and tetrameric acids have been reported.[52] The salts react with sodium hypochlorite to give N-chlorophosphonitrilates,[55] with oxidizing properties like organic N-chloro compounds. The materials contain up to 45% of available chlorine and are said to be readily and completely soluble in water. The same type of isomerism occurs in the phosphonitrilic esters.[56] The normal ester



is a colourless oil, soluble in water. The isomeric compound



prepared from the trisilver salt of trimetaphosphimic acid and silver iodide,[56] is crystalline (m.p. 74·5°) and forms a di-hydrochloride. The similarly prepared tetraethyl ester of the tetrameric N-ethyl acid is a yellowish oil. The singly-bonded trimeric ring system is broken down to linear derivatives in alkali.[56]

The grouping  is evidently more stable than  ,

mainly because of the great strength of the phosphoryl bond, and the thermal rearrangement of O-alkyl to N-alkyl esters has been demonstrated. It is catalyzed by alkyl halides.[262] The trimeric[57] (b.p. 127°/0·03 mm.) and tetrameric[58] dimethoxyphosphonitriles $P_3N_3(OMe)_6$ and $P_4N_4(OMe)_8$ have also been obtained. Other trimeric alkoxides,[57, 59, 61, 166, 276–7] phenoxides,[60, 245, 259] mercaptides[61, 198] and nitroxyalkyl esters[167] have been described, as have the pentameric, hexameric, heptameric, and octameric dimethoxy and diphenoxy phosphonitriles.[252] Several polyfluoroalkyl phosphonitrilates have been prepared by the action of the alkali-metal salts of polyfluorocarbinols on the chlorides.[62, 252] They are converted to chloro-fluoro-compounds by chlorination in carbon tetrachloride solution in ultra-violet light,[63] but have otherwise extraordinary chemical and thermal stability; they can be distilled at 500°C. without decomposition, and are only slowly attacked by hot acid or alkali. For their physical properties, see Table IX.

## Ammonolysis

Ammonia and amines also react with the phosphonitrilic chlorides, the main product from the trimer being the diamide-tetrachloride.[64] Complete ammonolysis is difficult, but can be achieved in liquid ammonia at room temperature within 48 hr.[65] Ammonolysis of the tetrameric chloride gives the diamide hexachloride and the tetra-amide tetrachloride[64, 66]; again, the fully-substituted amido-derivative is formed in liquid ammonia.[65] On heating, both trimeric and tetrameric phosphonitrilamides evolve ammonia, the eventual product being phospham, of empirical composition (PN:NH); its infra-red spectrum[67, 201–2] suggests that the typical phosphonitrilic bond is retained. In the presence of suitable impurities, triphosphonitrilic hexamide gives a friable polymeric foam.[246]

Substitution of the chlorine atoms by primary and secondary amine residues occurs comparatively readily, and such derivatives are numerous. Melting points of trimeric derivatives are given in Tables VII and VIII, and of tetrameric derivatives in Table X.

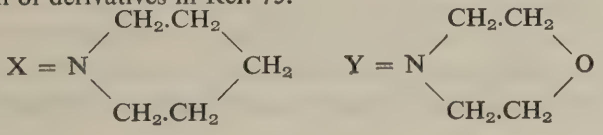
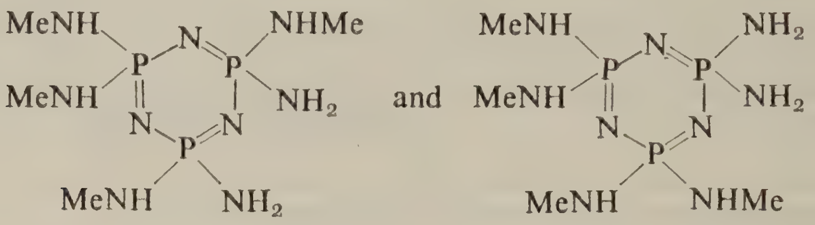
(c)

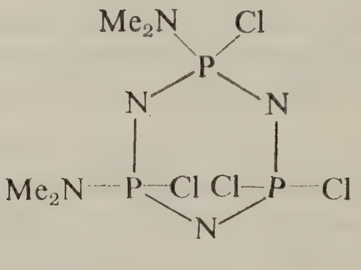


The trimeric tetrachloride-bis(ethylene-diamide)[70] and similar derivatives of aromatic diamines have also been prepared.[70] Charge-transfer type complexes between phosphonitrilic chlorides and phosphonitrilic amides have been described.[214] The dipole moments of a number of phosphonitrilic amides have been measured.[215]

Most mixed derivatives contain an even number of each constituent, as may be seen from Tables VIII and X. It has therefore often been supposed that the chlorine atoms in the phosphonitrilic chlorides are substituted in pairs. This is not always so. It has been shown[71] that in the trimeric tetrachloride bis-dimethylamide, the two amine groups are attached to different phosphorus atoms, since further reaction with dimethylamine gives a tris-dimethylamide in which all the phosphorus atoms are equivalent (NMR). By a combination of chemical and spectroscopic evidence, the orientations of several mixed trimeric amide derivatives have been worked out,[71] and the following pair of isomers recognized.



The mechanism of these substitution reactions is not yet known. They appear to be nucleophilic substitutions, and it is therefore not surprising that the attachment of an amido-group, capable of feeding electrons back to phosphorus, should discourage further attack at the same centre. It is consistent with this view that the NMR spectra of disubstituted aminolysis products of tetrameric phosphonitrilic chloride show that the amine groups occupy positions remote from each other.[75, 200] In the case of the bis-dimethylamido derivative made from the trimeric chloride and dimethylamine, both amido substituents, while being on different phosphorus atoms, lie on the same side of the ring.[168, 244] *Cis-trans* isomerization of these and other dialkylamido derivatives occurs in the presence of aluminium chloride[241] or substituted ammonium chlorides.[242]



However, geminal substitution by amines can occur[251] and has been established for partial substitution for ethylene imine.[169] Fully substituted trimeric and tetrameric amidophosphonitriles prepared by the action of ammonia or amines on the chlorides are numerous and have been listed,[170, 243–4, 252] as have derivatives with only a single alkylamino group.[284]

Orientational effects have been interpreted in terms of base strength,[71] and it is noteworthy that the phosphorus atom is strongly electrophilic. Trimethylamine reacts readily with triphosphonitrilic chloride, with evolution of methyl chloride and partial replacement of the chlorine atoms by dimethylamido-groups.[77] The importance of steric effects in substitution reactions has also been recognized.[76] The reaction of trimeric phosphonitrilic chloride with piperidine in toluene at 0° follows a mixed second and third order rate law, and is catalyzed by tri-*n*-butylamine.[239] The aminolysis of phosphonitrilic fluorides, chlorides, and bromides by propylamine in acetonitrile is also of second order, the reactivity of the halides being in the order $(PNBr_2)_4 > (PNBr_2)_3 \sim (PNCl_2)_4 > (PNCl_2)_3 \sim (PNF_2)_4 > (PNF_2)_3$.[283]

### Reactions with Grignard Reagents

The phosphonitrilic chlorides also undergo substitution reactions with Grignard reagents; hexaphenyl triphosphonitrile has been obtained in small yield from phenyl magnesium bromide and the trimeric chloride.[27, 78] Alkyl magnesium halides react with all three chlorine atoms of tris-dimethylamido-trichloro-triphosphonitrile; the amine groups were removed subsequently with anhydrous hydrogen chloride.[79] With phenyl magnesium bromide, the tetrameric chloride gave[80] two tetraphenyl derivatives, in which degradative experiments showed the phenyl groups to be present in pairs. Two octaphenyl derivatives were also isolated: later workers[216] have claimed that these are 2,2,6,6-tetraphenyl-4,4,8,8-tetrachloro-tetraphosphonitrile (m.p. 212·5°) and 2,2,4,4-tetrachloro-6-phenyl-6-triphenyl phosphinimino triphosphonitrile (m.p. 181°), formed by ring contraction. Similar triphenyl-phosphinimino derivatives can be formed by the action of triphenyldibromophosphorane on aminophosphonitriles.[272]

### Friedel–Crafts Reaction

The trimeric chloride also undergoes the Friedel–Crafts reaction with benzene and aluminium chloride, with the formation of diphenyl-tetrachloro-triphosphonitrile.[27] Several compounds have been prepared from this by reaction with ammonia or amines; for m.p., see Table VIII and Ref. 279. Further phenylation of the diphenyl-tetrachloro compound under more rigorous conditions gives the 2,2,4,4-tetraphenyl and 2,2,4,4,6,6-hexaphenyl derivatives. Toluene and chlorobenzene react similarly, but other aromatic hydrocarbons give no products which can be isolated.[280] Similarly the reaction of *trans*-2,4,6-trichloro-2,4,6-triphenyltriphosphonitrile[283] with benzene and aluminium chloride can be made to give good yields of the 2,4-dichloro-2,4,6,6-tetraphenyl- or 2-chloro-2,4,4,6,6-pentaphenyl derivatives.[264] Part of the chlorine in the trimeric and tetrameric chlorides can be replaced by radicals, formed by the action of ultra-violet light on solutions of the chlorides in benzene and in decahydronaphthalene.[82] Butoxy-phosphonitriles have been obtained, probably in a highly polymeric form, by the action of high-energy electrons (0·6 Mev.) on a solution of the tetrameric chloride in butanol.[83] The reaction of phosphonitrilic halides with sodium in liquid ammonia can be used in the quantitative determination of the halogen.[84] Trimeric phosphonitrilic chloride also undergoes a remarkable reaction with sodium benzoate, and with the salts of other organic acids, to give benzonitrile or its equivalent. It is suggested that the normal benzoate which is formed first undergoes a tautomeric change to an N-benzoyl compound.[85] Exchange of oxygen and nitrogen then occurs, by a mechanism which may be similar to that of the replacement of nitrogen by oxygen in the hydrolysis of the trimeta-phosphimate ion.[86] The phosphonitrilic esters undergo a similar reaction, giving ethyl chloride, ethyl phosphenate and 2,4,6-triphenyl-1,3,5-triazine.[250] Trimeric phosphonitrilic chloride also reacts with silver trifluoro-acetate, with the formation of trifluoro-acetonitrile.[87]

The reactions of phosphonitrilic derivatives with electron acceptors have been less studied. The trimeric and tetrameric chlorides are sufficiently basic to take up one

Number of protons taken up by the phosphonitrilic chlorides $(NPCl_2)_n$ in 100% sulphuric acid[161]

| $n$ | 3 | 4 | 5 | 6 | 7 | 8 |
|---|---|---|---|---|---|---|
| No. of protons (cryoscopic) | 1·2 | 2·0 | 2·0 | 2·0 | 2·3 | 2·8 |
| No. of protons (conductimetric) | 1·14 | 1·72 | 2·20 | 2·63 | 2·20 | 2·60 |

and two protons respectively[70] to give the compounds $(PNCl_2)_3,HClO_4$ and $(PNCl_2)_4,2HClO_4$, which can be recrystallized from acetic acid containing perchloric acid. They explode on heating. A comparable result was obtained by cryoscopy in sulphuric acid[2]; the pentameric and hexameric chlorides also take up two protons each.

The trimeric chloride is the strongest base of the series,[2] and is comparable in this respect with benzoic acid. Electron release to phosphorus, especially by amido-groups, increases the base strength considerably. In nitrobenzene, the amidophosphonitriles are stronger bases than the parent amine[209]: the relative base strengths in nitrobenzene are a good measure of proton-accepting capacity.[210] There is good evidence[209, 211] that protonation takes place on the ring, rather than in exocyclic positions. Ethylphosphonitriles are also quite strongly basic:

Further study of the homologous series of phosphonitrilic chlorides shows an interesting alternation both of basicity and of ionization potential, consistent with the modulation of the main $\pi$-system by weaker Hückel-type interactions in the $\pi'$ in-plane system.[220]

($\Delta pK = \log_{10} K_3/K_n$ where $K_n$ is the equilibrium constant for the reaction $(NPCl_2)_n + HCl \rightarrow (NPCl_2)_n,HCl$ in carbon tetrachloride.)

The trimeric chloride adds three moles of sulphur trioxide,[88] the addition compound, $(PNCl_2,SO_3)_3$, being obtained as a glassy mass which yields both sulphuric and sulphamic acids on hydrolysis, and decomposes thermally above 50°C. into chlorine, nitrogen, sulphur dioxide, thionyl chloride and sulphuryl chloride. The reaction of phosphonitrilic chloride trimer with sulphur trioxide and hydrogen chloride, or with chlorosulphonic acid, yields $PNS_2O_5Cl_4$, a colourless liquid, b.p. 55–6° at 0·02 mm., for which the formula $ClSO_2OPCl_2{=}NSO_2Cl$ has been suggested.[240] The adduct $(PNCl_2)_3,2AlCl_3$ has also been reported[27] as a pale yellow amorphous mass. There is little or no spectrophotometric evidence for the formation of complexes in solution between trimeric phosphonitrilic chloride and iodine,[223–4] benzene, hexamethylbenzene, *s*-trinitrobenzene, naphthalene, pyridine, methanol or chloranil,[224] though there is some cryoscopic evidence for a naphthalene complex.[225]

## PHOSPHONITRILIC POLYMERS

Some phosphonitrilic derivatives, principally the halides and isothiocyanates, form rubber-like high polymers on simple heating. Attention has been concentrated on the chlorides, particularly the trimer. Polymerization of the ordinarily-prepared material begins at about 250° and is rapid at 350°, though reaction is extremely slow at this temperature if the chloride is pure enough.[89] Depolymerization begins at higher temperatures, and the high polymer can be converted into a mixture of cyclic polymers by distillation *in vacuo*, provided that the temperature does not rise above 380°C.[90] The equilibrium among the lower polymers at 600° has been studied qualitatively,[90] and the polymerization shown to be exothermic.[90] The heats of polymerization of the cyclic chlorides have been measured directly by differential thermal analysis, and decrease steadily (per $PNCl_2$ group), the polymerization of the hexameric chloride being almost athermal.[91, 238]

| | $(PNCl_2)_3$ | $(PNCl_2)_4$ | $(PNCl_2)_5$ | $(PNCl_2)_6$ |
|---|---|---|---|---|
| Heat of Polymerization of $\frac{1}{n}(PNCl_2)_n$ ($-\Delta H$, kcal./mole) | 0·46 | 0·22 | 0·16 | 0·04 |

The kinetics of the polymerization of the trimeric and tetrameric chloride have been investigated, in bulk and in solution. An early claim[92] that oxygen was a catalyst was later withdrawn.[93] Later work[94–5] showed that the trimer polymerizes more rapidly than the tetramer[94] (its heat of polymerization is the greater[91]), that the rate is proportional to the concentration of the trimer,[95] and that the reaction is catalyzed by a number of oxygen-containing organic compounds (e.g. benzoic acid, acetone, ethanol, ethyl ether, methanol) and by some metals (zinc, tin, sodium). The specific rates per mole of catalyst are not very different,[94–5] suggesting that the reactions are all catalyzed by the same entity, and that the mechanism is the same in all cases. The authors propose an ionic mechanism,[95] the rate-determining step being the bimolecular reaction between a linear radical-ion $P_3N_3Cl_5^+$ and a neutral molecule $P_3N_3Cl_6$. Simple radical initiation seems unimportant; neither $\gamma$-radiation,[96] high energy electrons[212] nor ultra-violet radiation causes polymerization, though 50 kv. *X*-rays are more effective, especially just below the melting point.[213] The catalysis observed with *tert*.-butyl peroxide[94] persists to too high a temperature for it to be due to methyl radicals. The rate of polymerization of the trimeric chloride, as catalyzed by benzoic acid, has been investigated[97] over the range 200–220°, the rate constant conforming to the general equation $k(\text{min.}^{-1}) = 2{\cdot}75 \times 10^8 e^{-24{,}300/RT}$. The rate of depolymerization[98] of the high polymer is first-order in the high polymer, the rate constant being given by $k(\text{min.}^{-1}) = 4{\cdot}5 \times 10^7 e^{-26{,}000/RT}$. The activation energy is subject to an uncertainty of ±2 kcal./mole.

Like natural rubber, stretched polyphosphonitrilic chloride gives an *X*-ray fibre-diagram.[99] An approximate structure has been worked out, in which the $PNCl_2$ groups form a helical chain.[99–100] Measurements of elastic moduli[99, 101] show that polyphosphonitrilic chloride can be regarded as a linear polymer without cross-links, and they have also been used[102–3] to obtain approximate values of the molecular weight ($3{\cdot}7$–$7{\cdot}8 \times 10^4$). Higher, and probably more reliable, values have been obtained[104] by light-scattering measurements ($2{\cdot}18$–$3{\cdot}17 \times 10^5$) but the values depend, in any case, on the method of preparation of the sample.

The rate of hydrolysis of polymeric phosphonitrilic chloride in aqueous acetone is first-order in the polymer for part of its course, the rate constant at 25°C. being $5{\cdot}48 \pm 0{\cdot}28 \times 10^{-3}$ min.$^{-1}$, but the reaction does not go to completion.[105] Linear phosphonitrilic chlorides of general formula $(PNCl_2)_n$,HCl, where $n$ is about 14, are polymerized further by the action of a little water.[26] All the chlorine in them can be replaced by methoxy groups, about 10% of the methyl groups migrating in the sense

$$\text{—P(OMe)}_2\text{=N—} \rightarrow \text{P(O)(OMe)—NMe—}$$

The same chlorides react with sodium *tert.*-butoxide with the formation of sodium polymetaphosphimates and *iso*butylene.[26] Complete replacement of the chlorine in the high polymer by methoxy-groups has been achieved.[57] For the effect of high-energy electrons in promoting a combined esterification and polymerization see Ref. 83.

Polymerization of phosphonitrilic chloride trimer at pressures of 10 kbars and above indicates that increasing pressure favours the formation of the rubbery high polymer thermodynamically but is kinetically unfavourable. There appears to be no difference in the hydrolytic or thermal stability between the polymer formed at high pressures and that obtained at 1 atm.[171] Graft co-polymers between phosphonitrilic chloride polymer and styrene prepared by irradiation techniques show a reduced susceptibility to hydrolysis.[172]

Trimeric phosphonitrilic fluoride can also be polymerized by heat.[41] Polyphosphonitrilic fluoride remains rubber-like down to very low temperatures (−78°), but is even more susceptible to atmospheric moisture than the chloride.[42] Polymerization of the trimeric[49] and tetrameric[50] isothiocyanates occurs at a comparatively low temperature (150°).

Neither alkyl[36–7] nor aryl[38] derivatives polymerize further on heating; the former decomposes instead. Secondary reactions also occur on heating many other phosphonitrilic derivatives. The trimeric anilide loses aniline reversibly on heating,[68] insoluble phosphams of formula (NP:NPh) being eventually formed. Diethyl ether is eliminated irreversibly from hexa-ethoxy triphosphonitrile[56]; migration of alkyl groups from oxygen to nitrogen occurs at the same time,[26, 56] and saturated[37] and unsaturated hydrocarbons may be eliminated. It is probable that similar eliminations occur in the polymerization of phosphonitrilic derivatives of phenols and anilides.[106] Inorganic polymerization processes, including condensation reactions, have been reviewed.[107]

In many cases, the failure of thermal polymerization is more likely to be due to easy decomposition of the groups attached to phosphorus than to the intrinsic instability of the high-polymeric phosphonitrilic chain itself. Polymeric phosphonitriles have been prepared at much lower temperatures in another way, which is based in principle on an earlier preparation of phosphinimines.[108] The equation for the general reaction is:

$$R_2PX + MN_3 \rightarrow R_2PN_3 + MX \rightarrow R_2PN + N_2 + MX$$

the halide being heated with an alkali metal azide in an inert solvent above the decomposition temperature of the azido-phosphine. In published examples M is lithium[109] or sodium,[110] R is bromine,[110] phenyl[110] or trifluoromethyl,[111] and X either chlorine or bromine. The products appear to be of intermediate size, the polymeric mixture of phenyl chloro-phosphonitriles having an average molecular weight above 5000.[110] The mixture of bromides (m.p. 23–40°) was converted into the elastomer on heating *in vacuo* at 195–200°. Similar treatment of the mixture of diphenyl phosphonitrile polymers[110] gave a 33% yield of the tetramer $(Ph_2PN)_4$, m.p. 319·5–320°. The polymeric bis-trifluoromethylphosphonitrile,[109] $[(CF_3)_2PN]_n$, has m.p. 90–94°, is amorphous to *X*-rays, and is very resistant to heat and to acids. Treatment with alkali results in partial hydrolysis, half of the trifluoromethyl groups being liberated as fluoroform.[109] Allyl triphosphonitrilate has been polymerized to low molecular weight products of considerable thermal stability.[233]

## STRUCTURE OF PHOSPHONITRILIC DERIVATIVES

There are some disagreements about individual assignments for the trimeric bromide,[248, 268–9, 288] chloride[111–2, 206–7, 253, 268] and fluoride,[113, 206, 268] though their infra-red and Raman spectra are all consistent with $D_{3h}$ symmetry. Force constants have been calculated for the trimeric chloride and fluoride.[273] Some force constants of the trimeric chloride have been calculated,[114] but the data on which they are based are not well established. Infra-red spectra of several trimeric phosphonitrilic esters have been determined,[115] and the main features of the infra-red spectra of trimeric and tetrameric derivatives compared.[58]

The detailed structure of the trimeric chloride was determined first by electron diffraction.[116] Later crystal structure determination[117–8] showed that the equality of bond lengths is maintained in the crystal, but the molecules are slightly deformed, probably by lattice forces. Structural information is collected in Table XI.

The nuclear quadrupole spectrum of the trimeric chloride at 14° has four absorption frequencies at 27·630, 27·704, 27·834, 27·903 Mc. sec.$^{-1}$, consistent with the crystal structure,[119–21] though the Cl–P–Cl angles are rather large, and may imply a degree of bond bending.[274] Preliminary results[122] on the crystal structure of the trimeric bromide show that its molecular structure is similar to that of the chloride.

The Raman and infra-red spectra of the tetrameric chloride do not allow a unique assignment of molecular symmetry; they are most nearly in accord with a planar skeleton of symmetry $D_{4h}$,[268] though $D_{2d}$, in which only the phosphorus atoms would be in a plane, is not excluded.[112, 288] In the crystal[123–5] the molecule has $S_4$ symmetry. The symmetry $D_{4h}$ has also been suggested[208] for the tetrameric bromide, $(PNBr_2)_4$, though here again $S_4$ symmetry is possible in the crystal.[161, 288] Structural details are given in Table XI. The nuclear quadrupole spectra[119–20] indicate four

non-equivalent chlorine atoms, and are therefore inconsistent with the crystal structure determination, but the lines are of variable relative intensity, and may indicate contamination of the sample with a polymorphic form.[13]

The main features of the vibrational spectra[45, 113, 206, 268] of the tetrameric fluoride are consistent with a symmetry $C_{2h}$, but the deviation from planarity is probably small. In the crystal the symmetry of the ring, though not of the fluorine atoms, is experimentally indistinguishable from $D_{4h}$, though this high symmetry is not required by the space group.[127–8] Structural data for this molecule and for octakis-(dimethylamido) tetraphosphonitrile[131] are given in Table XI. The skeletal symmetry in this last molecule is close to $D_{2d}$. Data on the tetrameric bromide are not sufficient to establish the symmetry $D_{4h}$, which would be expected.[268] Numerical values of vibrational frequencies of $(PNCl_2)_3$,[112] $(PNCl_2)_4$,[112] $(PNF_2)_3$,[113] $(PNF_2)_4$,[113] $(PNBr_2)_3$, $(PNBr_2)_4$ and $(PNBr_2)_5$[248] are given in Tables XII–XVI. For other values see references 253, 268.

Less is known of the higher homologues. The cyclic nature of the chlorides $(PNCl_2)_{5-8}$ is suggested by their low dipole moments[130] and their infra-red spectra[130]; it is proved by their $^{31}P$ NMR spectra, which show that all the phosphorus nuclei in the same polymer have the same environment.[13] The same conclusion follows for the fluorides from the details of the infra-red spectra,[45] especially the structure of the $PF_2$ symmetrical stretching bands, and from the fact that they are prepared from the cyclic chlorides. The electrical conductivity of the chlorides, however, is compatible with an ionization mechanism in the sense:

$$(PNCl_2)_3 \rightleftharpoons [P_3N_3Cl_5]^+ + Cl^-$$

rather than with the electronic conductivity to be expected from a purely aromatic system.[247, 278]

The equality of the P–N bonds in all the structures so far determined, and their shortness compared with the single P–N bond length of 1·78 Å.[131] in the phosphoramidate ion $[NH_3PO_3]^-$, suggest at least limited delocalization rather than the alternate single and double bonds formally required by the normal valencies of phosphorus and nitrogen. The P–N bond energy term (72·3 kcal.)[16] deduced from the heats of formation of the trimeric and tetrameric chlorides (below) is higher than expected for a single bond, and a similar conclusion follows from the heats of formation of the other compounds quoted, and from the high value of the P–N stretching frequency (1218 cm.$^{-1}$) of the trimeric chloride.[112]

Since all the 3*p* orbitals of phosphorus are used in formation of four tetrahedrally-directed σ-bonds, the ring π-bonds must be formed by overlap of a 2*p*π-orbital on nitrogen and a 3*d*π-orbital on phosphorus. Two *d*-orbitals have the right symmetry to interact in this way. One is in a plane tangential to the ring, and perpendicular to it, the other is in a plane which bisects the NPN angle internally. The former is polarized more strongly by the ring nitrogen atoms, and has been supposed, on these grounds, to be the more strongly involved.[133–4] Delocalization energy is expected to increase steadily with ring size, in contrast to carbocyclic aromatics. If both $d\pi$-orbitals contribute equally,[135] delocalization occurs only in successive 3-centre PNP groups, and $\pi$-electron energies (per electron) should remain constant. The relative extents to which the two orbitals participate are not yet certain, but the reality of the $\pi$-bonding to which they both contribute is shown by the tendency of tetrameric molecules to approximate to $D_{2d}$ symmetry, a configuration which uniquely equalizes $\pi$-contributions round the ring, if the natural angles are too small for planarity.

The large angles at nitrogen, however, show that the lone pairs there are delocalized to some extent, the phosphorus atom acting as an acceptor, and so forming a second $p\pi$-$d\pi$ bond perpendicular to the first in the NPN plane. Two more $d$-orbitals are (unequally) involved in the formation of these new ($\pi'$) bonds, which are expected to reduce the base strength, and increase the torsional flexibility about the P–N bond. Molecular deformation appears particularly easy in the phosphonitrilic fluorides,[45] where the $\pi$- and $\pi'$-contributions would be most nearly equal, because of the high electronegativity of the fluorine atoms. The ultra-violet spectra are not decisive on the question of $\pi$-bonding. The chlorides absorb increasingly down to 2000 A.[13] or 1850 A. (trimer)[136] without reaching a maximum; the trimeric and tetrameric fluorides have intense peaks at 1494 ± 5 A. and 1475 ± 5 A., respectively.[136] The interpretation of the spectra is not yet known in detail, but the spectra of the chlorides are only slightly changed on solution of the compounds in sulphuric acid,[13] suggesting that the absorption is due to an $n \rightarrow \pi^*$ transition on the halogen atoms. Bonding problems in these compounds have been discussed,[177, 161] and further data on solvent effects on their ultra-violet and infra-red spectra have been presented.[226] $^{31}$P nuclear magnetic resonance chemical shifts have been recorded for a wide range of phosphonitrilic compounds.[270]

## APPLICATIONS OF PHOSPHONITRILIC DERIVATIVES

There are several proposed applications in the preparation of resins resistant to high temperatures. Phosphonitrilic derivatives improve the high-temperature properties of phenolic resins,[137] and can be used in the manufacture of semi-ceramic materials.[138] Polymeric phosphonitrilic chlorides have been used in conjunction with asbestos, glass, or other inorganic fibres to make insulating materials which are both flexible at ordinary temperatures and resistant to high temperatures.[139–41, 178] Trifluorophenoxy derivatives of phosphonitriles are fluids of high thermal stability.[271]

Resins are formed by condensation of the phosphonitrilic chlorides with butylamine[142]; the condensation products of phosphonitrilic chlorides with secondary and tertiary aromatic amides have been found to be compatible with other polymers.[143] The products of the reactions of phosphonitrilic chlorides with alcohols, phenols, naphthols, mercaptans or thiophenols have been suggested as plasticizers for resins, lacquers or varnishes.[144] Thermally stable low polymers are formed by the reaction of hexaphenyldichlorotetraphosphonitrile and diols.[254] Phosphonitrilic esters, prepared by the action of alcohol and pyridine on the rubber-like high polymer, can be used as plasticizers for nitrocellulose lacquers and films.[145] The phosphonitrilic chlorides have shown some advantage over other catalysts in the polymerization of low-molecular siloxanes,[146] and tertiary olefines can be polymerized[147] in contact with the monomeric phosphonitrilic chloride derivative, $PNCl_2,POCl_3$. The partial hydrolysis products of polyphosphonitrilic chlorides have been proposed[148] as constituents of heat-resisting paints.

Phosphonitrilic chlorides can be used in processes for the flame-proofing of fabrics.[179] The chlorine atoms can be substituted by hydroxy-, amino-, hydrazino- or other groups, resinous materials being formed with or without the use of cross-linking agents.[149] Amino-derivatives of the phosphonitrilic chlorides can also be used directly.[12] The use of the condensation product of a phosphonitrilic polymer with a chloro-aniline and a polyamino compound ensures that flame-proofing properties are retained after repeated laundering.[150] Useful flame-proofing properties are also obtained from the reaction product of phosphonitrilic polymers and a 2:3 dihaloalcohol,[151] and, particularly, from the addition products of unsaturated phosphonitrilic esters and saturated polyhalogeno-hydrocarbons.[152]

The phosphonitrilic chlorides[153] and their derivatives[144, 154] have also been suggested as oil additives, with the object of obtaining increased load capacity, viscosity index and resistance to corrosion. Pour-point depressants have been prepared by polymerizing phosphonitrilic esters in the presence of a Friedel–Crafts catalyst.[155] Phosphonitrilic compounds may also be of use as hydraulic fluids[144] and as fuel additives in internal combustion engines, where they decrease cylinder deposits.[156] The products obtained by reaction of a phosphonitrilic chloride polymer with a fluoroarylhydroxy or fluoroalkarylhydroxy compound are used as hydraulic fluids, transformer oils and heat exchange fluids.[180, 260] Phosphonitrilic chlorides have also been tested for their effectiveness in the control of surface ignition.[157]

A heat resistant plastic dielectric has been obtained from a resin containing phosphonitrilic chloride, diphenylsilanediol and asbestos,[181] and polymeric phosphonitrilic chlorides have been used as binders for abrasive wheels.[182] Products with semiconductor properties are reported to be formed by copolymerization of phosphonitrilic chloride and acrylonitrile.[183] Phosphonitrilic chloride trimer or tetramer can be used as a photographic hardening agent.[184] Aziridinyl phosphonitrile derivatives are powerful insect sterilants.[285]

### SECTION XIX

# PHOSPHORUS PSEUDOHALIDES

### BY A. F. CHILDS

CYANIDES, cyanates and thiocyanates are frequently referred to as pseudo-halides or halogenoids, since they can show a close chemical and physical resemblance to halides. The pseudohalide derivatives of phosphorus are no exception to this rule. For example, the hydrolysis of phosphorus(III) halides and pseudohalides follows the same general course:

$$PX_3 + 3H_2O \rightarrow HPO(OH)_2 + 3HX \qquad (X = F, Cl, Br, I, CN, OCN, SCN)$$

Furthermore such phosphorus pseudohalides can be prepared by metathesis between phosphorus halides and metal pseudohalides, while intermediate mixed halide–pseudohalides, such as $POCl_2(OCN)$, can be isolated in many cases. For these reasons it was thought desirable to discuss the phosphorus pseudohalides in the present work, although they had not been treated in the previous edition. Derivatives of other pseudohalides (–SeCN, –TeCN, $-N_3$, –OCl) have not apparently received any attention.

The phosphorus(III), phosphoryl and thiophosphoryl cyanides, cyanates and thiocyanates are covalent compounds. In their behaviour they broadly resemble the corresponding bromides or iodides, though exhibiting certain additional reactions typical of the pseudohalogen radical. A study of their behaviour[1] suggests that the stability of the P–X bond is in the order:

$$F > Cl > Br > CN > I > SCN \qquad (\simeq OCN\ ?).$$

Many of the pseudohalides polymerize at room temperature, or more rapidly when heated, to give solids of unknown composition.

Cyanides, cyanates and thiocyanates can each exist in one of two isomeric forms, and the structure of the phosphorus compounds has been a matter of some debate. Phosphorus(III) cyanide has been firmly established as a cyanide, $P(-C{\equiv}N)_3$ by an *X*-ray crystal structure determination,[2] while the infra-red spectrum of diphosphorus tetracyanide[3] and the mass spectrum of phosphorus(III) cyanide difluoride[4] suggest that these have a similar structure. However, molar refractivity[5] and infra-red[6] studies show that $P(NCS)_3$ and $PO(NCS)_3$ are both *iso*thiocyanates, while $P(NCO)_3$, $PO(NCO)_3$[7] and $P_2(NCO)_4$[8] all appear to have an *iso*cyanate structure. Much more evidence is required before any general rule can be established.

The stability of compounds containing both halide and pseudohalide groups is very variable. Some compounds, such as $PF(NCO)_2$, $PF_2(NCS)$, $PCl_2(NCO)$, $POCl_2(NCO)$, are relatively stable and can be stored for long periods at room temperature without disproportionation. Others (e.g., $PCl(NCO)_2$,[9] $PCl(NCS)_2$, $PCl_2(NCS)$[10]) slowly disproportionate even at room temperature, while others again ($PF_2(NCO)_2$,[9] $PBr_2CN$,[11] $PF_2CN$ [4]) are so unstable that they can hardly be prepared in the pure state. As yet there seems to be no general theory which correlates this behaviour.

## PHOSPHORUS CYANIDES AND *ISO*CYANIDES

### Phosphorus(III) Cyanide

Although crude specimens of phosphorus(III) cyanide may have been obtained earlier by the interaction of phosphorus and mercuric cyanide,[12–13] this substance was first obtained reasonably pure by the reaction of phosphorus(III) chloride with silver cyanide,[14–15] a method still recommended for its preparation. In a typical procedure,[16] dry silver cyanide and phosphorus(III) chloride were heated together in an evacuated sealed tube at 105°–150°C. for 24–8 hr. After excess phosphorus(III) chloride had been distilled off, the residue was sublimed under a high vacuum at 120°C. Variations of this preparation have been reported.[1,17] Other workers have carried out the reaction in an anhydrous solvent under reflux,[18] and by passing phosphorus(III) chloride vapour over silver cyanide in a heated tube.[19] Phosphorus(III) cyanide has also been obtained by the reaction of silver cyanide with phosphorus(III) bromide[11,21] or phosphorus(V) chloride,[1,15] or by the interaction of phosphorus(III) chloride with trimethylcyanosilane.[22]

Phosphorus(III) cyanide forms white needles or plates, m.p. 200–203°C., which sublime only a few degrees above the melting point.[15] It is only slightly soluble in chloroform, ether, carbon disulphide, phosphorus(III) chloride,[15] carbon tetrachloride or benzene,[18] but dissolves to about 15% in acetonitrile.[16]

The crystals of phosphorus(III) cyanide are tetragonal, of space group $I\bar{4}2d$, having 16 molecules in a unit cell, dimensions $a = b = 14{\cdot}00$, $c = 10{\cdot}81$ Å. From their acicular habit, it is possible that the crystals may be monoclinic at the sublimation temperature and transform to the tetragonal form on cooling.[2] The same study showed that the compound has the cyanide structure, $P(C{\equiv}N)_3$. The molecule is pyramidal with $C_{3v}$ symmetry, having $P{-}C = 1{\cdot}78$, $C{\equiv}N = 1{\cdot}15$ Å., $<C{-}P{-}C = 93°$ and $<P{-}C{\equiv}N = 172°$.[2] The non-linearity of the $P{-}C{\equiv}N$ group is unexpected, and is perhaps due to interactions in the crystal which may not occur in the isolated molecule.[23]

Two studies of the infra-red and Raman spectra of phosphorus(III) cyanide were in general agreement,[16,23] though the conclusions differed from those of earlier workers.[17] The fundamental frequencies suggested ($a_1$; 2206, 620, 468, 145: $e$; 2202, 581, 452, 314, 159 cm.$^{-1}$) accord with the $C_{3v}$ symmetry deduced from the crystallographic study.[23] Force constants have been calculated from these data.[24] The $^{31}P$ nuclear magnetic resonance spectrum shows a chemical shift $\delta_P$ of $+135{\cdot}7$ p.p.m.[21]

Phosphorus(III) cyanide is very reactive substance, and should be handled in a dry inert atmosphere.[16] Under these conditions it appears to be indefinitely stable at room temperature, and melts without decomposition, but prolonged heating leads to polymerization, with formation of a reddish brown solid.[18] In air it ignites when touched with a warm rod,[15,18] and it is rapidly decomposed by atmospheric moisture with the formation of hydrogen cyanide, phosphorous acid and a yellow amorphous material of high phosphorus content[1,15,18] which may be a sub-cyanide.[16]

The reaction with water is violent, the main products being phosphorous acid and hydrogen cyanide:

$$3H_2O + P(CN)_3 \rightarrow HPO(OH)_2 + 3HCN$$

However, particularly in neutral solution, a small amount of phosphine is formed,[19] perhaps by local overheating of intermediate hydrolysis products, since it is not observed when ice cooling is employed.[1] In alkaline solution phosphite is still the main product, but several other phosphorus oxyanions are formed, as shown earlier (page 472).[25] The analogous reaction with tritium oxide has been used to prepare tritium cyanide.[26] Alcohols react similarly to give trialkyl phosphites and hydrogen cyanide:

$$3ROH + P(CN)_3 \rightarrow P(OR)_3 + 3HCN$$

**Refs. p. 594**

although alkyl cyanide is also obtained[15] presumably by some such reaction as:

$$3ROH + P(CN)_3 \rightarrow HPO(OR)_2 + RCN + 2HCN$$

There is no reaction with dry ammonia in the cold, but when heated a black insoluble material of unknown composition is formed.[15]

### Mixed Phosphorus(III) Cyanide Halides

An attempted preparation of phosphorus(III) bromide dicyanide by reaction of the appropriate quantities of phosphorus(III) bromide and silver cyanide yielded only phosphorus(III) cyanide and unchanged bromide.[11] Hence either the bromocyanide was formed and then disproportionated, or the intermediate bromocyanides are considerably more reactive towards silver cyanide than is phosphorus(III) bromide itself. Phosphorus(III) cyanide difluoride has, however, been prepared by the reaction of phosphorus(III) difluoride iodide with copper(I) cyanide. It is a colourless volatile liquid which disproportionates appreciably to $PF_3$ and $P(CN)_3$ in 1 hr. at $-20°$. The $^{19}F$ and $^{31}P$ nuclear magnetic resonance spectra support the formula $F_2PCN$, while the infra-red and Raman spectra are compatible with a pyramidal ($C_s$) structure.[4]

### Diphosphorus Tetracyanide (Phosphorus Dicyanide) $P_2(CN)_4$

Diphosphorus tetraiodide reacts with silver cyanide in an inert solvent, yielding $P_2I_n(CN)_{4-n}$ ($n < 4$). The reaction is favoured by use of an excess of silver cyanide, and polar solvents such as $CH_3CHCl_2$. Diphosphorus tetracyanide is isolated by precipitation with petroleum ether or by fractional crystallization. It is a white solid, very sensitive to oxidation and hydrolysis, which disproportionates and polymerizes without melting or subliming. The infra-red spectrum, with bands at 2199, 2275 and 628 cm.$^{-1}$, suggests a cyanide ($P–C{\equiv}N$) structure analogous to that of phosphorus(III) cyanide.[8] In view of the instability of diphosphorus tetracyanide, the failure of a previous attempt to obtain it by reduction of phosphorus(III) cyanide with phosphorus at 210°[15] is not surprising.

### Phosphorus(V) Cyanide

The reaction of phosphorus(V) chloride with silver cyanide at room temperature yields only phosphorus(III) cyanide, together with cyanogen[1] or cyanogen chloride.[15] However, at $-39{\cdot}5$°C. the pressure over a mixture of phosphorus(III) cyanide and cyanogen falls to a constant value of 12·4 mm. This presumably represents the dissociation pressure of phosphorus(V) cyanide, since it lies between the initial vapour pressure of the cyanogen and that of pure phosphorus(III) cyanide.[1]

## PHOSPHORUS CYANATES AND *ISO*CYANATES

### Phosphorus(III) *Iso*cyanate

Phosphorus(III) *iso*cyanate was first prepared by reaction of phosphorus(III) chloride with silver cyanate in benzene,[27] a procedure which is still much used. Other workers have used lithium cyanate[28]; sodium or potassium cyanate in a polar solvent such as acetonitrile, nitromethane, acetone,[29] or liquid sulphur dioxide[30]; or cyanic acid in the presence of an acid acceptor.[31] The reaction of phosphorus(III) iodide with silver cyanate in nitromethane also yields the *iso*cyanate,[32] as does the disproportionation of the mixed phosphorus(III) chloride *iso*cyanates.[33]

Phosphorus(III) *iso*cyanate is a colourless liquid; b.p. 169·3°/760 mm.,[27] 78°/20 mm.,[30] 64–6°/10 mm.[29]; m.p. −2°,[27,34] refractive index for white light 1·5352,[27] 1·5329/25°.[31] Other properties of the pure liquid are recorded in Table I. On standing the substance slowly solidifies, forming a white solid, m.p. 80–95°, which can be reconverted to the original *iso*cyanate, b.p. 169°, by distillation.[7,27,34] The molecular weight of this new solid is unknown, but its formation is accompanied by the appearance of a second peak in the gas–liquid chromatogram,[7] and polymerization is presumably involved.

The infra-red and Raman spectra support an *iso*cyanate structure (P–N=C=O) for the molecule[7,34] and can best be explained by assuming $C_{3v}$ symmetry,[7,35–36] although it is not established whether the P–N=C=O groups are linear or bent.[7] The liquid is transparent in the ultra-violet region above 2300 A.[7,37] The nuclear magnetic resonance spectrum has been recorded.[38]

A study of the use of phosphorus(III) *iso*cyanate as a solvent (specific conductivity $1{\cdot}89 \times 10^{-5}$ ohm$^{-1}$/25°) showed that while it dissolved many organic compounds, inorganic compounds and elements tested were insoluble. Sulphuric acid, silver nitrate, acetic acid and acetaldehyde reacted violently.[34]

Phosphorus(III) *iso*cyanate also reacts rapidly with water,[32,34] and must be handled in a dry atmosphere. The products of hydrolysis by alkali have been discussed[25] (see page 472). Although, unlike phosphorus(III) cyanide, the *iso*cyanate does not inflame on warming in air, it is rapidly oxidized by nitrogen dioxide[39] or sulphur trioxide[30] forming phosphoryl cyanate. Iodine dissolves slowly in phosphorus(III) *iso*cyanate giving a red-brown solution (cf. the violet solution in $PCl_3$) from which an orange solid with the formula $P(NCO)_3I$ can be isolated. This may be analogous to $PCl_3I$ (Mellor, VIII, 1045). Chlorine, on the other hand, reacts vigorously to give a yellow oil, which forms a yellow solid on treatment with carbon tetrachloride. This solid may be a phosphorane, $P(NCO)_3Cl_2$, since it yields phosphate on hydrolysis,[40] although the evidence does not exclude the possibility of its being $PCl_5$.

Phosphorus(III) *iso*cyanate undergoes exchange reactions with other covalent compounds, the course of which is governed by the distillation of the most volatile component. Thus benzoyl chloride and mercuric chloride yield phosphorus(III) dichloride *iso*cyanate, or chloride di-*iso*cyanate, while aluminium chloride forms phosphorus(III) chloride and aluminium cyanate.[41] Alkyl or aryl *iso*cyanatidites are formed by reaction with the corresponding phosphites.[42]

The incorporation of phosphorus(III) *iso*cyanate in phenol-formaldehyde,[43] polyurethane,[44] epoxy[45] or polyester[46] resins has been claimed to improve their resistance to combustion, and their adhesion to wood or metal, while resins have been obtained by its reaction with aldehydes (e.g., PhCHO), hydroxyl or amino-compounds.[20,47] The *iso*cyanate has less effect on the octane rating of gasoline than phosphorus(III) *iso*thiocyanate.[48]

## MIXED PHOSPHORUS(III) *ISO*CYANATE HALIDES

### Phosphorus Fluoride *Iso*cyanates

If phosphorus(III) *iso*cyanate is heated with powdered sublimed antimony(III) fluoride a mixture of phosphorus(III) fluoride di-*iso*cyanate, $PF(NCO)_2$, and difluoride *iso*cyanate, $PF_2(NCO)$, is formed, and may be separated by fractional distillation.

Phosphorus fluoride di-*iso*cyanate is a colourless liquid, b.p. 98·7°C., f.p. −55·0°C., refractive index (20°, white light) 1·4678, molecular refractivity 25·25. Other properties are listed in Table I. The liquid shows a critical solution temperature of −16° in carbon disulphide.

|  | 135/30 mm. |  |  |  |  |  |  |  |

(a) At 760 mm. Hg unless stated otherwise.
(b) Rough estimate from recorded boiling points.

Phosphorus difluoride *iso*cyanate has a much lower stability (cf. $PF_2Br$) and rapidly gives phosphorus(III) fluoride on distillation, even at −35°, though it may be stored for a few days in a closed vessel at 0°. Like $PF(NCO)_2$ it is a colourless liquid with an unpleasant irritating odour, b.p. 12·3°C., f.p. ~ −108°C., refractive index (4·4°, white light) ~ 1·3695, molecular refractivity ~ 17·38. Both compounds are hydrolyzed by water, $PF(NCO)_2$ about as fast as $PCl_3$, $PF_2(NCO)$ somewhat less readily. $PF(NCO)_2$ does not add sulphur at temperatures up to 143°C.[9]

## Phosphorus Chloride *Iso*cyanates

Gradual addition of silver cyanate to excess of phosphorus(III) chloride, either alone or in the presence of a solvent such as carbon disulphide or benzene, similarly gives a mixture of phosphorus(III) chloride di-*iso*cyanate and dichloride *iso*cyanate, which can be separated by distillation.[49] The interaction of phosphorus(III) *iso*cyanate with phosphorus(III) chloride,[10, 49] benzoyl chloride, or mercuric chloride,[41] also gives small yields of these mixed chloride *iso*cyanates. Ligand exchange between phosphorus chloride and *iso*cyanate is slow at room temperature but accelerated by heating,[38] though accurate equilibrium data could not be obtained because of the instability of $P(NCO)_3$.[10]

Phosphorus(III) chloride di-*iso*cyanate, $PCl(NCO)_2$, is a colourless liquid, b.p. 67–8°/50 mm., 134·6°/760 mm. (extrap.), m.p. −50°C.[33] It fairly rapidly disproportionates on standing, yielding phosphorus(III) *iso*cyanate and phosphorus(III) dichloride *iso*cyanate, $PCl_2(NCO)$. This decomposes more slowly (6% in 4 months at room temperature). It is a colourless liquid, b.p. 104·5°, m.p. −99°.[49] Other properties of these compounds are given in Table I.

## Phosphorus Bromide *Iso*cyanates

Ligand exchange between phosphorus(III) bromide and phosphorus(III) *iso*cyanate is fairly rapid at 80°, but mixed *iso*cyanates have not been isolated, although their $^{31}P$ nuclear magnetic resonance spectra have been recorded.[38]

## Phosphoryl *Iso*cyanate

Phosphoryl *iso*cyanate, $OP(NCO)_3$, can be prepared by the action of silver cyanate on phosphorus(III) cyanate in refluxing benzene. Only a low yield of the desired product is obtained, together with a large amount of a water-sensitive, yellowish solid of high melting point, which is formed by polymerization. Better yields are reported from the oxidation of phosphorus(III) *iso*cyanate with $NO_2$ in carbon tetrachloride[39] or sulphur trioxide in liquid sulphur dioxide.[30]

Phosphoryl *iso*cyanate is a colourless liquid, b.p. 193·1°/760 mm. (extrap.)[50] 88°/10 mm.,[30] m.p. 5°, refractive index 1·4804.[50] When heated it is slowly converted to the insoluble polymer mentioned above. The infra-red and Raman spectra of phosphoryl *iso*cyanate closely resemble those of phosphorus(III) *iso*cyanate, with the addition of two phosphoryl vibrations,[7] and like that compound it probably has trigonal pyramidal ($C_{3v}$) symmetry.[7, 35, 36] The ultra-violet spectrum shows a weak absorption at 2660 Å.[7, 37]

Phosphoryl *iso*cyanate has been claimed to give the properties of flame resistance, and adhesion to metal or other surfaces, to cellulose,[60] phenol-formaldehyde,[43] polyurethane,[44] epoxy[45] and other resins.[61] It has also been used to coat pigments for use in polyurethanes[62] and to form polymers with inorganic materials containing active hydrogen.[47]

**Refs. p. 594**

## MIXED PHOSPHORYL *ISO*CYANATE HALIDES

### Phosphoryl Fluoride *Iso*cyanates

Phosphoryl difluoride *iso*cyanate, POF$_2$(NCO), was first prepared by the reaction of antimony(III) fluoride with phosphoryl dichloride *iso*cyanate.[51] It has also been obtained by the interaction of phosphorodifluoridic anhydride with potassium cyanate[52]:

$$F_2P(O)OP(O)F_2 + KOCN \rightarrow F_2P(O)NCO + KPO_2F_2$$

or of silicon tetra*iso*cyanate with phosphoryl fluoride[53]:

$$Si(NCO)_4 + 4POF_3 \rightarrow 4F_2P(O)NCO + SiF_4$$

It is a colourless liquid, b.p. 68–68·5/760 mm.,[51] $n_{\mathrm{D}}^{25}$ 1·3381, $d_4^{24}$ 1·5899. Other physical properties are given in Table I, and the $^{19}$F and $^{31}$P nuclear magnetic resonance spectra in Table II. The infra-red spectrum has been reported.[52, 53]

Phosphoryl difluoride *iso*cyanate is stable at room temperature in a dry atmosphere,[51] but polymerizes to a yellow solid if heated.[53] It is rapidly hydrolyzed by water, and reacts with alcohols or phenols to give difluorophosphoryl carbamates, F$_2$PONHCOR, and with amines, giving the analogous ureas, F$_2$PONHCONHR.[51] It has been claimed to inhibit the growth of plants[63] and to stabilize liquid ozone.[64]

Phosphoryl chloride fluoride *iso*cyanate, POClF(NCO), is a by-product from the reaction of antimony fluoride with phosphoryl dichloride *iso*cyanate. It is a liquid, b.p. 101–103°C., $n_{\mathrm{D}}^{25}$ 1·4024.[51]

*Table II.—Nuclear Magnetic Resonance Data on the Phosphorus* Iso*cyanates and Related Compounds*

(a) PO(NCO)F$_2$ has a $^{19}$F N.M.R. spectrum with $J_{F\text{–}P}$ = 998 c.p.s., $\delta_F$ +72·2,[52] 72·0[53] p.p.m. with respect to CCl$_3$F.

(b) Reference standard 85% H$_3$PO$_4$.

### Phosphoryl Chloride *Iso*cyanates

Phosphoryl dichloride *iso*cyanate, $POCl_2(NCO)$, is commonly made by the reaction of phosphorus(V) chloride with methyl or ethyl carbamate.[54,57] The reaction appears to proceed through the intermediate formation of a N-carboalkoxyiminophosphoryl chloride, which is stable at 0–10°, but decomposes at 20–40°, with evolution of alkyl chloride[57,65]:

$$PCl_5 + H_2NCOOR \xrightarrow{0-10^\circ}$$

$$Cl_3P = N{\cdot}COOR(+2HCl) \xrightarrow{20-40^\circ} Cl_2PO(NCO)(+RCl)$$

If carried out cautiously the reaction gives an excellent yield of product, but the second stage can be very violent or even explosive, and is often moderated by carrying it out in a solvent, such as methylene chloride[56] or ethylene chloride.[66,67] Alternatively, an N-substituted carbamate can be used:

$$Me_2NSO_2NHCOOR + PCl_5 \xrightarrow{85-115^\circ} Cl_2PO(NCO) + Me_2NSO_2Cl + HCl + RCl$$

but this involves the fractional distillation of the dichloride *iso*cyanate from dimethylaminosulphonyl chloride.[55] Ligand exchange in the system $POCl_3$–$P(NCO)_3$ has been shown to be a slow process, even on prolonged heating.[38]

Pure phosphoryl dichloride *iso*cyanate is a colourless liquid, b.p. 19·7–20·0°/5 mm.,[54] 45–6°/20 mm.,[57] 136–8° (decomp.)/760 mm.,[54] $n^{21} = 1{\cdot}4682$,[58] $n_D^{15} = 1{\cdot}470$,[54] $d_4^{15} = 1{\cdot}649$ g./c.c.[54] The infra-red spectrum has been reported.[81] It reacts with small quantities of water giving N-dichlorophosphoryl carbamic acid[68,69]:

$$Cl_2PONCO + H_2O \rightarrow Cl_2PONHCOOH$$

The reaction is best carried out by the addition of the *iso*cyanate to 36% aqueous hydrochloric acid in carbon tetrachloride at −20°, followed by gentle warming of the mixture to 20°, when the carbamic acid crystallizes out. N-Dichlorophosphoryl carbamic acid decomposes above 73°, giving some phosphoryl dichloride *iso*cyanate, together with a residue of $HOPO({=}NCOOH)_x$, which decomposes further to $(N{=}PO(OH))_x$ and $(PON)_x$ at higher temperatures. Phosphorus(V) chloride converts the carbamic acid to phosphoryl dichloride *iso*cyanate:

$$Cl_2PONHCOOH + PCl_5 \rightarrow Cl_2PO(NCO) + POCl_3 + 2HCl^{69}$$

Phosphoryl dichloride *iso*cyanate reacts analogously with alcohols or phenols to give N-dichlorophosphoryl carbamates:

$$Cl_2PO(NCO) + ROH \rightarrow Cl_2P(O)NHCOOR$$

and with amines to give ureas:

$$Cl_2PO(NCO) + RR'NH \rightarrow Cl_2P(O)NHCONRR' \rightarrow (RR'N)_2P(O)NHCONRR'^{54}$$

### Thiophosphoryl *Iso*cyanates

Thiophosphoryl *iso*cyanate, $PS(NCO)_3$, has been obtained in poor yield together with much polymeric material by the addition of sulphur to phosphorus(III) *iso*cyanate in a sealed tube at 140°. The direct reaction of thiophosphoryl chloride with silver cyanate in refluxing xylene was too slow to afford a practical method of preparation,[59] though there is evidence of the formation of the intermediate $Cl_2PS(NCO)$ from thiophosphoryl chloride and potassium cyanate.[66]

Thiophosphoryl *iso*cyanate is a colourless viscous liquid, b.p. 135°/30 mm., 215° (decomp.)/760 mm., refractive index for white light 1·5116, $d = 1{\cdot}538$ g./c.c. Other physical properties are given in Table I. Hydrolysis in nitric acid yields sulphur, claimed as evidence for a P=S group, rather than the isomeric P=O(SCN).[59]

### **Diphosphorus Tetra-*iso*cyanate** (Phosphorus Di-*iso*cyanate, $P_2(NCO)_4$)

Diphosphorus tetraiodide reacts with silver cyanate in an inert solvent, yielding diphosphorus tetra-*iso*cyanate, which closely resembles the tetracyanide (*q.v.*) in its physical and chemical properties. Infra-red absorption bands at 1420 and 763 cm.$^{-1}$ support the *iso*cyanate structure for this compound.[8]

## PHOSPHORUS THIOCYANATES AND *ISO*THIOCYANATES

### Phosphorus(III) *Iso*thiocyanate

Early attempts to prepare phosphorus(III) *iso*thiocyanate by reaction of phosphorus(III) chloride with silver or lead thiocyanate gave impure products,[15,70] but better results were obtained by conducting the reaction in the presence of charcoal to remove impurities which catalyzed decomposition.[33] The compound can also be made by the reaction of phosphorus(III) chloride with ammonium thiocyanate in boiling benzene,[3,71] mercurous thiocyanate in carbon tetrachloride[1] or potassium thiocyanate in liquid sulphur dioxide.[72,73]

Phosphorus(III) *iso*thiocyanate is a colourless highly refractive liquid, b.p. 87–8°C./0·08 mm.,[73] 118–20°C./1 mm.,[6] 163–168°C./15–17 mm. (decomp.),[71,74] f.p. −4°C., $d_4^{15} = 1{\cdot}483$ (see also Table III). The molecular refractivity (50·99,[6] 54·45 (recalc. from the data of ref. 74)) agrees more closely with the calculated value for $P(NCS)_3 = 52{\cdot}53$ than for $P(SCN)_3 = 57{\cdot}15$.[6] However, the crude material is said to contain two compounds, one of which dissolves much more readily in water than the other, giving thiocyanic and phosphorous acids. This has been claimed as evidence for the presence of some of the thiocyanate isomer.[71] Nevertheless, the infra-red and Raman spectra, which show strong bands at 1930 and 1050 cm.$^{-1}$, support the *iso*thiocyanate structure,[6,73] while the 7*a* and 9*e* fundamental vibrations observed accord with $C_{3v}$ symmetry, although it is not possible to determine whether the P–N=C=S groups are linear.[6]

If heated above 105° phosphorus *iso*thiocyanate polymerizes or decomposes to a black solid, and distillation above this temperature is always accompanied by considerable loss.[3] Even in sealed ampoules at room temperature in the absence of air, the substance darkens and deposits a brown polymeric solid.[1,73] Hydrolysis gives phosphorous acid and thiocyanic acid with smaller amounts of other phosphorus oxyacids and hydrogen sulphide[1,25] (see also page 472). Alcoholysis yields tri-(or di-)ethyl phosphite and thiocyanic acid with a trace of *iso*perthiocyanic acid[75]:

$$P(NCS)_3 + 3EtOH \rightarrow P(OEt)_3 + 3HSCN$$

$$3HSCN \xrightarrow{H^+} C_2H_2N_2S_3 + HCN$$

Aniline, even in excess, only gives a 1 : 1 adduct:

$$P(NCS)_3 + PhNH_2 \rightarrow PhNHCSNHP(NCS)_2$$

which reacts much more vigorously with water than does the parent *iso*thiocyanate.[3,74]

Sulphur dioxide oxidizes phosphorus *iso*thiocyanate to a mixture of phosphoryl and thiophosphoryl *iso*thiocyanates[76]:

$$3P(NCS)_3 + SO_2 \rightarrow SP(NCS)_3 + 2OP(NCS)_3$$

*Table III.—Physical Properties of the Phosphorus* Iso*thiocyanates*

### Mixed Phosphorus(III) *Iso*thiocyanate Halides

Phosphorus(III) difluoride *iso*thiocyanate, $PF_2(NCS)$, has been made by the action of antimony(III) fluoride on phosphorus(III) *iso*thiocyanate. It is a colourless liquid, b.p. 90·3°C., m.p. −95°C., refractive index (white light, 20°) 1·4978, $d_4^{20}$ 1·452, molar refractivity 25·66 (see also Table III). It is infinitely miscible with carbon disulphide above −50°C. The chemical stability of the compound lies between that of $FP(NCO)_2$ and that of $F_2P(NCO)$.[9]

Mixtures of phosphorus(III) chloride or bromide and phosphorus(III) *iso*thiocyanate very rapidly undergo ligand exchange. Even at room temperature new nuclear magnetic resonance absorption lines show after a few minutes, and an equilibrium is reached in 12 hr., which is close to that expected for random reorganization. These results do not support the theory[77] that a non-linearity of chemical shifts in a series of mixed compounds is associated with a non-statistical ligand distribution. In these two cases the distribution is statistical, but the chemical shifts do not alter linearly (see Table IV).[10,38]

| | Coupling constant $J_{F-P}$, c.p.s. | Chemical shift $\delta_F$ p.p.m.$^{(a)}$ | Line intensity | |
| $OP(NCS)_2F$ | 957 | +55·0 | 1:1 | 52 |
| $OP(NCS)F_2$ | 1012 | 71·6 | 1:1 | 52 |
| $SP(NCS)_2F$ | 1061 | 27·4 | 1:1 | 52 |
| $SP(NCS)F_2$ | 1123 | 36·6 | 1:1 | 52 |

(a) Reference compounds 85% $H_3PO_4$ or $CCl_3F$.

Because of rapid rearrangement it is difficult to isolate pure compounds in these series, but phosphorus dichloride *iso*thiocyanate has been reported to be a colourless liquid, b.p. 148°C. (decomp.), m.p. $-76$°C., $d_4^{20}$ 1·546, which hydrolyzes as rapidly as phosphorus trichloride.[33]

## Phosphoryl *Iso*thiocyanate

Phosphoryl *iso*thiocyanate is prepared by the action of phosphoryl chloride on lead thiocyanate in boiling cumene,[3,74] ammonium thiocyanate in benzene,[71] acetonitrile[73] or liquid sulphur dioxide,[78] silver thiocyanate in benzene,[50] or potassium thiocyanate in acetonitrile[72,73] or benzene.[79] After removal of the solvent, or in certain cases extraction of the residual solid with carbon tetrachloride, the crude phosphoryl *iso*thiocyanate is purified by distillation; b.p. 106–7°C./0·5 mm.[73], 145°/5–6 mm.,[79] 159°/11 mm.,[74] 300° (extrap.)/760 mm., m.p. 13·8°C.,[50] $d_4^{15} = 1{\cdot}518$ g./c.c., $n_D^{15} = 1{\cdot}6918$.[74]

Phosphoryl *iso*thiocyanate is a colourless liquid which decomposes to an orange[50] or black[3] polymer when heated above 250°. The molar refractivity (57·65,[6] 55·76 (calc. from the data of ref. 74)) agrees with that calculated for $OP(NCS)_3$ (58·45) rather than the value for $OP(SCN)_3$ (63·07). The infra-red and Raman spectra[6,73] support this, and are in accord with a $C_{3v}$ symmetry for the molecule.[6] Nuclear magnetic resonance data are given in Table IV.

The *iso*thiocyanate is rapidly and completely hydrolyzed by water[71] or 6N nitric acid[50]:

$$PO(NCS)_3 + 3H_2O \rightarrow 3HSCN + H_3PO_4$$

and gives a strong thiocyanate reaction with acidified iron(III) nitrate. It undergoes ligand exchange with mercury(II) chloride, benzoyl chloride, or dodecylsilicon trichloride[41]:

$$PO(NCS)_3 + 3PhCOCl \rightarrow POCl_3 + 3PhCO(NCS)$$
$$PO(NCS)_3 + HgCl_2 \rightarrow POCl_3 + Hg(NCS)_2$$
$$PO(NCS)_3 + C_{12}H_{24}SiCl_3 \rightarrow POCl_3 + C_{12}H_{24}Si(NCS)_3$$

and reacts with diamines to give polymers of unknown composition.[79]

## Mixed Phosphoryl *Iso*thiocyanate Halides

Phosphoryl difluoride *iso*thiocyanate is prepared by the action of difluorophosphoric anhydride on potassium thiocyanate[52]:

$$F_2P(O){-}O{-}POF_2 + KSCN \xrightarrow{25°C} F_2PO(NCS) + KPO_2F_2$$

Phosphoryl fluoride, thiocyanogen and polythiocyanogen are formed as by-products. Phosphoryl difluoride *iso*thiocyanate is a colourless liquid, b.p. 35–6°/87 mm. It disproportionates when heated, giving phosphoryl fluoride di-*iso*thiocyanate, b.p. 64–5°/3·5 mm. The infra-red and nuclear magnetic resonance spectra of the two substances have been recorded[52] (see also Table IV).

Phosphoryl chloride does not undergo ligand exchange with phosphoryl *iso*thiocyanate at room temperature during 1 week, but reacts after heating for several hours at 130–150°, reaching an equilibrium after 154 hr. which differs very little from that theoretically predicted for random distribution.[78] No physical properties except the nuclear magnetic resonance spectrum were recorded in this study. However, phosphoryl dichloride *iso*thiocyanate has been obtained in low yield by the reaction of phosphoryl chloride with silver thiocyanate[49] or potassium thiocyanate.[66] It is a colourless liquid, b.p. 101°/41 mm., 173°/760 mm., m.p. $-55$°C., $n^{20}$ 1·5649, $d^{25}$ 1·587, which shows significant disproportionation after 1 month at 25°C.[49]

**Refs. p. 594**

### Thiophosphoryl *Iso*thiocyanate

Thiophosphoryl chloride reacts with potassium thiocyanate in acetonitrile[72,73] or ammonium thiocyanate in liquid sulphur dioxide in an autoclave at 100°C.[78] to give thiophosphoryl *iso*thiocyanate, $SP(NCS)_3$. The same product is obtained in small yield by the oxidation of phosphorus(III) *iso*thiocyanate with sulphur dioxide[76]

$$3P(NCS)_3 + SO_2 \rightarrow SP(NCS)_3 + 2OP(NCS)_3$$

Thiophosphoryl *iso*thiocyanate is a liquid, b.p. 121–3°/0·3 mm.,[73] 124°/0·1 mm.[78] The nuclear magnetic resonance spectrum has been determined[78] (see Table IV).

### Mixed Thiophosphoryl *Iso*thiocyanate Halides

If thiophosphoryl *iso*thiocyanate is added dropwise to antimony(III) fluoride at 100°C. and 1–2 mm., a mixture of thiophosphoryl difluoride *iso*thiocyanate, b.p. 89·5–90°/760 mm., and thiophosphoryl fluoride di-*iso*thiocyanate, b.p. 66–7°/1·5 mm., is formed. Both are pale yellow liquids which darken in the presence of traces of water. The infra-red spectra have been recorded.[52] Other physical data are given in Tables III and IV.

Thiophosphoryl chloride or bromide reacts with thiophosphoryl *iso*thiocyanate only after prolonged heating.[38,78] Thiophosphoryl dichloride *iso*thiocyanate can be made by reaction of thiophosphoryl chloride with potassium thiocyanate. The nuclear magnetic resonance spectra are recorded (Table IV).

### Other *Iso*thiocyanates

Pyrophosphoryl *iso*thiocyanate has been obtained as a red involatile oil by the action of dry potassium thiocyanate on pyrophosphoryl chloride in acetonitrile.[80]
